Nestin-positive Cells Become Osterix-expressing Osteoblast Precursors in the Perichondrium during Early Endochondral Bone Development. Noriaki Ono^{*1}, Wanida Ono², Paul Frenette³, Henry Kronenberg².¹Massachusetts General Hospital & Harvard Medical School, USA, ²Massachusetts General Hospital, USA, ³Ruth L. & David S. Gottesman Institute for Stem Cell & Regenerative Medicine, USA

Nestin-positive cells that support hematopoietic stem cells are putative mesenchymal stem cells in adult bone marrow. The relationship of these cells to osteoblast precursors in fetal life is unknown. Previous studies have shown that, during early endochondral bone development, osterix-expressing osteoblast precursors in the perichondrium translocate to the marrow space in a pericyte-like manner. To determine the possible involvement of nestin-positive cells in this process, we studied triple-mutant mice carrying a green fluorescent protein under the nestin promoter (Nes+ or Nes-GFP) and an inducible cre recombinase under the osterix promoter (Ox-CreER) that activates a Rosa26 tomato reporter upon tamoxifen injection. At embryonic day 10.5 (E10.5), Nes+ cells were distributed throughout the limb bud in a reticular manner, and most of these cells coexpressed the endothelial marker, CD31. When the distinct growth cartilage started to elongate at E12.5, Nes+ cells were found in the innermost portions of the perichondrium (PC), but not within the cartilage itself. At E13.5, Ox+ cells began to appear in the PC adjacent to the incipient hypertrophic cartilage (HC). In this part of the PC, most of the Nes+ cells were also positive for either Ox or CD31. We thereafter chased the descendants of these Ox+ cells (Ox-E13.5 cells) by a pulse-chase protocol. Ox-E13.5 cells translocated into the future marrow space, proliferated and differentiated into osteoblasts of the spongiosa. After E15.5, Nes+ cells were found in the innermost portions of the PC and the primary spongiosa, while Ox+ cells were found in the PC adjacent to the HC and in trabecular/cortical bone. Many Ox-E13.5 cells also expressed Nes-GFP in the primary spongiosa and contributed extensively to bone formation after 3 days of chase at E16.5. However, Ox-E13.5 cells did not express Nes-GFP in the perichondrium at E16.5. Furthermore, when chased further for 7 days until the time of birth (P0), Ox-E13.5 cells seldom expressed Nes-GFP in the primary spongiosa, and no Nes+ Ox-E13.5 cells were found in the perichondrium. Interestingly, Ox-E13.5 cells disappeared almost completely by postnatal day 21, with only a few osteocytes and bone lining cells remaining in the diaphysis. These findings indicate that Nes+ cells are heterogeneous in the embryonic perichondrium, and that a subset of Nes+ cells becomes Ox+ cells during bone development. Ox-expressing cells do not indefinitely renew themselves.

c-Cbl Silencing in Mesenchymal Cells Promotes Osteoblast Differentiation by Decreasing STAT5-Runx2 Interaction. François-Xavier Dieudonné^{*1}, Nicolas Sèvre¹, Jing-Jie Weng², Yeu Su², Pierre J. Marie¹. ¹Inserm UMR-606 & University Paris Diderot, France, ²Institute of Biopharmaceutical Sciences, National Yang-Ming University, Taiwan

Ubiquitin ligase-dependent degradation of proteins is an important process governing bone cell proliferation, differentiation and apoptosis. The E3 ubiquitin ligase c-Cbl is responsible for the downregulation of multiple proteins including receptor tyrosine kinases (RTKs). We previously showed that selective inhibition of c-Cbl interaction with RTKs results in increased mesenchymal cell differentiation into osteoblasts. In this study, we investigated whether overall silencing c-Cbl in mesenchymal cells might promote osteoblast differentiation, and we determined the mechanisms involved in this effect. Using two shRNA targeting distinct c-Cbl domains that interact with either RTK or ubiquitin, we found that c-Cbl silencing increased cell proliferation in murine C2C12 and C3H10T1/2 multipotent mesenchymal cells, and human clonal multipotent bone marrow-derived F/Stro-1A+ stromal cells. Additionally, c-Cbl silencing increased alkaline phosphatase (ALP) staining and activity and promoted the expression of osteoblast markers (Runx2, ALP, type I collagen) in these mesenchymal cell lines. This positive effect on osteoblast differentiation translated into increased matrix mineralization *in vitro*, showing that overall c-Cbl silencing increases osteogenic differentiation in murine and human mesenchymal cells. Analysis of the molecular mechanisms revealed that c-Cbl silencing increased the expression of platelet-derived growth factor receptor alpha and insulin like growth factor receptor, suggesting that these receptors may mediate part of the effect of c-Cbl silencing on osteoblast differentiation. We performed immunoprecipitation (IP) analyses with the goal of identifying other target proteins that may mediate the effect of c-Cbl in mesenchymal cells. IP analyses revealed that c-Cbl physically interacts with STAT5, and that STAT5 interacts with Runx2 in mesenchymal cells. Silencing c-Cbl using shRNA increased STAT5 protein level which resulted from decreased c-Cbl-mediated ubiquitination of STAT5. Pharmacological inhibition of STAT5 activity abrogated the positive effect of c-Cbl shRNA on osteoblast gene expression and *in vitro* osteogenesis. The data reveal that overall inhibition c-Cbl promotes the osteogenic differentiation program in murine and human mesenchymal cells, and indicate that this effect involves decreased c-Cbl-mediated STAT5 ubiquitination resulting in increased STAT5-Runx2 interaction. This uncovers a novel mechanism by which c-Cbl controls the osteogenic capacity of mesenchymal cells.

Fate Mapping with Osterix Cre Mice Reveals the Origin and Contribution of Bone Marrow Mesenchymal Stem Cells. Peter Mave^{*}, Yaling Liu, Sara Strecker, Liping Wang, Mark Kronenberg, David Rowe. University of Connecticut Health Center, USA

The developmental origin of adult bone marrow mesenchymal stem cells and their *in vivo* differentiation into more mature cell types has remained speculative. Here we carry out fate mapping studies utilizing Osterix-EGFPcre and Osterix-CreERT mice by intercrossing these lines with a floxed-stop tdTomato Cre reporter line (Ai9). Bone marrow stromal cultures derived from Osterix-EGFPcre;Ai9 mice result in the fluorescent marking of an adherent, mesenchymal population that is present at the earliest stages of culture and retains BMSC-like multipotent properties. Assessment of Ai9 Cre reporter expression in the bone marrow identifies several connective tissue related cell types in addition to cells of the osteoblast lineage, including reticular, vascular smooth muscle, adipocytic, and perineurial cells. Interestingly, adipose tissue and smooth muscle lined blood vessels lying outside the bone do not retain Cre reporter expression, suggesting a distinct origin and novel compartmentalization within the bone marrow. Temporal activation of Osterix-CreERT at E14.5 substantiates our constitutive Osterix-EGFPcre fate mapping studies and provides evidence that the embryonic perichondrium is a multipotent progenitor cell population that gives rise to much more than the osteoblast lineage and is the likely source of adult BMSCs. Furthermore, transplantation of adult BMSCs derived from Osterix-EGFP;Ai9 day 5 stromal cultures into a long bone defect resulted in the differentiation of Ai9 marked BMSCs into many of the same cell types defined by our fate mapping studies, including reticular cells, marrow adipocytes, and osteoblasts. Collectively, our studies indicate that BMSCs originate from an osterix-expressing perichondrial precursor cell population and they contribute to an array of connective tissue related cell types present within the bone marrow.

Nocturnin, a Marrow Stromal Cell Deadenylase, Regulates Lineage Allocation Through Changes in Mitochondrial Bioenergetics. Anyonya Guntur^{*1}, Phuong Le¹, Sheila Bornstein², Sutada Lotinun³, Roland Baron⁴, Carla Green⁵, Clifford Rosen². ¹Maine medical center research institute, USA, ²Maine Medical Center, USA, ³Harvard School of Dental Medicine, USA, ⁴Harvard School of Medicine & of Dental Medicine, USA, ⁵Department of Neuroscience, University of Texas Southwestern Medical Center, USA

Nocturnin (*Noc*), a circadian deadenylase regulated by PPARG, is highly expressed in bone marrow stromal cells (MSCs). *Noc*-/- mice are lean, resistant to high fat diet induced obesity and have high bone mass. Rosiglitazone (Rosi) an agent that activates PPARG, markedly enhances the expression of *Noc*, causes significant trabecular bone loss and increases marrow adipogenesis in mice. Thus we hypothesized that *Noc* is important in regulating stromal cell fate either towards the adipogenic or osteogenic lineage in response to Rosi. To test this further, we treated 12 wk *Noc*-/- mice and their age- and gender matched WT controls(+/+) with 20 mg/kg/day Rosi for 8 wks. Unlike +/+ mice, Rosi treated *Noc*-/- mice had a two fold increase in trabecular BV/TV and a nearly 2 fold rise in BFR/TV (p<0.05) despite no change in total osteoblast number. We next studied the amino acid sequence of NOC and identified a mitochondrial target sequence in the N-terminus with a very high probability (0.98%) of localization to the mitochondria. Utilizing an epitope tagged NOC expression plasmid, we showed that NOC co-localizes with a resident mitochondrial protein, suggesting a potentially novel role for this deadenylase, either directly or indirectly by regulating mitochondrial metabolism. To study if *Noc* determines cell fate by influencing cellular bioenergetics and function, we tested the metabolic profile of MC3T3E1 cells over expressing *Noc* and compared them to GFP control cells. Previously, we showed that over-expression of *Noc* in pre-osteoblastic cells inhibited osteogenesis and conversely in 3T3L1 cells enhanced adipogenesis, two distinct cell types with different energy needs. To define the role of mitochondrial bioenergetics in cell fate, we utilized the XF24 extracellular flux analyzer and studied the oxygen consumption rate (OCR) and extracellular acidification rate (ECAR) of MC3T3E1 cells in response to mitochondrial stress during a pre differentiation state. *Noc* over expressing cells had lower basal OCR as well as reduced ECAR (i.e. a measure of glycolysis) compared to GFP expressing control cells. Taken together these data suggest that *Noc*, by targeting the mitochondria, affects bioenergetics thereby regulating cellular work and lineage allocation. Importantly, we hypothesize that the intracellular machinery controlling glucose and oxygen uptake in the mitochondria is a powerful influence on ultimate MSC fate.

Osteoblastic Differentiation of Bone Marrow Stromal Cells is Sexually Dimorphic. Stefano Zanotti^{*}, Ernesto Canalis. St. Francis Hospital & Medical Center, USA

Skeletal integrity is preserved by the coordinated activity of osteoblasts and osteoclasts, and a decline in the number and function of osteoblasts may reduce bone mass. Osteoblastogenesis, the commitment of bone marrow stromal cell precursors to the osteoblastic lineage, determines osteoblast number. Although sex determines bone mass in humans and rodents, the mechanisms involved are understood poorly. Therefore, we tested whether primary bone marrow stromal cells harvested from male or female littermate mice, either from a tropism for Friend leukemia virus-B (FVB) or C57BL/6 genetic background, display a different potential for osteoblastic differentiation. Cells from FVB and C57BL/6 female mice exhibited suppressed formation of mineralized nodules when compared to cells from male littermates. Accordingly, alkaline phosphatase activity, and alkaline phosphatase and osteocalcin transcript levels, were reduced by 80% in cells from female mice in relation to cells from males, indicating that osteoblastogenesis *in vitro* is sexually dimorphic. These findings acquire further relevance in the study of osteoblastogenesis in genetically modified mouse models, which often display a sexually dimorphic skeletal phenotype. This was tested in a model of conditional inactivation of hairy and enhancer of split (*Hes1*), a Notch target which is a determinant of osteoblastogenesis. Conditional inactivation of *Hes1* in osteoblasts increased bone mass by enhancing bone formation exclusively in male mice, and *Hes1* inactivation in bone marrow stromal cells had a sexually dimorphic effect on osteoblastogenesis. *Hes1* null cells from male mice exhibited enhanced formation of mineralized nodules and alkaline phosphatase activity, whereas in *Hes1* null cells from females both parameters of osteoblastogenesis were suppressed. In conclusion, bone marrow stromal cells from female mice exhibit reduced potential for osteoblastic differentiation than cells from males, a difference that is accentuated in the context of *Hes1* inactivation. Therefore, cells from donors of different sexes should retain their individual identity for the study of osteoblastogenesis.

Wnt7b Promotes Bone Formation in vivo. Jianquan Chen^{*1}, Xiaolin Tu², Kyusang Joeng¹, Liang Ma¹, Fanxin Long³. ¹Washington University, USA, ²Indiana University School of Medicine, USA, ³Washington University School of Medicine, USA

Wnt signaling has emerged as an important mechanism for regulating both embryonic skeleton development and postnatal bone formation. However, the endogenous Wnt ligands involved in these processes and their specific downstream mechanisms are not well understood. We have previously shown that Wnt7b is expressed in the osteogenic perichondrium during embryonic limb development, and mouse embryos lacking Wnt7b in osteoprogenitor cells exhibit a delay in ossification. To investigate further the role of Wnt7b in both embryonic and postnatal bone formation, we generated a knockin mouse line (termed as R26-Wnt7b) by targeting Wnt7b cDNA into the ubiquitously active Rosa26 locus so that Wnt7b can be overexpressed in a Cre-dependent manner. Constitutive activation of Wnt7b expression with either Sp7-Cre or 2.3Col1-Cre led to a generalized increase in bone mass, a phenotype that began in the late-stage embryo and intensified in postnatal life. The increase of bone mass was caused by a combination of increased osteoblast number and enhanced osteoblast activity, without an overall change in bone resorption activity. To test whether Wnt7b can stimulate bone formation specifically in the postnatal animal, we generated a BAC transgenic mouse line (referred as Runx2-rtTA) by inserting the cDNA for reverse tetracycline transactivator (rtTA) into the Runx2 locus so that the expression of rtTA is driven by the Runx2 regulatory elements. Induction of Wnt7b expression by doxycycline in 1-month-old mice with the genotype of Runx2-rtTA; TetO-Cre; R26-Wnt7b stimulated bone formation, without overtly affecting bone resorption. In summary, these findings identify Wnt7b as a potent bone anabolic signal that can function both in the embryo and in the postnatal skeleton.

PTH Signaling in Osteoblasts Necessary for Vascular Invasion of Cartilage. Tao Qiu^{*1}, Janet Crane², Chunyi Wen³, Lingling Xian¹, William Lu⁴, Xu Cao². ¹Johns Hopkins University School of Medicine, USA, ²Johns Hopkins University, USA, ³Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong, ⁴The University of Hong Kong, Hong Kong

Longitudinal growth of postnatal bone requires precise control on growth plate cartilage from chondrocytes through autocrine, paracrine, and endocrine hormone signaling. However, it is not clear how the cartilage is regulated by the endocrine signals. Parathyroid hormone (PTH) regulates both bone remodeling and cartilage development. To examine its effect on the longitudinal growth of bone, knockout mice were generated with deletion of the PTH receptor (PTH1R) in mature osteoblasts using the osteocalcin-promoter (*OC-cre:PTH1R^{fl/fl}*) where PTH signaling is well

documented to occur. The mice exhibited postnatal growth retardation with profound defects in growth plate cartilage, ascribable predominantly to a reduction in hypertrophic differentiation of chondrocytes, expansion of pre-hypertrophic zone, and decreased bone formation at trabecular bone and metaphyseal periosteum, resulting in premature closure of the growth plates and shortened long bones. This cartilage phenotype is distinct to those seen in the mice with the chondrocyte-specific deletion of PTH1R, in which the chondrocyte differentiation is accelerated. Therefore, PTH signaling in osteoblasts may signal to chondrocyte hypertrophy as loss of this signaling pathway impairs chondrocyte differentiation in growth plate cartilage.

Mechanistic analysis revealed that endochondrial angiogenesis and vascular invasion of cartilage were impaired in *OC-cre:PTH1R^{fl/fl}* mice, suggesting that the disrupted supply of blood vessels attenuated the chondrocyte hypertrophy. To test whether the loss of the vasculature was sufficient to restrain chondrocyte differentiation and rule out the effect of mosaic-expression of osteocalcin-Cre in cartilage, we studied a mouse model with deficiency of PECAM-1, a primary constituent of vascular endothelial cell-cell junctions, reasoning that the disruption of the vasculature alone would then mimic the effect of *OC-cre:PTH1R^{fl/fl}* mice on chondrocytes. Indeed, PECAM-1 knockout mice exhibit a similar bone phenotype to that seen in *OC-cre:PTH1R^{fl/fl}* mice. Importantly, PECAM-1 knockout mice showed a dramatic decrease in the number of hypertrophic chondrocytes, as demonstrated by significantly decreased expression of ColX. These studies identify PTH as an external organizer of cartilaginous growth plate in longitudinal growth of bone and reveal a previously unrecognized function for bone and osteoblasts in maintaining chondrocyte hypertrophy in postnatal life.

Parathyroid Hormone-related Peptide (PTHrP) Inhibits Chondrocyte Hypertrophy by Promoting Nuclear Translocation of Histone Deacetylase (HDAC) 4. Shigeki Nishimori^{*1}, Forest Lai¹, Elena Kozhemyakina², Eric Olson³, Andrew Lassar², Henry Kronenberg¹. ¹Massachusetts General Hospital, USA, ²Department of Biological Chemistry & Molecular Pharmacology, Harvard Medical School, USA, ³UT Southwestern Medical Center At Dallas Department of Molecular Biology, USA

Both PTHrP and HDAC4 delay chondrocyte hypertrophy but the molecular mechanisms of these processes have not been clarified. Lassar's group used primary chick chondrocytes and a chondrogenic cell line to show that PTHrP uses HDAC4 nuclear translocation to accomplish this delay in differentiation (MCB 2009). Here we report *in vivo* genetic and molecular evidence that supports this hypothesis.

Three genetic tests support the hypothesis that PTHrP and HDAC4 work in a common pathway: (1) The HDAC4 knockout (KO) mouse shows a phenotype similar to that of the PTHrP KO mouse; (2) Even though PTHrP heterozygotes (HET) and HDAC4 HET have normal growth plates at birth, the PTHrP and HDAC4 double HET mouse exhibits accelerated chondrocyte hypertrophy; and (3) The effects of transgenic (Tg) expression of PTHrP driven by the collagen 2 (Col2) promoter to suppress chondrocyte hypertrophy (Col2-PTHrP-Tg; Wier et al, PNAS 1996) is blocked by knocking out the HDAC4 gene (HDAC4-KO; Col2-PTHrP-Tg).

Class IIa HDACs (HDAC4, 5, 7, 9) have large N-terminal extension with conserved binding sites for the chaperon protein 14-3-3 and the transcription factor myocyte enhancer factor 2 (MEF2). Class IIa HDACs shuttle between nucleus and cytoplasm through regulated phosphorylation and dephosphorylation at the 14-3-3 binding sites. Lassar's group used their *in vitro* model to show that PTHrP signaling leads to dephosphorylation of HDAC4 phospho-S246, through activation of protein phosphatase 2A. Freed of binding to cytoplasmic 14-3-3 proteins, HDAC4 then translocates to the nucleus and represses the action of MEF2C, the master transcriptional regulator of chondrocyte hypertrophy.

To assess HDAC4 nuclear translocation downstream of PTHrP signaling *in vivo*, we examined HDAC4 cellular localization by immunohistochemistry using confocal fluorescent microscopy. Nuclei of the proliferating chondrocytes in the newborn Col2-PTHrP-Tg mouse show intense and dense HDAC4 signals. In contrast, in the newborn PTHrP KO mouse, HDAC4 signals are sparse in the nuclei, but high in the cytoplasm. We also assessed phosphorylation of S246 of HDAC4 in both mice using an HDAC4 phospho-S246 specific antibody. HDAC4 phospho-S246 was detected in the PTHrP KO mouse but not in the Col2-PTHrP-Tg mouse by immunohistochemistry and Western blot. These results are consistent with the idea that PTHrP inhibits chondrocyte hypertrophy by inducing HDAC4 dephosphorylation and subsequent HDAC4 nuclear translocation.

Nmp4/CIZ Closes The Parathyroid Hormone Anabolic Window By Suppressing The Osteoprogenitor Pool. Paul Childress*¹, Yongzheng He², Mark Hood, Jr.³, Marta Alvarez¹, Melissa Kacena¹, Michael Hanlon⁴, Bryce McKee³, Feng-Chun Yang⁵, Joseph Bidwell¹. ¹Indiana University School of Medicine, USA, ²Department of Pediatrics, Indiana University School of Medicine, USA, ³Department of Anatomy & Cell Biology, Indiana University School of Medicine, USA, ⁴Iowa State University College of Veterinary Medicine, USA, ⁵Indiana University, USA

Parathyroid hormone (PTH) anabolic potency or its anabolic window for treating osteoporosis is intrinsically limited by unknown mechanisms. We have previously reported that disabling the transcription factor *Nmp4/CIZ* in mice expands this anabolic window while modestly elevating bone resorption. This previous study showed that wild type (WT) and *Nmp4*-knockout (KO) mice exhibited equivalent PTH-induced increases in bone after 2wks of treatment but by 7wks the null mice showed significantly more new bone. Interestingly, at 3wks of treatment serum osteocalcin, a marker for bone formation and osteoblast number peaked in WT mice but continued to increase in the null mice. To determine if this is when bone formation diverges between the genotypes and to investigate its cellular basis here we treated 10-wk-old null and WT animals with human PTH (1-34) [30 µg/kg/day] or vehicle for 3wks. At the end of treatment femoral trabecular architecture was evaluated using microCT analysis and bone marrow (BM) and peripheral blood (PBL) phenotypic cell profiles were assessed with clonogenic assays, flow cytometry, and hematology profile analyses. To analyze the data we employed a two-way ANOVA using genotype and treatment as the independent variables. If a genotype x treatment interaction was indicated, the data were analyzed by a Tukey HSD post hoc test to determine significant differences between the experimental groups. Statistical significance was set at $p < 0.01$. Hormone-treated *Nmp4*-KO mice gained over 2-fold more femoral trabecular bone (BV/TV) than did WT animals during the 3wk treatment period. There was no difference between genotypes in BM cellularity or the profiles of several blood elements. However, there was a 4-fold increase in *Nmp4*-KO CFU-F-ALK PHOS+ colonies (osteoprogenitors), a 1.6-fold increase in KO CFU-GM colonies (osteoclast progenitors), and a 2-fold increase in null BM CD8+ T-cells (which support osteoprogenitor differentiation). PTH had no effect on the size of any cell population. We propose that the extended and augmented anabolic activity in the *Nmp4*-KO mice first appears at 3wks of treatment and derives from an expanded osteoprogenitor pool, bolstered by the increase in BM CD8+T cells, thus sustaining bone formation after the WT osteoprogenitors are depleted. Additionally, this enhanced KO bone formation activity eclipses the elevated null osteoclastogenesis from the modestly enlarged CFU-GM pool.

G-protein Stimulatory Subunit Alpha and q/11 Family Together Maintain Stem-like Chondrocytes in the Quiescent Stage. Andrei Chagin*¹, Tatsuya Kobayashi², Jun Guo², Takao Hirai³, Karuna Vuppapalati⁴, Min Chen⁵, Stefan Offermanns⁶, Susan Mackem⁵, Lee Weinstein⁷, Henry Kronenberg². ¹Karolinska Institutet, Sweden, ²Massachusetts General Hospital, USA, ³Kyoto Prefectural University of Medicine, Japan, ⁴Karolinska Institute, Sweden, ⁵National Institutes of Health, USA, ⁶Max-Planck-Institute for Heart & Lung Research, Germany, ⁷National Institute of Diabetes & Digestive & Kidney Diseases, USA

Parathyroid hormone (PTH)-related protein (PTHrP), regulated by Indian hedgehog and acting through the PTH/PTHrP receptor (PPR), is crucial for normal cartilage development. Recently we have shown that ablation of the PPR in postnatal chondrocytes leads to disappearance of the epiphyseal growth plate. We have also observed ectopic apoptosis in the resting zone of the growth plate where stem-like chondrocytes are located. To explore the mechanism whereby PPR signaling controls the fate of these resting zone chondrocytes, we have examined in vivo the roles of the G proteins activated by the PPR in chondrocytes in preventing disappearance of the growth plate.

First, we generated mice with tamoxifen-inducible and cartilage-specific ablation of the heterotrimeric G-protein stimulatory subunit alpha (G_{α}). We found that inactivation of G_{α} in postnatal chondrocytes causes dramatically impaired bone growth associated with accelerated chondrocyte hypertrophy and growth plate disorganization. In contrast to mice lacking the PPR in cartilage, a disorganized remnant of growth cartilage persists in mice lacking G_{α} in cartilage. Slowly proliferating, stem-like chondrocytes were labeled with BrdU followed by a "chase" period; the recruitment of these chondrocytes into the proliferative pool was accelerated upon G_{α} ablation. In contrast, these cells underwent apoptosis upon ablation of the PPR. These contrasting fates of stem-like chondrocytes might contribute to remnant formation when only G_{α} is ablated in the growth plate. Matings to generate mice with defects in signaling by other G-proteins activated by the PPR showed that G_{α} synergizes with the Gq/11 family of heterotrimeric G-proteins in causing malformation of the growth plate, that inactivation of both pathways leads to apoptosis of stem-like chondrocytes and disappearance of the growth plate, and that neither G12/13 nor XLas do not contribute to the PPR phenotype. We conclude that G_{α} is the major mediator of the anti-differentiation

action of the PPR on postnatal chondrocytes, while activation of both G_{α} and Gq/11 signaling is required to maintain stem-like chondrocytes in the quiescent phase.

Hes1 is a Notch Target Gene that can Regulate Mesenchymal Progenitor Cell Proliferation and Differentiation during Skeletal Development. Timothy Rutkowski*¹, Anat Kohn¹, Anthony Mirando², Ryoichiro Kageyama³, Matthew Hilton². ¹University of Rochester, USA, ²University of Rochester Medical Center, USA, ³Kyoto University, Japan

We previously demonstrated that RBPjk-dependent Notch signaling suppresses mesenchymal progenitor cell (MPC) differentiation and induces proliferation during skeletogenesis. Several *Hes/Hey* factors are direct targets of RBPjk-dependent Notch signaling and critical Notch pathway components in progenitor cells. We also showed that knockdown of *Hes1* in MPCs resulted in accelerated differentiation during *in vitro* chondrogenesis, suggesting the importance of HES1 in this process. To determine whether HES1 is sufficient and/or required for MPC proliferation and differentiation during skeletal development in vivo, or whether HES1 is the sole regulator of the Notch-mediated suppression of MPC differentiation, we analyzed HES1 gain-of-function (GOF) (*Prx1Cre; Rosa-Hes1^{fl/fl}*), HES1 loss-of-function (LOF) (*Prx1Cre; Hes1^{fl/fl}*), and HES1 deficient Notch GOF (*Prx1Cre; Rosa-NICD1^{fl/+}; Hes1^{fl/fl}*) mice. Embryos were analyzed at E11.5, E12.5, E14.5, and E18.5 via whole-mount skeletal staining, ISH, and IHC of limb sections, and real-time RT-PCR of RNA isolated from limb-buds. Analyses demonstrated that HES1 GOF mutants exhibited reduced size of condensations and delayed chondrocyte gene expression via real-time RT-PCR and ISH. Proliferation analyses also indicated that HES1 GOF mutants had elevated MPC proliferation. These data demonstrate that sustained HES1 signaling is sufficient to induce MPC proliferation and delay differentiation but cannot block MPC differentiation and arrest chondrogenesis identical to sustained NOTCH1 signaling (*Prx1Cre; Rosa-NICD1^{fl/+}*). Interestingly, HES1 LOF embryos were analyzed using similar methods to determine whether MPC differentiation was accelerated as previously observed in RBPjk LOF mutants, although no striking chondrogenic changes were observed. Similar to other HES1 LOF models, we observed elevated *Hes5* gene expression in limb-bud MPCs following removal of *Hes1*, suggesting compensation from other *Hes* genes. Lastly, to determine whether *Hes1* is the sole Notch target required during Notch-mediated suppression of MPC differentiation, we analyzed HES1 deficient Notch GOF mice. Analyses demonstrated that sustained NOTCH1 signaling continued to suppress MPC differentiation in the absence of *Hes1*. Collectively, these data indicate that HES1 signaling is sufficient to delay MPC differentiation and induce proliferation, although additional HES/HEY factors or other Notch targets may be important in Notch-mediated regulation of MPCs during skeletogenesis.

Postnatal Growth Plate Integrity and Function Require Ext1 Expression and Heparan Sulfate Production. Federica Sgariglia*¹, Eiki Kovama¹, Julianne Huegel², Maurizio Pacifici², Motomi Enomoto-Iwamoto¹. ¹Children's Hospital of Philadelphia, USA, ²Thomas Jefferson University, USA

The growth plate is the key engine for skeletal development during embryogenesis and continues to function in skeletal growth until the end of puberty when skeletal maturity is reached. The prenatal and postnatal integrity and function of the growth plate are regulated by a complex array of local and systemic factors. Many of these factors, including hedgehog proteins and bone morphogenetic proteins, interact with heparan sulfate that in turn influences their distribution, availability and signaling activity. To determine whether the growth plate requires heparan sulfate continuously, we conditionally inactivated Ext1, the major Golgi-associated enzyme for HS synthesis, in cartilage at postnatal stages by mating *Ext1* floxed mice with *Col2-CreER* mice. Given that Cre effectiveness is usually not complete, we compared mice with the genotypes *Ext1^{fl/fl}; Col2CreER* and *Ext1^{fl/-}; Col2CreER*, expecting the latter to display more effective ablation. Mice and appropriate controls were injected with tamoxifen at postnatal day 5 (P5) and examined at various time points over the following 8 weeks. Limb and axial skeletal specimens were analyzed by soft x-ray, µCT, histology and gene expression. Anatomically, the mutant mice displayed growth retardation, scoliosis and limb deformities, especially bowing of the forearm, by 2 to 4 weeks post injection. Histologically, the mutant growth plates in long bones and ribs were disorganized. A major and consistent feature was a lateral expansion of the growth plates such that the extra cartilaginous tissue draped and surrounded the underlying trabecular bone. The organization of the ectopic cartilaginous tissue resembled that of a growth plate but oriented perpendicularly to the main growth plate axis, with small immature chondrocytes facing the adjacent periosteum and hypertrophic chondrocytes facing native growth plate and bone. Analyses of gene expression and protein signaling patterns indicated significant changes in growth plate regulatory circuits. Some of the injected *Ext1^{fl/-}; Col2CreER* mice died prematurely, possibly reflecting complete Ext1 ablation. The data indicate that heparan sulfate is in fact required for postnatal growth plate function and progression of normal skeletal growth. The aberrant ectopic cartilage in mutants is reminiscent of that forming in patients with

Hereditary Multiple Exostoses, a pediatric pathology caused by *Ext1* mutations, providing further clues as to the pathogenesis of exostosis formation.

Sclerostin Antibody Improves Bone Mass and Mechanical Properties in *Brtl/+* Model of Osteogenesis Imperfecta When Administered During Growth. Benjamin Sinder^{*1}, Logan White¹, Michael Ominsky², Michelle Caird¹, Joan Marini³, Kenneth Kozloff⁴. ¹University of Michigan, USA, ²Amgen Inc., USA, ³National Institute of Child Health & Human Development, USA, ⁴University of Michigan Department of Orthopaedic Surgery, USA

Osteogenesis imperfecta (OI) is a genetic collagen disorder characterized by brittle bones and presents most severely in children. Anti-resorptive bisphosphonates have their major effect on trabecular bone and have been used with mixed success to treat pediatric OI during growth. Enhanced cortical bone would be valuable for OI amelioration, however no anabolic therapy has demonstrated consistent effectiveness. Sclerostin is a negative regulator of the Wnt pathway, and a neutralizing sclerostin antibody (Scl-Ab) has demonstrated potential anabolic efficacy in other models of bone fragility. Previously, we have shown that Scl-Ab stimulates new bone formation in osteoblasts harboring a type I collagen mutation¹ and improves bone mass and mechanical properties in an adult mouse model of OI². No studies to date have investigated Scl-Ab in the rapidly growing OI skeleton. Therefore the purpose of this study was to evaluate Scl-Ab during growth in the *Brtl/+* mouse model of dominant OI with G349C substitution on one *coll1a1* allele. Three week old male WT and *Brtl/+* were treated with Scl-Ab or Vehicle twice per week, for five weeks, at 25mg/kg. All changes are $p < 0.05$ unless otherwise noted, $n = 7-8$ /group. Body weight was not affected by Scl-Ab. MicroCT of the distal metaphyseal femur revealed that in WT, Scl-Ab increased Tb.BMD (66%) and BV/TV (56%) by increasing both Tb.Th (31%) and Tb.N (18%). In *Brtl/+*, Scl-Ab treatment increased Tb.Th (12%) with a trend towards increased Tb.BMD (30%, $p = 0.10$). However, neither BV/TV ($p = 0.26$) nor Tb.N ($p = 0.54$) were significantly altered, suggesting a reduced response to Scl-Ab in *Brtl/+* femoral trabecular bone. At femoral mid-diaphysis, microCT analysis showed Scl-Ab significantly increased cortical thickness (WT 23%; *Brtl/+* 24%), cross sectional area (WT 28%; *Brtl/+* 27%), and the medial-lateral moment of inertia (WT 41%; *Brtl/+* 35%) by similar amounts in both genotypes. Functionally, Scl-Ab increased femoral diaphyseal Ultimate Force (WT 66%; *Brtl/+* 47%) and Stiffness (WT 49%; *Brtl/+* 67%) as measured by four-point bending. Post yield displacement was not affected by Scl-Ab in *Brtl/+*, suggesting that treatment did not change material brittleness. In summary, Scl-Ab increased bone mass and improved whole bone mechanical properties in young *Brtl/+* mice. These initial data support that Scl-Ab may be beneficial for the treatment of OI patients by reducing fracture risk.

Treatment with Sclerostin Antibody Improves Bone Mass and Whole Bone Strength in the *Crtap-/-* Model of Recessive Osteogenesis Imperfecta. Ingo Grafe^{*1}, Tao Yang², Erica Homan², Elda Munivez², Caressa Lietman², Brian Dawson², Gautam Sule², Terry Bertin², Franklin Asuncion³, Hua Zhu Ke³, Michael Ominsky³, Brendan Lee⁴. ¹Department of Molecular & Human Genetics, Baylor College of Medicine, USA, ²Baylor College of Medicine, USA, ³Amgen Inc., USA, ⁴Baylor College of Medicine & Howard Hughes Medical Institute, USA

Standard treatment for patients with Osteogenesis Imperfecta (OI) is limited to antiresorptive bisphosphonates, which do not completely correct the bone fragility and seem to be less effective in adults. Sclerostin antibody (Scl-Ab) has been shown to have beneficial osteoanabolic effects in models of osteoporosis and forms of OI resulting from mutations in the genes encoding type I collagen. However, Scl-Ab treatment has not been studied in models of OI caused by defects in posttranslational collagen modifications, where the pathomechanism may differ. Cartilage associated protein (CRTAP) plays a role in posttranslational type I collagen modification and its loss of function results in recessive OI in a mouse model and in patients. In this study we investigate the effects of Scl-Ab treatment in *Crtap-/-* mice.

Six week old female *Crtap-/-* mice were treated with Sclerostin antibody (Scl-Ab) for 6 weeks (25 mg/kg, s.c. injection, twice per week), PBS treated *Crtap-/-* and wildtype (WT) mice served as controls. After treatment, spines and femurs were analyzed by microCT, biomechanical properties were assessed by 3-point bending of femurs.

Compared to PBS treated *Crtap-/-* mice, microCT analysis of vertebral body L4 showed significant increases in bone volume (BV/TV, +104%), trabecular number (Tb.N, +45%), trabecular thickness (Tb.Th, +41%) and BMD (+10%) in Scl-Ab treated *Crtap-/-* mice. Compared to WT mice, Scl-Ab fully reversed the reduction in Tb.Th and BMD in *Crtap-/-* mice, while BV/TV and Tb.N remained reduced. Femurs of Scl-Ab treated *Crtap-/-* mice demonstrated significant increases in cortical thickness (+37%), CSMI (+41%) and BMD (+23%) compared to PBS treated *Crtap-/-* mice and were no longer lower than in WT mice. Biomechanical testing of the femur midshaft showed that *Crtap-/-* mice had significantly reduced whole bone strength parameters, and Scl-Ab significantly increased maximum load (+41%) and stiffness (+48%) to WT levels. At the material level, *Crtap-/-* mice had reduced post-yield displacement and toughness, reflecting the increased tissue brittleness expected with OI. Scl-Ab did not significantly affect these material properties.

Scl-Ab treatment improves bone mass and microarchitecture in *Crtap-/-* mice, resulting in increased whole femoral bone strength without an effect on material properties. The findings of this study suggest that Scl-Ab treatment may have beneficial effect in the treatment of patients with recessive OI.

***Pbx1* Is a Likely Candidate Gene for the Development of Fibro-osseous Lesions in Mice.** Cheryl Ackert-Bicknell^{*1}, Annerose Berndt², Clinton Cario², Beth Sundberg¹, John Sundberg¹. ¹The Jackson Laboratory, USA, ²University of Pittsburgh School of Medicine, USA

Fibro-osseous lesions are benign changes wherein normal bone is replaced with fibrovascular stroma. In humans, these lesions are found primarily in the jaw and tubular bones. They are more common in African American women, suggesting both a hormonal and a genetic etiology. In mice, there is also a higher incidence in females, however, these lesions occur primarily in the sternbrae, long bones, and vertebrae. In this study, we first determined the frequency and severity of fibro-osseous bone lesions in 12 and 20 month old female mice from 28 inbred strains. We then used these data to perform genome wide association (GWA) mapping to identify genetic loci associated with the development and severity of these lesions. Specifically, bones (calvaria, shoulder and elbow with associated long bones, hip and knee with associated long bones, ribs, and vertebrae from the thoracic, lumbar, and coccygeal regions) were examined histologically for the presence of fibro-osseous lesions. At 12 months of age, these lesions were rare; occurring in 3% of the 370 mice examined. At 20 months of age, these lesions affected 20% of the 280 mice examined, and were observed in 15 of the 28 strains. GWA scans for data collected from the 20 month old mice were performed using the efficient mixed-model association (EMMAX) algorithm using a 4 million SNP panel. Genetic loci associated with lesion development were mapped to Chromosome (Chr) 1 at 170.2 Mb, Chr 5 at 138.8 Mb, and Chr 15 at 68.7 Mb. The loci on Chrs 1 and 15 were also associated with lesion severity. *Pbx1*, is located at the peak for the locus on Chr 1. *Pbx1* binds to many transcription factors, is involved in organ development and is a suppressor of osteoblastogenesis. Furthermore, this gene is an oncogene and studies have shown that *Pbx1* guides Estrogen receptor alpha (*Esr1*) to target genes in aggressive breast cancer. In summary, we have shown that the mouse is an ideal model for the study of the pathological progression and genetic etiology of bone fibro-osseous lesions. Given the known functions of the *Pbx1* gene and the results of our genetic mapping study, we suggest that polymorphisms in *Pbx1* are associated with the development of this condition.

The Glucocerebrosidase (Gaucher Disease) Gene Functions in Immune Regulation and Skeletal Homeostasis. Pramod Mistry¹, Tony Yuen^{*2}, Ling-Ling Zhu², Jun Liu¹, Stephanie Halene¹, Mei Yang¹, Jameel Iqbal², Ruhua Yang¹, Wajahat Mehal³, Wei-Lien Chuang³, Dhanpat Jain¹, Jianhua Li⁴, Harry Blair⁵, Li Sun², Mone Zaidi⁶. ¹Yale School of Medicine, USA, ²Mount Sinai School of Medicine, USA, ³Genzyme Corporation, USA, ⁴Toussaint School of Medicine, USA, ⁵University of Pittsburgh, USA, ⁶Mount Sinai Medical Center, USA

The heterogeneous clinical presentation of patients with Gaucher Disease (GD1) cannot simply be explained by the lysosomal accumulation in macrophages of lipid substrates of the mutated enzyme glucocerebrosidase (GBA1). This macrophage-centric view also does not endorse emerging aspects of the disease, such as malignancies, gammopathies, autoimmune diathesis, Parkinson's disease, and osteoporosis, all of which are resistant to macrophage-directed enzyme replacement therapy. To understand the pathophysiology of the multi-system involvement in GD1, and to unravel new functions of the GBA1 gene in normal physiology, we conditionally deleted the gene using an Mx1 promoter in the hematopoietic and mesenchymal cell lineages in mice, *hitherto* termed GD1 mice. We fully recapitulated the visceral manifestations of human GD1. GD1 mice were also severely osteoporotic, with a marked reduction in bone formation rates *in vivo* and osteoblastogenesis *ex vivo*. Cytokine measurements, microarray analysis, and flow cytometry revealed widespread dysfunction of unexpected immune cell populations. Notably, the thymus exhibited the earliest and most striking alterations reminiscent of impaired T-cell maturation, aberrant B-cell recruitment, and enhanced antigen presentation. In contrast to the profound defects in the thymus, there were only limited cellular defects in peripheral lymphoid organs, namely the spleen, lymph nodes and bone marrow; these changes were restricted to mice with severe disease. The cellular changes were accompanied by elevated Th1 and Th2 cytokines that tracked with disease severity. Furthermore, as disease severity correlated with accumulating GBA1 substrates, namely glucosylceramide (GL1) and glucosylsphingosine (Lyso-GL1), we studied the effects of each lipid on the proliferation of bone marrow hematopoietic stem cell precursors (HSCs). The proliferation of multipotent precursors (MPP), short-term HSCs, and long-term HSCs was inhibited significantly by both GL1 and Lyso-GL1 *in vitro*. This suggests a direct role for lipid substrates in causing the extensive immune dysfunction in GD1. The results not only demonstrate that *GBA1* has a role in immune regulation, but also provide the first direct evidence for the involvement of cell lineages other than mononuclear phagocytes, most notably, T-cells, B-cells, dendritic cells, and osteoblasts, in the pathophysiology of GD1. Important therapeutic implications may eventually follow from these studies.

A Mouse Model of Cushing's Syndrome due to a Corticotrophin Releasing Hormone (*Crh*) Promoter Mutation develops Steroid Induced Osteoporosis. Liz Bentley^{*1}, Christopher Esapa², M. Andrew Nesbit², Rosie A Head², Holly Evans³, Darren Lath³, Tertius A Hough¹, Christine Podrini⁴, William Fraser⁵, Martin D Fray¹, Peter Croucher⁶, Matthew Brown⁷, Steve D. M. Brown¹, Roger D. Cox¹, Rajesh Thakker⁸. ¹MRC Harwell, United Kingdom, ²University of Oxford, United Kingdom, ³University of Sheffield, United Kingdom, ⁴Wellcome Trust Sanger Institute, United Kingdom, ⁵University of East Anglia, United Kingdom, ⁶Garvan Institute of Medical Research, Australia, ⁷Diamantina Institute of Cancer, Immunology & Metabolic Medicine, Australia, ⁸Nuffield Department of Clinical Medicine, University of Oxford, United Kingdom

Glucocorticoid-induced osteoporosis (GIOP) is a common condition for which effective and satisfactory treatments are not available. The availability of a mouse model for GIOP would facilitate investigations and *in vivo* assessment of treatments. In the course of our phenotype-driven screens of mouse mutants induced by the chemical mutagen N-ethyl-N-nitrosourea (ENU), we observed a mutant mouse with obesity, hyperglycaemia and low bone mineral density, features that are consistent with Cushing's syndrome. This phenotype was inherited as an autosomal dominant trait and the disease locus was mapped to chromosome 3 and to a 6.2Mbp interval that contained the gene encoding corticotrophin releasing hormone (*Crh*). DNA sequence analysis of the *Crh* gene did not identify any coding region mutations, in affected mice, but instead a T to C transition at -120bp, within the *Crh* promoter, was identified. Luciferase reporter assays demonstrated that this T to C transition resulted in a >2 fold increase in transcription activity in Neuro2a cells ($p < 0.001$). *In vivo* assessment of *Crh*^{120/+} mice revealed them to have, when compared to wild-type (*Crh*^{+/+} mice), elevated plasma concentrations of corticosterone (mean \pm SEM: *Crh*^{120/+} = 721.8 \pm 88.8 ng/ml; *Crh*^{+/+} = 414.3 \pm 59.5 ng/ml, $p = 0.01$), glucose (*Crh*^{120/+} = 24.12 \pm 4.23 mmol/L; *Crh*^{+/+} = 11.43 \pm 1.11 mmol/L, $p = 0.01$) and insulin (*Crh*^{120/+} = 3.99 \pm 0.55 ng/ml; *Crh*^{+/+} = 1.01 \pm 0.09 ng/ml, $p < 0.0001$). An analysis of cortico-endosteal bone structure using dynamic histomorphometric studies revealed that both male and female *Crh*^{120/+} mice, when compared to *Crh*^{+/+} mice, had reductions in mineralising surface area (males: *Crh*^{120/+} = 14.6 \pm 2.8; *Crh*^{+/+} = 56.8 \pm 3.4, females: *Crh*^{120/+} = 30 \pm 2.9; *Crh*^{+/+} = 63.8 \pm 5.4, $p < 0.01$),

mineral apposition rate (males: *Crh*^{120/+} = 1.2 \pm 0.2; *Crh*^{+/+} = 1.7 \pm 0.2, females: *Crh*^{120/+} = 1.4 \pm 0.2; *Crh*^{+/+} = 2.2 \pm 0.2, $p < 0.05$) and bone formation rate (males: *Crh*^{120/+} = 0.4 \pm 0.04; *Crh*^{+/+} = 1.1 \pm 0.1, females: *Crh*^{120/+} = 0.5 \pm 0.1; *Crh*^{+/+} = 1.6 \pm 0.1, $p < 0.01$). Further analysis of osteoblasts and adipocytes in bone, using static histomorphometry, showed a reduction in osteoblast number ($p < 0.05$) and the percentage of cortico-endosteal bone covered by osteoblasts ($p < 0.05$) in both male and female *Crh*^{120/+} mice which was accompanied by an increase in adipocytes in the bone marrow ($p < 0.01$). Thus, our studies have established a mouse model for Cushing's syndrome that develops osteoporosis.

A Key Pathological Role for the Wnt/b-catenin Signaling Pathway in Hypophosphatemic Rickets/Osteomalacia. Shuxian Lin^{*1}, Yong Jiang², Zhaowen Zong², Min Liu³, Ying Liu², Baozhi Yuan⁴, Marc Drezner⁴, Hua Zhu Ke³, J.Q. Feng². ¹Baylor College of Dentistry, USA, ²Baylor College of Dentistry, Texas A&M, USA, ³Amgen Inc., USA, ⁴University of Wisconsin, USA

Deletion or mutation of *Dmp1* or *PheX* leads to a hypophosphatemic rickets/osteomalacic disorder, in which increased FGF23 plays a key pathological role, although neither DMP1 nor PheX directly regulates FGF23 homeostasis. In this study, we initially showed that immunohistochemical evaluation of osteoblast/osteocytes from *Dmp1* knockout mice reveals elevated b-catenin expression levels. Subsequently, we crossed 3.2 kb-Col1^{ER} and Cre/ Catnb^{+/lox(ex)3} mice to generate offspring with constitutively activated b-catenin at postnatal day 3. Unexpectedly, these mice manifested a rickets phenotype, resembling that in *Dmp1* KO and *Hyp* mice, which included greatly expanded growth plates, short limbs and tail, malformed epiphysis, and defected metaphyses. To determine whether blocking Wnt/b-cat signaling will rescue the phenotype in *Dmp1* knockout mice, we crossed *Dmp1* knockout and 2.3 *Col1-Dkk1* transgenic mice, generating offspring that overexpressed DKK1 (a potent inhibitor of Wnt/b-catenin signaling pathway) in osteoblasts. By 3-weeks, the targeted expression of DKK1 and consequent blockade of Wnt/b-catenin signaling significantly improved the following elements of the rickets/osteomalacic phenotype: 1) FGF23, PTH, and Pi levels; 2) skeleton length (long bone and vertebrae); 3) growth plate thickness; 4) epiphysis and metaphysis phenotype; 5) cell proliferation (BrdU); 6) molecular bone markers (FGF23, b-catenin, Col I, BSP, OPN, OSX, E11 and SOST), and 7) bone mineralization and formation rates. By 8 weeks, the *Dmp1* knockout phenotype was further improved. Taken together, we demonstrate for the first time that an abnormal high level of Wnt/b-catenin expression in *Dmp1* knockout mice is a key pathologically local factor responsible for defects in osteoblast maturation into osteocytes and high FGF23 expression, leading to hypophosphatemic rickets. This study has clinical relevance, as a high Pi diet alone fails to fully restore the osteomalacic status in patients, and normalizing the Wnt/b-catenin signaling may benefit these patients. (This research was supported by DE018486).

Lack of Value of Serum Sex Steroid Measures in the Prediction of Osteoporosis and Fracture Risk in Community-dwelling, Ambulatory Older Men. Eric Orwoll¹, Jodi Lapidus¹, Ying Wang¹, Carrie Nielson¹, Andrew Hoffman², Howard Fink³, Gail Laughlin⁴, Sundeep Khosla⁵, Oregon Health & Science University, USA, ²Stanford University, USA, ³GRECC, Minneapolis VA Medical Center, USA, ⁴University of California, San Diego, USA, ⁵College of Medicine, Mayo Clinic, USA

Serum estradiol (E), sex hormone binding globulin (SHBG) and testosterone (T) have all been associated with BMD and fracture risk in populations of older men. Measures of T are commonly used in clinical evaluations of osteoporosis in men, but the value of these measures for risk assessment in individuals has not been formally assessed.

In the MrOS Study, 1563 community-dwelling, ambulatory men >65 yrs had baseline assays of E and T by mass spec, and SHBG by RIA. We assessed baseline BMD and subsequent BMD change by DXA, and ascertained incident fractures over 10 yrs. The value of T, E and SHBG levels for predicting the rate of BMD change was assessed via fit statistics from linear regression models. The ability of T, E and SHBG to predict BMD status (T score <-2.5 vs >-2.5) and fracture risk was assessed via logistic regression models. We initially considered models that were unadjusted, thus simulating the clinical situation, but also considered models with age and BMI adjustments. Finally, we examined clinical thresholds of E, T and SHBG to assess predictive utility. For each model we computed the area under the receiver operating characteristic curve (AUROC) to evaluate discriminative ability, and used net reclassification improvement (NRI) and integrated discrimination improvement (IDI) to assess improvement in risk prediction over a baseline model containing age, BMI and BMD.

Results: T, E and SHBG provided virtually no benefit for the prediction of BMD status, BMD loss or fracture risk. For instance, the AUROCs for hip fracture prediction using continuous T, E or SHBG alone were between 0.54-0.59 whereas the AUROC using baseline age+BMI+ BMD was 0.82. Moreover, when added to age+BMI+BMD, measures of sex steroids and SHBG (examined as continuous variables) did not improve the predictive value for any endpoint (p values for NRI and IDI insignificant for all). When conventional cutpoints for low sex steroids were examined there was no improvement. Results were unchanged when bioavailable T and E were examined. When only men with low BMD (T score -1.0 to -2.5) were analyzed the results were essentially the same.

Summary: In individual older men there appears to be low predictive value for sex steroid and SHBG measurements in assessing BMD status, rate of BMD change or fracture risk. There is little indication for including T, E or SHBG measures for estimating the risk of developing osteoporosis or fracture in community-dwelling older men.

Serum DKK-1 Levels and the Risk of in Relation to the Occurrence of Osteoporosis-related Fractures : The CEOR Study. Mohammed-Salleh Ardawi¹, Abdulraheem Rouzi², Sharifa Al-Sibiani³, Nawal Al-Senani⁴.
¹Center of Excellence for Osteoporosis Research & Faculty of Medicine, Saudi Arabia, ²Center of Excellence for Osteoporosis Research & Department of Obstetrics & Gynecology, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, ³Center of Excellence for Osteoporosis Research, & Department of Obstetrics & Gynecology, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, ⁴Center of Excellence for Osteoporosis Research & Department of Obstetrics & Gynecology, Faculty of Medicine, & KAU Hospital, King Abdulaziz University, Saudi Arabia

Background: Dickkopf-1 (DKK-1) is involved in the regulation of bone formation through the inhibition of the Wnt/ β -catenin signaling pathway. DKK-1 over-expression in osteoblasts results in osteopenia and inhibits fracture repair, whereas DKK-1 activation in osteoblasts contributes to the pathogenesis of glucocorticoid- and/or estrogen deficiency-mediated osteoporosis. We therefore hypothesized that postmenopausal women with increased circulating DKK-1 levels have a greater risk for osteoporosis-related fractures (ORFs).

Subjects and Methods: We examined the association between circulating DKK-1 [measured by ELISA method, (Biomedica Gruppe, Biomedica Medizinprodukte GmbH & Co KG, Austria)] levels and the risk of ORFs in 707 postmenopausal women, 50 years of age or older in a population-based study with a mean follow-up period of 5.2 ± 1.3 years. Multivariate Cox proportional-hazards regression models were used for analysis of the risk of fracture with adjustment for age, body-mass index and other potential risk factors that may be associated with the risk of fracture or with higher circulating levels of serum DKK-1.

Results: High serum DKK-1 levels were associated with an increased risk of ORFs (Table 1). Following adjustment for age and other confounders, the relative risk of ORFs for each increment of 1 SD in DKK-1 level was about 2-fold among postmenopausal women. [RR = 1.98 (95% CI: 0.98-4.20)]. Further, women in the highest quartile of DKK-1 levels had an increase in the risk of ORFs so that the risk was 3.4-fold for DKK-1. The risk of ORFs that was attributable to DKK-1 levels (in the highest quartile) was estimated at 31.7%. The association between DKK-1 levels and the risk of fracture seems to be independent of bone mineral density and other confounding risk factors for fracture.

Conclusions: Higher serum DKK-1 levels are associated with a greater risk of ORFs independent of several other risk factors among postmenopausal women. Serum DKK-1 measurement holds promise as a risk factor for ORFs in postmenopausal women.

Table 1: Increased levels of serum DKK-1 and the risk of ORFs in postmenopausal women.

| | Relative risk (95% CI) for 1 SD increase | | Relative risk (95% CI) for levels < highest quartile | |
|----------------------|--|------------------|--|------------------|
| | Unadjusted | Adjusted | Unadjusted | Adjusted |
| Serum DKK-1 (pmol/L) | 1.86 (0.87-3.79) | 1.96 (0.97-4.12) | 3.36 (1.61-7.05) | 3.38 (1.49-7.89) |

All relative risk values were adjusted for age, BMI, BMD, hand grip strength, physical activity-score, dietary calcium intake, hand grip strength and BMD. Q1, Q2, Q3, Q4 quartiles for serum DKK-1 (pmol/L) were: Q1 = <81.9; Q2 = 81.9-105.2; Q3 = 105.3-133.2; Q4 = >133.2, respectively.

Association between Hypovitaminosis D, Secondary Hyperparathyroidism, Bone Loss and Hip Fractures in the Prospective Population-based OPRA Study of Elderly Women. David Buchebner¹, Fiona McGuigan², Karl Obrant³, Paul Gerdhem⁴, Kristina Akesson⁵.
¹Halmstad Hospital, Sweden, ²University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, ³University Hospital, Sweden, ⁴Karolinska Institutet, Sweden, ⁵Skane University Hospital, Malmö, Sweden

Background: Deficiency in vitamin D can cause secondary hyperparathyroidism, high bone turnover, bone loss and mineralization defects and is suggested to play a role in the development of osteoporosis and fragility fractures. In this study we investigated long term assessment of serum vitamin D and PTH to determine if hypovitaminosis D and elevated PTH lead to higher bone loss and increased hip fracture incidence in elderly women.

Methods: Study participants were Swedish women from the population based Malmö OPRA cohort. 1044 women, all 75y old, attended at baseline (BL), 715 attended at 5y. Bone mineral density (BMD) was assessed using a Lunar DPX-L DXA scanner. Serum 25-hydroxy vitamin D (25OHD) was available for 987 (BL), and 640 (5y) women, classified as: >75 nmol/l; 50-75 nmol/l; <50 nmol/l. Serum PTH

measurements were available for 999 (BL), and 694 (5y) women, classified as: normal (<6.8pmol/l) or high (>6.8pmol/l). Fracture data was ascertained from X-rays at the Dept. Radiology, Skane University Hospital, Malmö for mean follow-up of 9.0 years (range 7.4-10.9).

Results: Bone loss at 5 years was higher at the hip in women who, at both BL and 5y, had the lowest 25OHD (<50 nmol/l) compared to the other 2 groups (≥ 50 nmol/l): FN (16.7% v 6.9% v 7.8%); Troch (16.5% v 7.7% v 7%) and TH (10.7% v 6.2% v 6.5%) (p<0.). Similarly for PTH, there was higher loss in the high compared to the normal PTH group: FN (11.6% v 7.5%); Troch (9.8% v 7%); TH (8.7% v 6.3%). Women with low 25OHD (<50 nmol/l) and high PTH lost significantly more bone, with the highest loss at the trochanter.

The proportion of women who had 25OHD <50nmol/l at baseline was 4%, increasing to 17% at 5y. Of those who were low at baseline, 17% sustained at least one hip fracture during follow-up compared to 11% who had a hip fracture and had >50 nmol/l values (p=ns). Of the women who were low at 5y, 16% sustained at least one hip fracture during follow-up compared to 7% who had a hip fracture and values >50 nmol/l (p<0.05). S-PTH was not associated with more fracture, irrespective of 25OHD.

Conclusions: In this population sample of elderly women, vitamin D and PTH played a role in long term bone loss. Vitamin D status was associated with increased hip fracture incidence, whereas we could not confirm the hypothesis of elevated PTH increasing the risk of hip-fractures.

Disclosures: David Buchebner, None.

Bone Turnover Marker Balance and Turnover: Association with Fracture Risk in the OPUS Study. Fatma Gossiel¹, Richard Jacques², Judith Finigan³, David Reid⁴, Christian Roux⁵, Dieter Felsenberg⁶, Claus-C Glueer⁷, Richard Eastell³.
¹The University of Sheffield, United Kingdom, ²School of Health & Related Research, University of Sheffield, United Kingdom, ³University of Sheffield, United Kingdom, ⁴University of Aberdeen, United Kingdom, ⁵Hospital Cochin, France, ⁶Charité - Campus Benjamin Franklin, Germany, ⁷Christian Albrechts Universitaet zu Kiel, Germany

Postmenopausal osteoporosis is characterised by an increase in bone turnover and an imbalance between bone resorption and bone formation. An approach has been described 'The Bone Marker Plot' that allows calculation of the rate of bone turnover and balance between bone formation and bone resorption from measurement of bone turnover markers. The aim of this study was to apply this approach to the prediction of fractures in older women. We studied 745 older women (55 to 80 years) and 213 younger women (20 to 39 years) from the Osteoporosis and Ultrasound Study (OPUS). We included women with bone turnover marker measurements who had no disease known to affect bone turnover, no anti-resorptive treatments close to baseline or during the study, and, if in the older group, were postmenopausal. We measured serum procollagen type I N-propeptide (PINP) and C-telopeptide of type I collagen (CTX) by automated immunoassay analyser (iSYS, IDS) on the samples taken at baseline. We calculated the multiple of the median for bone formation (PINP) and bone resorption (CTX) and the rate of bone turnover was calculated as the square root of the sums of the squared multiples of medians and the balance was calculated from the ratio of the formation multiple of median to the resorption multiple of median. The data were log transformed. We collected information about non-vertebral fractures by questionnaire and vertebral fractures by spinal radiographs after an interval of 6 years. There were 115 women with incident fractures over 6 years (23 vertebral, 92 non-vertebral). The older women had higher rates of bone turnover and more negative balance than the younger women (Mahalanobis distance 0.83, p<0.001). The women with vertebral fractures had more negative balance than those without fractures (odds ratio 0.61, 95% CI 0.40 to 0.93, p=0.020) but not significantly different turnover. The women with non-vertebral fractures had more negative balance than those without fractures (odds ratio 0.65, 95% CI 0.45 to 0.94, p=0.021) but not significantly different turnover. This suggests that balance rather than turnover may be an important determinant of fracture risk in older women.

Can Functional Muscle Testing Improve Fracture Risk Assessment in an Ageing Female Population. Nicola Crabtree¹, Natalie Bebbington², Katie Stant³, Helen Duff³, Jim Parle³, Neil Gittoes⁴.
¹Birmingham Children's Hospital, United Kingdom, ²Queen Elizabeth Hospital Birmingham, United Kingdom, ³University of Birmingham, United Kingdom, ⁴Queen Elizabeth Hospital, Edgbaston, United Kingdom

Osteoporotic fracture risk increases with age and decreasing bone density. Additionally, ageing causes muscle mass to decline and the risk of falling to increase. However, falls risk is currently not included in the frequently used fracture risk calculator (FRAXTM). The aim of this study was to investigate the relationship between bone strength, muscle function and previous fracture in a sub group of the SCOOP study cohort.

The SCOOP study is a RCT which aims to demonstrate whether community-based screening for osteoporosis reduces the incidence of fractures and is cost effective in older women. It is a 7-year prospective study which has recruited 12,495 women between 70 and 85 years. As part of the study DXA scanning was offered to women considered to be at high risk of fracture estimated from clinical risk factors. At our centre, 1692 subjects were recruited of whom 390 attended for DXA scanning. Of these, 290 had muscle function assessed using the chair rising test (CRT) on the Leonardo™ ground force reaction plate. Hip strength index (HSI) was estimated using the advanced hip analysis tools on the GE Lunar iDXA™.

A significant decrease with age was observed for femoral neck BMD, yet HSI remained constant (1.42[0.37]). A significant decrease was noted in muscle power ($p < 0.0001$) and this correlated with a small but significant increase in chair rise time ($p = 0.015$). Women with $HSI \leq 1$ were significantly slower (3.0 vs. 2.4s per chair rise, $p = 0.005$) and had less muscle power (4.4 vs. 5.8 Watts/kg, $p < 0.0001$) than those with $HSI > 1$. Previous fracture incidence was greatest (73.9%) in those women where $FSI \leq 1$ and $CRT > 2.5$ secs and lowest (34.6%) in those where $FSI > 1$ and $CRT \leq 2.5$ secs, suggesting that those with the lowest bone strength and highest risk of falling had the greatest risk of fracture.

Identifying those persons who have both reduced bone strength and reduced muscle strength may better predict future fracture in an ageing female cohort and timed chair rises may prove to be a simple but useful addition to FRAX™ when considering future fracture risk.

Osteoporosis Screening in Women 50-64 years-old: Comparison of U.S. Preventive Services Task Force 2011 Screening Strategy and Two Traditional Screening Strategies in Women's Health Initiative participants. Carolyn Crandall¹, Joseph Larson², Meghan Donaldson³, Andrea LaCroix², Jane Cauley⁴, Jean Wactawski-Wende⁵, Margery L.S. Gass⁶, John Robbins⁷, Nelson Watts⁸, Kristine Ensrud⁹. ¹University of California, Los Angeles, USA, ²Fred Hutchinson Cancer Research Center, USA, ³University of British Columbia/Vancouver Coastal Health Research Institute, Canada, ⁴University of Pittsburgh Graduate School of Public Health, USA, ⁵University at Buffalo, USA, ⁶The North American Menopause Society, USA, ⁷University of California, Davis Medical Center, USA, ⁸Mercy Health Osteoporosis & Bone Health Services, USA, ⁹Minneapolis VA Medical Center / University of Minnesota, USA

Purpose. For women age 50-64, the U.S. Preventive Services Task Force (USPSTF) recommends bone mineral density (BMD) testing if the 10-year major fracture risk is $\geq 9.3\%$ using Fracture Risk Assessment Tool (FRAX without BMD). The impact of this strategy compared with others (the Simple Calculated Osteoporosis Risk Estimation [SCORE] and the Osteoporosis Self-Assessment Tool [OST]) on the number of younger postmenopausal women identified for BMD testing and proportion of those with osteoporosis correctly identified are uncertain. In addition, it is uncertain how the USPSTF strategy compares with other strategies to discriminate between those with and without osteoporosis.

Methods. We examined baseline questionnaire and BMD data from participants aged 50-64 years at the 3 clinical sites of the WHI that measured BMD (dual energy-x-ray absorptiometry). We included data from all participants aged 50-64 years who were not using bisphosphonates, raloxifene, calcitonin, or parathyroid hormone ($N = 5165$). We assessed the proportion of women who would be recommended for BMD screening using the USPSTF approach, OST (OST score < 2) and SCORE (score > 7) strategies. We calculated the percentage of women in specific T-score categories (T-score > -1 , $-1 \leq T\text{-score} < 2.5$, and T-score ≤ -2.5) who would be recommended for BMD testing and assessed the sensitivity, specificity, and area under the receiver operating curve (AUC) to discriminate those with and without osteoporosis as defined by T-score ≤ -2.5 .

Results. The proportions of women who would be selected for BMD testing were: 15.2% for the USPSTF (FRAX), 31.5% for SCORE, and 36.0% for OST strategies. Under the USPSTF (FRAX) strategy, only 34.1% of women with T-score ≤ -2.5 would be recommended for BMD testing, compared with 74.0% with SCORE and 79.8% with OST. The sensitivity, specificity, and AUC for identifying T-score ≤ -2.5 were 34.1%, 85.8%, and 0.60 for the USPSTF (FRAX), 74.0%, 70.8%, and 0.72 for SCORE, and 79.8%, 66.3%, and 0.73 for OST screening strategies. Stratifying for baseline hormone therapy use did not substantially alter these results.

Conclusions. Among women aged 50-64, the proportion with T-scores ≤ -2.5 identified was 1/3rd using USPSTF strategy, 3/4 using SCORE strategy, and 4/5 using OST strategy. The USPSTF strategy was modestly better than chance alone and inferior to conventional SCORE and OST strategies in discriminating between women with and without osteoporosis.

Inhibition of Sclerostin With AMG 785 in Postmenopausal Women With Low Bone Mineral Density: Phase 2 Trial Results. Michael R. McClung¹, Andreas Grauer², Steven Boonen³, Jacques P. Brown⁴, Adolfo Diez-Perez⁵, Bente Langdahl⁶, Jean-Yves Reginster⁷, Jose R. Zanchetta⁸, Leonid Katz², Judy Maddox², Yu-Ching Yang², Cesar Libanati², Henry G. Bone⁹. ¹Oregon Osteoporosis Center, USA, ²Amgen Inc., USA, ³Leuven University, Belgium, ⁴Laval University & CHUQ Research Centre, Canada, ⁵Autonomous University of Spain, Spain, ⁶Aarhus University Hospital, Denmark, ⁷University of Liège, Belgium, ⁸Instituto de Investigaciones Metabólicas, Argentina, ⁹Michigan Bone & Mineral Clinic, USA

Purpose: In preclinical studies, administration of antibodies that neutralize sclerostin result in increased bone mass and strength. We report the primary and key secondary endpoints of a phase 2 trial, evaluating the efficacy and safety of the human sclerostin antibody AMG 785/CDP7851 in postmenopausal women with low bone mineral density (BMD).

Methods: This international, randomized, placebo-controlled, phase 2 study enrolled postmenopausal women aged 55 to 85 years with a lumbar spine, total hip, or femoral neck T-score ≤ -2.0 and ≥ -3.5 . During the first 12 months, women were randomized to one of 5 regimens of subcutaneous AMG 785 (70 mg QM, 140 mg QM, 210 mg QM, 140 mg Q3M, 210 mg Q3M) or placebo, and one of 2 open-label active comparators: 70 mg weekly oral alendronate (ALN) or 20 μ g daily subcutaneous teriparatide (TPTD). The primary endpoint was percentage change from baseline in lumbar spine BMD at month 12 (AMG 785 compared with placebo).

Results: The women enrolled in the study ($N=419$) had a mean age of 67 years, and mean lumbar spine, total hip, and femoral neck T-scores of -2.3 , -1.5 , and -1.9 , respectively. All AMG 785 doses significantly increased BMD compared with placebo at each of the 3 sites at month 12 ($p < 0.005$). The largest gains were observed with AMG 785 210 mg QM which resulted in rapid increases in BMD reaching 11.3% at the lumbar spine and 4.1% at the total hip (Figure). These increases were significantly greater than those achieved with ALN and TPTD ($p < 0.0001$). All doses of AMG 785 increased serum PINP and reduced serum CTX from baseline by week 1. Bone turnover marker changes with ALN and TPTD showed expected profiles (ie, decreases in both markers with ALN, and increases in both markers with TPTD). In general, adverse events were balanced between the placebo and total AMG 785 groups with the exception of generally mild injection site reactions (4% placebo; 12% AMG 785).

Conclusion: AMG 785 led to rapid and marked increases in lumbar spine and hip BMD which were superior to those observed with ALN and TPTD. These gains are a testimony to the mechanism of action evidenced by a simultaneous stimulation of bone formation and decrease in bone resorption. AMG 785 was generally well tolerated. These data support the continued clinical investigation of AMG 785 as a potential therapeutic agent for the treatment of women with postmenopausal osteoporosis.

Blosozumab, a Humanized Monoclonal Antibody against Sclerostin, Demonstrated Anabolic Effects on Bone in Postmenopausal Women. Juliet McCole¹, Theresa Womack², Leijun Hu², Cheng Cai Tang³, Alan Chiang². ¹Eli Lilly & Company, Erl Wood, United Kingdom, ²Eli Lilly & Company, USA, ³Eli Lilly & Company, Singapore

Objective: Two clinical studies were conducted to assess the safety, tolerability, pharmacokinetics (PK), pharmacodynamics (PD), and potential immunogenicity of single and multiple escalating doses (IV and SC) of blosozumab in postmenopausal women, including prior/current alendronate users.

Research Design and Methods: These phase 1 studies were subject- and investigator-blind, placebo-controlled, randomized studies evaluating escalating doses of blosozumab: single IV doses up to 750 mg, single SC dose of 150mg, multiple IV doses up to 750mg every 2 weeks (Q2W) and multiple SC doses up to 270mg Q2W. Up to 8 subjects were randomized to each dose in the single dose study and up to 12 subjects to each dose in the multiple dose study. Safety parameters, including adverse events, and pharmacodynamic effects, including bone mineral density (BMD) and immunogenicity, were assessed for up to 12 weeks after the final dose of blosozumab.

Results: Blosozumab was well tolerated with no safety concerns identified following single or multiple administrations up to 750mg. Clinically and statistically significant bone biomarker responses were observed in sclerostin, procollagen-1 N-terminal peptide (PINP), bone specific alkaline phosphatase (BSAP), osteocalcin (OC), and carboxyterminal cross-linking telopeptide of collagen type 1 (CTx). A clinically and statistically significant anabolic response on bone was demonstrated through BMD following single and multiple (up to 5) administrations of blosozumab. There was up to a 3.41% (1.35,5.47) and up to a 7.71% (5.74, 9.67) [least-squares mean (90% confidence interval)] change from baseline in lumbar spine BMD at Day 85 following a single or multiple administration of blosozumab, respectively. The effects generally showed dose-related effects over the dose range tested and prior alendronate use did not appear to have a major impact. Antibodies to blosozumab were detected

but there was no pattern with regards to dose or route of administration and no suggestion of a neutralizing effect in terms of PK or PD parameters.

Conclusions: Blosozumab was well tolerated and exhibited anabolic effects on bone in these studies. These data support further investigation of blosozumab as a potential anabolic therapy for osteoporosis.

Effects of Odanacatib on BMD and Overall Safety in the Treatment of Osteoporosis in Postmenopausal Women Previously Treated with Alendronate. Tobias De Villiers¹, Sydney Bonnick², Alberto Odio³, Santiago Palacios⁴, Roland Chapurlat⁵, Boyd Scott⁶, Celine Le Bailly De Tillegem⁷, Carolyn DaSilva⁸, Albert Leung⁹, Deborah Gurner¹⁰. ¹Mediclinic Panorama, South Africa, ²Clinical Research Center of North Texas, USA, ³Alta California Medical Group, USA, ⁴Instituto Palacios, Salud y Medicina de la Mujer C/Antonio Acuña, Spain, ⁵E. Herriot Hospital, France, ⁶Merck & Co., Inc., USA, ⁷Merck Sharp & Dohme Corp., USA, ⁸Merck, USA, ⁹Merck Research Laboratories, USA, ¹⁰MSD, USA

Odanacatib (ODN) is a potent, orally-active cathepsin K inhibitor being developed for the treatment of postmenopausal osteoporosis. This study evaluated the effects of ODN 50mg once weekly (OW) on BMD and biochemical markers of bone turnover in patients previously treated with alendronate (ALN) (dosed daily or weekly) for ≥3years as well as the safety and tolerability of ODN. This study was not designed nor had the power to evaluate the effect of ODN on fractures.

This was a randomized, double-blind, placebo-controlled, 24-month study. The primary endpoint was % change from baseline at Month 24 of femoral neck (FN) BMD. 243 postmenopausal women ≥60 years of age with low BMD T-score (T-score range ≤-2.5 but >-3.5) at the total hip, FN or trochanter but no history of hip fracture and who had been treated with ALN for ≥3years were randomized in a 1:1 ratio to receive ODN 50mg OW or placebo OW for 24 months. All patients received vitamin D₃ 5600 IU/wk and calcium supplementation (to 1200 mg/day). BMD was assessed by DXA at baseline, 6, 12 and 24 months. Biochemical markers of bone turnover (s-CTX, u-NTx, s-BSAP and s-PINP) were measured at baseline and 3, 6, 12, 18 and 24 months.

In the placebo group, BMD at the FN and trochanter were not significantly different from baseline levels for the first 12 months, but declined significantly from baseline by Month 24 (-0.94% and -1.35%, respectively). Total hip BMD declined in a linear manner from baseline to month 24 (-1.87% at 24 months). At the lumbar spine (LS), BMD was not significantly different from baseline for the entire 24 months of the study. In the ODN group, BMD changes from baseline at 24 months were significant vs placebo at all 3 hip sites and the LS. The changes from baseline were 1.73%, 1.83%, 0.83% and 2.28%, respectively, for the FN, trochanter, total hip and LS. ODN 50mg OW significantly decreased the biomarker of bone resorption, u-NTx/Cr, and significantly increased biomarkers of bone formation, s-PINP and s-BSAP, compared to placebo. The increase observed for the bone resorption marker s-CTX with ODN treatment was unexpected. AEs were comparable between the 2 treatment arms. The overall safety profile appeared similar between ODN 50mg OW and placebo.

In this study ODN provided incremental BMD gains in osteoporotic women following ALN treatment. Biomarker results suggest that ODN decreases bone resorption while preserving bone formation.

Effects of Odanacatib on the Distal Radius and Tibia in Postmenopausal Women: Improvements in cortical geometry and estimated bone strength. Anne De Papp¹, Angela Cheung², Sharmila Majumdar³, Kim Brixen⁴, Roland Chapurlat⁵, Bernie Dardzinski¹, Antonio Cabal¹, Nadia Verbruggen⁶, Shabana Ather⁷, Elizabeth Rosenberg¹. ¹Merck & Co., Inc., USA, ²University Health Network, Canada, ³University of California, San Francisco, USA, ⁴Institute for Clinical Research, Denmark, ⁵E. Herriot Hospital, France, ⁶Merck Sharpe & Dohme, Belgium, ⁷Merck & Co, Inc., USA

The cathepsin K inhibitor odanacatib (ODN), a novel antiresorptive that preserves bone formation, is currently in phase 3 development for postmenopausal osteoporosis. In a phase 2 study, 5 years of ODN 50 mg once weekly progressively increased areal BMD at the lumbar spine and total hip (11.9 % and 8.5% from baseline, respectively). ODN reduced bone resorption markers while preserving bone formation markers. In an OVX primate model, ODN has been shown to increase cortical thickness and periosteal bone formation at the central femur and femoral neck. In order to determine the effect of ODN on cortical geometry and to estimate bone strength, we conducted a randomized, double-blind placebo-controlled trial, using high resolution quantitative computerized tomography (HR-pQCT) of the distal radius and distal tibia. A total of 214 postmenopausal women, of mean age 64.0 ± 6.8 years and baseline lumbar spine T-score -1.81 ± 0.83, were randomized to oral ODN 50 mg or PBO weekly for 2 years. Lumbar spine areal BMD % change from baseline at 1 year (primary endpoint) was statistically significantly greater for ODN than PBO (3.49% treatment difference, p<0.001). After 2 years, there were significantly greater improvements with ODN than PBO in total, trabecular, and cortical volumetric BMD; cortical thickness; and estimated strength (failure load) of the distal radius using HR-pQCT-based finite element analysis (exploratory endpoints, FIGURE). At the radius, odanacatib attenuated the increase in cortical porosity that was seen in the placebo group (treatment difference in least squares mean % change from baseline -7.68, p=0.066). At the distal tibia, changes in volumetric BMD and cortical thickness were similar to changes at the radius. Safety and tolerability were similar between treatment groups. In conclusion, odanacatib increased cortical and trabecular density and improved cortical thickness of the distal radius and distal tibia, and improved the estimated bone strength in the distal radius compared to placebo.

Figure. Distal Radius HR-pQCT Endpoints in Postmenopausal Women at Month 24

NOTE: HR-pQCT endpoints were exploratory and there was no adjustment for multiplicity.

Bone Material Strength in Bisphosphonate-related Atypical Femoral Fractures Measured by 'in vivo' Microindentation. Robert Guerri Fernandez^{*1}, Jose Manuel Quesada Gomez², Xavier Nogues³, Leonardo Mellibovsky⁴, Lluís Puig⁵, Guv Yoskovitz⁶, Natalia Garcia Giralt⁵, Elisa Torres del Pliego⁷, Paul Hansma⁸, Adolfo Diez-Perez⁹. ¹Fundacio IMIM, Spain, ²Quesper R&D, Spain, ³Institut Municipal D'Investigació Mèdica, Spain, ⁴Hospital del Mar. IMIM. URFOA., Spain, ⁵Hospital del Mar. IMIM. URFOA, Spain, ⁶IMIM, Spain, ⁷Hospital del Mar. IMIM.URFOA, Spain, ⁸University of California, Santa Barbara, USA, ⁹Parc De Salut Mar, Spain

Atypical femoral fractures (AFFx) associated with long-term bisphosphonates (LTB) treatment are a growing safety concern. Their aetiology is not known but a deep alteration in bone material strength is likely given their clinical characteristics. In an AFFx series, we analyzed the strength of bone material by microindentation.

Patients and methods

Four groups of patients were included: 6 AFFx, 38 typical osteoporotic fractures, 6 LTB and 20 controls without fracture. A general laboratory work-up, bone densitometry by dual-energy X-ray absorptiometry, and bone microindentation testing at the tibia was done in all patients. Total indentation distance (Total ID), Indentation distance increase (IDI) and Creep indentation distance (Creep ID) were measured (microns). Age-adjusted ANCOVA analysis was used for comparisons between groups.

Results: Control individuals were significantly younger than the fracture groups. Bisphosphonate exposure was on average 5.5 years (range 5-12) for the AFFx group and 5.4 years (range 5-8) for the LTB group. Total ID (microns) was 36 (±6) for controls, 38(±4) for LTB, 46(±4) for AFFx and 47 (±13) for typical femoral fractures (mean ± SD), and IDI values were 13 (±2), 16 (±6), 19 (±3) and 18 (±5), respectively.

After adjusting by age, statistically significant differences were seen between controls and typical (P<0.001) and atypical fractures (P=0.03) for Total ID as well as for IDI (P<0.001 and P<0.05 respectively). There were no differences in Creep ID between groups.

Conclusions: Our data suggest that patients with AFFx have a deep deterioration in bone material strength at a tissue level not seen in LTB-treated cases. Since patients on bisphosphonates at risk of AFFx are not detected by bone mineral density tests, this finding strongly suggests an underlying bone condition in this subset of patients.

Quantitative Bone Histomorphometry in Patients with Bisphosphonate-Associated Atypical Subtrochanteric Femur Fractures Before and after 12 months of Teriparatide. Paul Miller^{*1}, Ed McCarthy². ¹Colorado Center for Bone Research, USA, ²John Hopkins Medical School, USA

Purpose: Atypical subtrochanteric femur fractures (ASFF) have been associated with long-term bisphosphonate (BP) administration. The mechanism whereby BP's may be linked to the greater risk of ASFF is unknown, but may be associated with a reduction in bone remodeling. Recombinant human 1-34 parathyroid hormone (rh-1-34 PTH) increases bone remodeling. It is unknown what effect administration of rh 1-34 PTH may have on remodeling in these patients. We report the results of paired bone biopsies done before and 12 months after treatment with rh 1-34 PTH in 15 patients with bisphosphonate associated ASFF.

Methods: Fifteen post-menopausal women on long-term alendronate who presented with ASFF underwent double tetracycline labeled transiliac bone biopsies between 6 weeks to 7 months following their ASFF. All patients already had intramedullary rods placed. The patients then received teriparatide (rh 1-34 PTH), 20ug/day for 12 months at which time a second biopsy was obtained from the opposite iliac crest. Quantitative histomorphometric analysis was performed and parameters were compared to published normative reference standards as well as to each patient's baseline biopsy.

Results: The baseline mineral apposition rate (MAR) in the group averaged 0.278 um/day (normal: 0.66-0.83 um/day) and was zero in 7 patients. After teriparatide administration the average MAR increased to 0.647 um/day. All 7 patients who had immeasurable MAR at baseline increased their MAR following teriparatide (average: 0.673 um/day). Likewise the bone formation rate (BFR) at baseline averaged 1.692 %/yr (normal: 8.6-21.8 %/yr) and was also zero in the same 7 patients that had immeasurable MAR. Following teriparatide the BFR increased in all patients, including the 7 with immeasurable MAR to an average of 4.03 %/yr.

Conclusions: Bone remodeling in patients with bisphosphonate associated ASFF is, on average, lower than published normal reference values but increase after discontinuation of bisphosphonates and 12 months of teriparatide administration. The baseline biopsies were heterogeneous in their quantitative parameters, though 7/15 patients had immeasurable MAR and BFR. The observations in this uncontrolled analysis do not confirm any pathophysiological link between bisphosphonate exposure and the development of ASFF but do suggest that (along with BP discontinuation) teriparatide may increase MAR and BFR in these patients who present with these ASFF. It remains unknown if teriparatide would prevent early fractures from progressing.

Mechanoregulation of Cortical and Trabecular Bone Adaptation Measured by Examining Dynamic Bone Morphometry and the Mechanical Environment. Annette Birkhold^{*1}, Hajar Razi¹, Richard Weinkamer², Georg Duda¹, Sara Checa¹, Bettina Willie¹. ¹Julius Wolff Institute, Charité Universitätsmedizin Berlin, Germany, ²Max Planck Institute of Colloids & Interfaces, Germany

Bone can adapt to mechanical stimuli to attain its structure. However, the exact mechanisms of adaptation remain unclear. We hypothesize that both trabecular and cortical bone adapt to a similar amount to changes in the global loading by reduced resorption and increased formation.

We performed in vivo loading on the left tibia of ten female adult (26wk old) C57Bl/6 mice (right limb as internal control). In vivo microCT was performed at day 0, 5, 10, and 15. Images were registered with an algorithm overlaying data of the same limb at different time points. Resulting volumes were separated into trabecular and cortical bone. Constant, formed and resorbed bone volumes (BV), as well as corresponding parameters normalized to the total bone volume (BV/TBV), formation and resorption surface areas (SA) and normalized parameters (SA/TSA), bone formation (BFR) and resorption rates (BRR), mineral apposition (MAR) and resorption rates (MRR) were determined and validated with histomorphometry data. The local mechanical strains were determined with finite element method using a submodelling technique. Regional elasticity was in accord with the average BMD of the fibula, distal and proximal tibia. FEMs were validated with strain gauge data.

Mechanical loading significantly increased surface area of trabecular bone formation, but not MAR. The effect of loading on formed surface area was more prominent in cortical than in trabecular bone (cortical 6.6, trabecular 2.0 fold increase). Resorption area was reduced in cortical and trabecular bone (cortical 1.9, trabecular 1.5 fold decrease), but MRR was not altered. Higher strain levels were predicted in the cortical region (tensile 533-1627 microstrain, compressive 378-3012 microstrain) than in the trabecular region (tensile 393-707 microstrain, compressive 388-1442 microstrain).

Bone adapts to the loading by an increased formation and a reduced resorption, but in cortical bone the increase in bone apposition was much greater (figure). These data suggest adaptation is likely caused by a higher amount of osteoblast being recruited (or lining cells turning into osteoblasts), rather than by increasing the velocity of bone formation. The relationship between increased area of formation in cortical bone and higher tissue strain indicates that a threshold for increasing the number of osteoblasts may exist. Further investigations will determine local differences in the mechano-responsiveness of cortical and trabecular bone, as well as age related alterations.

Force Induced Cytoskeletal Reorganization in MSC Requires mTORC2 Signaling at Focal Adhesions. Buer Sen^{*1}, Zhihui Xie², Natasha Case³, William Thompson⁴, Maya Styner³, Janet Rubin³. ¹University of North Carolina At Chapel Hill, USA, ²University of North Carolina, USA, ³University of North Carolina, Chapel Hill, School of Medicine, USA, ⁴University of Delaware, USA

The ability of cells to sense and transduce mechanical input involves focal adhesions (FA), which transmit outside-in information via integrins to signaling molecules co-localized within the FA. We published that mTORC2 (the rapamycin-insensitive rictor-associated mTOR) is a novel target of mechanical force: mTORC2

activates Akt, which through GSK3β inhibition leads to increased β-catenin and inhibition of adipogenesis of mesenchymal stem cells (MSC). Interestingly, mTORC2 has been shown to have a role in generating baseline cytoskeletal structure. As we have previously shown that MSC respond to mechanical input by generating more cytoskeletal structure, i.e., increased FAs connected by F-actin stress fibers, we wished to ascertain if mechanically activated mTORC2 was involved in this cytoskeletal reorganization. To activate mTORC2 signaling we applied cyclical strain (100 cycles x 2% strain) to marrow derived MSCs. RNA silencing of rictor (partner of mTOR) prevented strain, but not insulin, induced Akt serine 473 phosphorylation, confirming the role of mTORC2 signaling in Akt activation by strain. We next immunoprecipitated with vinculin to capture FA associated proteins: acute strain application induced both rictor and Akt association with FAs. Immunofluorescence staining for vinculin and rictor confirmed that mechanical loading induced rictor co-localization at FAs. Inhibition of mTOR activity blocked strain induced association of rictor/Akt with vinculin. The initial recruitment of mTORC2 to vinculin was shown to rely on tension development from disordered actomyosin as inhibition of myosin II kinase eliminated mechanical Akt activation and prevented the association of rictor/Akt with FAs. mTORC2 was next shown to be critical for the cytoskeletal reorganization induced by strain; FA assembly and their interconnection by radial stress fibers was completely prevented by both rictor silencing and by inhibition of mTOR. We further ascertained that the mTORC2 effector, Akt, was required for FA assembly, as inhibition of Akt activity phenocopied mTORC2's role in cytoskeletal reorganization. Our data shows that mechanically-induced rictor/Akt association with FA-vinculin is critical for strain-induced radial stress fiber association at the focal adhesion complex. As such, strain activation of mTORC2 prevents adipogenesis of MSC both through initiating β-catenin signaling and by increasing focal adhesion assembly.

Cumulative Effects of Strontium Ranelate and Free-fall Impact Exercise in a Female Ovariectomized Rat Model. Priscilla C. Aveline^{*1}, Jérôme Touvier¹, Eric Lespessailles¹, Claude-Laurent Benhamou¹, Gael Y. Rochefort². ¹EA4708 I3MTO, Orléans Hospital, France, ²EA4708 I3MTO, Orléans Hospital, France, France

Physical exercise is known to exert beneficial effects on bone status. Strontium Ranelate (SrRan) was shown to have anti-osteoporotic properties in clinical studies and animal models. The combination SrRan + physical exercise has not yet been tested. We have mounted a study testing impact activity (EXE), or SrRan, or both in female rats either ovariectomized (OVX) or not (SHAM).

We have studied 8 groups of 12 female Wistar rats, 5 weeks old at baseline: SHAM (Sh), SHAM/SrRan (ShSr), SHAM/EXE (ShE), SHAM/EXE/SrRan (ShESr), OVX (O), OVX/SrRan (OSr), OVX/EXE (OE) and OVX/EXE/SrRan (OESr). Animals in the EXE groups were subjected to 10 impacts per day from 45 cm high, 5 days a week during 8 weeks. SrRan group animals were treated orally with 625 mg/kg of SrRan in 0.5 % carboxymethylcellulose (vehicle) per day during 8 weeks. Bone mineral density (BMD) and content (BMC) (whole body and left femur) were measured by DXA (Hologic Discovery) at weeks 0, 4 and 8. Morphological properties of trabecular and cortical bone from femur, tibia and L2 to L4 vertebrae were analyzed by µCT (Skyscan, 1072). A technique of image analysis assessing bone cortical geometry was settled. Osteocyte apoptosis was studied by cleaved caspase-3 immunostaining and expressed as a percent of total cells.

MicroCT analysis (femur, tibia and L2-L4 vertebrae) showed a deleterious effect of OVX, and a beneficial effect of SrRan and of EXE on BV/TV, Tb.N, Tb.Th, Tb.Pf, Tb.Sp and SMI. A significant additive effect of SrRan and EXE on these parameters was found. Cortical thickness was increased in SrRan groups; Ct.Po and Po.N were improved at femur and tibia levels in the SrRan groups, and significantly more in the EXE + SrRan groups.

OVX groups had a significantly higher osteocyte apoptosis versus SHAM animals. EXE did not significantly reduce osteocyte apoptosis in SHAM and OVX groups while SrRan significantly reduced osteocyte apoptosis in all groups. There was no significantly cumulative effect of EXE and SrRan on this parameter.

These data suggest that physical activity and SrRan may have a cumulative effect both on trabecular bone mass and microarchitecture as well as on cortical geometry and porosity. SrRan significantly reduced osteocyte apoptosis in cortical bone without significant cumulative effect with EXE. These data constitute the first description of an additive effect of SrRan plus EXE on bone status, and of a beneficial effect of SrRan on osteocyte apoptosis.

Exercise during recovery from HU proved beneficial to most densitometric and biomechanical properties of bone as measured at the end of recovery and after a subsequent period of disuse (2nd HU). Cancellous bone strength exhibits the most dramatic increases with exercise during recovery and is well preserved after the 2nd HU. Thus, incorporating resistance exercise during recovery from disuse not only provides benefits during reloading but also for subsequent unloading even with cessation of exercise.

Site- and Compartment-specific Effects of Microgravity on the Skeleton in Mice Flown on the STS-135 Shuttle Mission. Rachel Ellman^{*1}, Virginia Ferguson², Eric Livingston³, Michael Lemus³, Leann Louis¹, Jordan Spatz⁴, Kelly Warmington⁵, Hong Lin Tan⁵, Dave Hill⁵, Marina Stolina⁵, Denise Dwyer⁵, Sutada Lotinun⁶, Roland Baron⁷, Chris Paszty⁸, Louis Stodieck², Mary Boussein¹, Ted Bateman⁹. ¹Beth Israel Deaconess Medical Center, USA, ²University of Colorado, USA, ³University of North Carolina, Chapel Hill, USA, ⁴Harvard-MIT Division of Health Sciences & Technology (HST), USA, ⁵Amgen Inc., USA, ⁶Harvard School of Dental Medicine, USA, ⁷Harvard School of Medicine & of Dental Medicine, USA, ⁸Amgen, Inc., USA, ⁹University of North Carolina, USA

Astronauts have high rates of bone loss following exposure to microgravity. Yet, the mechanisms that contribute to this profound bone loss are incompletely understood. Animal models are commonly used to study interactions between reduced loading and bone loss, but there are few data describing bone responses to microgravity in mice. Thus, the aim of this study was to assess site-specific changes in bone and muscle in mice exposed to microgravity via a 13 day flight on the space shuttle Atlantis. Female C57Bl/6N mice (9 wks old) were assigned to flight (FL, n=15) or ground-controls (GR, n=14) according to total body (TB) BMD and body mass. Mice were acclimated to cages and food for 2 weeks prior to start of the study. Outcomes included: in vivo BMD (total body, spine, leg and arm), ex vivo normalized muscle mass, and microarchitecture (tibia, femur, humerus), as well as serum markers of bone metabolism at end of study. Results: While both groups lost body weight (-8 and -6% in GR and FL), total lean/fat mass ratio did not differ between groups. There was significant muscle atrophy in hindlimbs (-3 to -18% in GR vs. FL, p < 0.05), but not in the forelimbs, where biceps mass was 18% higher in FL vs. GR (p < 0.05). Bone changes followed similar pattern as muscle, with greater effects in the hindlimb than forelimb. TB and leg BMD increased in GR, but acquisition was diminished with spaceflight (TBMD: 6.6% vs. 2.2% in GR vs. FL; Leg BMD: 9.0 vs. 1.3% in GR vs. FL, p < 0.01 for both), whereas arm BMD did not differ between groups. Tb.BV/TV was approx. 35% lower in FL vs. GR at the proximal tibia and distal femur (p < 0.01), but was only 22% lower in FL vs. GR at the proximal humerus (p < 0.05). Tb.Th was lower in FL than GR (-14 to -22%, p < 0.05), but Tb.N was unaffected. Cortical BA/TA was 4-8% lower in FL vs. GR at mid-tibia and femur, but was unchanged at the humerus. Serum measures were consistent with both lower bone formation (decr. osteocalcin and PINP) and higher bone resorption (decr. OPG, incr CTX1) in FL vs. GR. Serum sclerostin levels did not differ between groups at study end. In summary, short exposure to microgravity (13 days) induced significant deterioration of bone that was more pronounced in the hindlimb than forelimb, consistent with changes in muscle mass. Increased use of the forelimbs in the cages with wire floors and walls may have provided some protection from effects of microgravity in the forelimb.

Connexin 43 Deficiency Protects Against Skeletal Changes Associated with Mechanical Unloading. Shane Lloyd^{*1}, Gregory Lewis², Yue Zhang¹, Emmanuel Paul², Henry Donahue¹. ¹The Pennsylvania State University College of Medicine, USA, ²Penn State College of Medicine, USA

Gap junctions (GJs) are small protein channels that allow for direct cell-to-cell communication. Connexin 43 (Cx43) is the predominant GJ in bone and has been shown to have an integral role in the skeletal response to mechanical loading both in vitro and in vivo. However, little work has focused on the role of Cx43 in the response to unloading. Practical unloading scenarios include extended bed rest due to neurological injury, reduced physical activity associated with aging, or the microgravity environment.

We utilized skeletally mature mice with an osteoblast and osteocyte specific, osteocalcin-driven deficiency of Cx43 (cKO) or their wild-type (WT) littermates. Mice were subjected to three weeks of normal loading conditions (Control) or unloading via hindlimb suspension (Suspended) (4 groups, n=10-15/group). Mice were subjected to baseline and endpoint MicroCT scans. Dual-label quantitative dynamic histomorphometry was conducted.

At baseline, cKO mice demonstrated a cortical osteopenic phenotype, with reduced cortical thickness and bone mineral density and increased porosity. There was no trabecular phenotype. Loss of trabecular bone following three weeks of unloading was significantly attenuated in cKO mice (Figure 1AB). In cKO, there was reduced loss of trabecular BV/TV (-53% vs. -67%, p < 0.01), trabecular thickness (-21% vs.

Exercise during Recovery between Two Bouts of Disuse Mitigates Bone Loss on Second Exposure. Yasaman Shirazi-Fard^{*}, Estela Gonzalez, Joshua Davis, Ramon Boudreaux, Derrick Morgan, Kevin Shimkus, Susan Bloomfield, Harry Hogan. Texas A&M University, USA

The bone response to repeat exposures of disuse remains a concern for astronaut health and for clinical patients experiencing periods of bed rest or non-weightbearing. Previously, we reported that, regardless of age, bone loss during a subsequent period of disuse is milder than the initial exposure. This experiment assessed effects of resistance exercise during recovery between two bouts of disuse in distal femur metaphysis (DFM) and femur diaphysis (FD) bone. We hypothesized that exercise would not only enhance recovery but would also mitigate impact of the 2nd disuse.

Adult male Sprague-Dawley rats (6mo.) were assigned to age-matched cage controls (CC) and hindlimb unloaded (HU) groups by body weight and total (integral) vBMD. HU animals were exposed to 28d of hindlimb suspension (1HU), followed by 56d of recovery (1HU+R), and then a 2nd HU exposure (2HU). HU animals also performed squat jumping resistance exercise during recovery for 7 weeks (3d/wk) with exercise intensity increasing weekly. Groups (n=15) were euthanized at baseline, the end of the exercise protocol (1HU+EX, CC9), and after the 2nd HU (2HU+EX, CC10). Excised femora were scanned by pQCT at DFM and FD and tested to failure by 3-pt bending at FD and reduced platen compression at DFM.

DFM total BMC and vBMD for 1HU+EX recovered more completely (+23.1%, +14.3%) compared to 1HU+R (+3.6%, +3.9%). During the 2nd HU, tot BMC in 2HU+EX increased (+2.9%) while 2HU decreased (-1.9%). Tot vBMD decreased during the 2nd HU in both 2HU+EX (-2.0%) and 2HU (-6.9%). FD cortical BMC and vBMD recovered more in 1HU+EX (+10.7%, +2.4%) than 1HU+R (+7.4%, +0.16%). Cortical vBMD in 2HU+EX increased 3.8% vs. a decrease of 1.8% in 2HU. Exercise did not improve FD ultimate strength during recovery or during the 2nd HU. DFM ultimate stress from RPC testing increased +217% for 1HU+EX compared to 114% for 1HU+R and was significantly higher in 2HU+EX compared to 2HU by 342% or CC10 by 183%.

-35%, $p < 0.001$), and connectivity density (-50% vs. -64%, $p < 0.05$). There was no difference in loss of cortical bone between genotypes. Bone formation was dramatically suppressed during unloading of WT mice at both the endocortical (-100% Ec.BFR, -70% Ec.MS/BS) and periosteal surfaces (-60% Ps.BFR, -38 Ps.BFR ($p < 0.05$ for all)). This was not observed in cKO mice, where bone formation and mineralizing surface were maintained at control levels (Figure 2).

Taken together, these results indicate that defective Cx43 expression and/or gap junctional intercellular communication desensitizes bone to the effects of mechanical unloading, and that this may be due to an inability of mechanosensing osteocytes to effectively communicate the unloading state to osteoblasts to suppress bone formation. Combined with published reports from our laboratory demonstrating that Cx43 cKO mice have increased sensitivity to mechanical loading, these findings suggest that Cx43 may be a potential therapeutic target for investigation as a countermeasure to unloading and age-related bone loss.

Osteocytes in the Homeostasis of Remote Organs. Mari Sato^{1*}, Noboru Asada¹, Kentaro Minagawa¹, Yuko Kawano¹, Hiroki Kawano¹, Kanako Wakahashi¹, Akiko Sada¹, Kyoji Ikeda², Toshimitsu Matsui¹, Yoshio Katayama¹. ¹Hematology, Dept. Med., Kobe Univ., Japan, ²National Center for Geriatrics & Gerontology, Japan

Reduced mechanical stress to bone in bedridden patients and astronauts leads to osteoporosis and immune suppression, and osteocytes are known as mechanosensory cells in bone. Here we show amazing functions of osteocytes to regulate an immune organ, thymus, and a metabolic organ, liver, both remote from bone. We utilized transgenic (TG) mice in which inducible and selective ablation of osteocytes is achieved *in vivo* through targeted expression of diphtheria toxin (DT) receptor. A single injection of DT in TG mice at 15 weeks of age generates osteocyte-less (OL) mice. Three weeks after DT injection, OL mice displayed severe lymphopenia and thymic atrophy (90% reduction in cellularity, $n=8$, $p < 0.0001$), but these phenotypes were restored as osteocytes were replenished 3 months after DT injection. B cell precursors in the bone marrow (BM) were also drastically decreased (pre-B cells by 89%, $n=3$, $p < 0.05$; pro B cells by 79%, $n=3$, $p < 0.01$), however, common lymphoid progenitors were only minimally affected (34%, $n=10$, $p < 0.01$). Hematopoietic stem cell activity, as assessed by competitive repopulation, and colony-forming myeloid precursors were not impaired. Analysis of B-lymphoid long-term BM cultures revealed that OL BM failed to produce B cells because of depletion of lymphoid-supporting CD45-VCAM-1+ stromal cells. Moreover, immunohistochemical analysis of the thymus showed that K8+ cortical thymic stromal cells were greatly reduced and their mesh network became sparse. Neither *in vivo* supply of T cell progenitors nor humoral factors by sharing the circulation with a normal partner in parabiosis rescued the thymic atrophy in OL mice. These results suggest that thymic atrophy in the absence of osteocytes was due to impaired thymic microenvironment. Since they also suggest that osteocytes control thymic stroma via a non-humoral signal, we speculated the involvement of the nervous system. To test this, we ablated osteocytes following destruction of ventromedial hypothalamic nucleus (VMH) or arcuate nucleus (ARC)

which controls food intake as well as bone mass. Although thymic atrophy was not restored, VMH or ARC destruction in OL mice unexpectedly caused massive fatty liver, which implies that some signal from osteocytes may normally suppresses fat accumulation in the liver caused by excessive food intake. Collectively, these results uncover surprising functions of osteocytes in the homeostasis of multiple remote organs.

PTH/PTHrP Receptor Signaling in Osteocytes Regulates Anabolic and Catabolic Bone Responses to PTH by Modulating Bone Remodeling via Sclerostin and RANKL Expression. Vaibhav Saini^{1*}, Keertik Fulzele², Kevin Barry³, Dean Marengi³, Sutada Lotinun⁴, Roland Baron⁵, Paola Pajevic Divieti⁶. ¹MGH, Harvard Medical School, USA, ²Massachusetts General Hospital; Harvard Medical School, USA, ³MGH, USA, ⁴Harvard School of Dental Medicine, USA, ⁵Harvard School of Medicine & of Dental Medicine, USA, ⁶MGH- Harvard Medical School, USA

PTH is the only available anabolic agent to treat osteoporosis. Osteocytes may partially mediate the anabolic effects of PTH by suppressing Sclerostin, a Wnt signaling inhibitor. To investigate the role of PPR signaling in osteocytes, we generated mice lacking PPR in osteocytes (OcyPPRKO). Littermates carrying the floxed PPR alleles were used as controls. qPCR showed significantly decreased PPR transcripts in the osteocyte-enriched long bones of OcyPPRKO compared with control, demonstrating successful PPR ablation. Next, the role of PPR signaling in osteocytes in anabolic and catabolic bone responses was evaluated. For anabolic regimen, 8-week-old females were injected with 80µg/kg/day hPTH(1-34) for 4 weeks whereas for catabolic treatment, 13-week-old males were infused for 2 weeks with 100µg/kg/day. MicroCT analysis of femurs showed significantly higher cortical thickness ($p < 0.05$, $N > 4$) and bone area ($p < 0.05$, $N > 4$) in control animals treated with intermittent PTH as compared with vehicle whereas, as expected, continuous PTH induced a significant decrease in bone volume ($p < 0.05$, $N = 6$) and trabecular number ($p < 0.05$, $N = 6$) and increase in trabecular spacing ($p < 0.05$, $N = 6$) in control mice. In contrast, these parameters remained unchanged in OcyPPRKO mice treated with intermittent or continuous PTH. Histomorphometric analysis of anabolic or catabolic response to PTH in OcyPPRKO showed significantly reduced osteoblast numbers ($p < 0.05$, $N > 4$), and reduced, though not significant, osteoclast numbers were observed in OcyPPRKO than control. TRAP staining showed a lack of multinucleated TRAP+ osteoclasts in OcyPPRKO trabecular and cortical bone as compared with control. Immunohistochemistry of tibiae showed increased Sclerostin and decreased RANKL expression in osteocytes of OcyPPRKO than control. Lastly, to determine osteoclastogenic potency, osteoclast precursors from wild type spleens were co-cultured with osteocyte-enriched long bones from OcyPPRKO and control. Upon PTH treatment, a significantly reduced number of multinucleated osteoclasts were detected in OcyPPRKO co-culture compared to control ($p < 0.05$, $N = 3$). Osteoprotegerin treatment completely abrogated osteoclast formation in both groups, indicating that PPR signaling in osteocytes regulates osteoclastogenesis via a RANKL-mediated pathway. In summary PPR on osteocytes regulates RANKL expression, which in turn regulates osteoclast formation, and thus bone remodeling.

Inhibition of Wnt1 Class Induced Lrp6 Signaling Normalizes Bone Mass in *Sost*; *Lrp5* Double Knockout Mice. Ming-Kang Chang^{1*}, David Jenkins², Ina Kramer¹, Seth Ettenberg², Marcel Merdes¹, Christine Henninger¹, Feng Cong², Michaela Kneissel¹. ¹Novartis Institutes for Biomedical Research, Switzerland, ²Novartis Institutes for BioMedical Research, USA

Sclerostin, encoded for by *Sost*, is an osteocyte secreted negative regulator of bone formation. Sclerostin is thought to exert its action by binding to the Wnt co-receptor Lrp5 and possibly Lrp6 thus blocking Wnt/beta-catenin signaling in cells of the osteoblastic lineage. We have shown previously that *Sost*; *Lrp5* double knockout (dKO) mice present with reduced bone overgrowth compared to *Sost* single knockout (KO) mice. To test whether the remaining bone overgrowth could be abolished by blockage of Lrp6 mediated Wnt signaling, we utilized three Lrp6 targeting antibodies that recognize different epitopes on Lrp6 and have distinct modes of action as previously described (1). First we injected 12-week-old *Sost* KO and control females ($n=5-8$ /group) for one month either with antibody A - blocking Wnt1 class mediated signaling, but potentiating Wnt3a class mediated signaling, or antibody B - displaying the reverse pattern, or antibody C - blocking both types of signaling, or vehicle. Computed tomography analysis revealed that blocking Wnt1 class mediated signaling reduced the abnormal bone gain in *Sost* KO mice and to a lesser extent also reduced growth related bone gain in control mice. This effect was irrespective of enhancement (antibody A) or blockage (antibody C) of Wnt3a class mediated signaling. Reversely and consistently, promotion of Wnt1 class mediated signaling in the absence of Wnt3a class mediated signaling (antibody B) further enhanced the abnormal bone gain of *Sost* KO mice and induced bone gain also in control mice. These data indicate that sclerostin mediates its action *in vivo* in part by interfering with signaling induced upon

Wnt1 class ligands binding to Lrp6, but not by Wnt3a class ligands. Hence, we next administered antibody A for one month to 12-week-old *Sost;Lrp5* dKO females in addition to *Sost* KO and control mice (n=8-10/group). The antibody reduced as expected again abnormal bone gain in *Sost* KO mice, while impacting bone density also in wildtype mice, though to a smaller extent. Importantly, the partial bone overgrowth still present in *Sost;Lrp5* dKO was completely abolished upon antibody treatment. Together, we conclude that sclerostin indeed exerts its action *in vivo* by targeting both Lrp5 and Lrp6 to block Wnt/ β -catenin signaling. Moreover the data suggest that Wnt1 type ligand mediated signaling has a dominant role in adult bone mass regulation over Wnt3a type ligand mediated signaling.

Expression of Notch in Osteocytes Prevents Disuse Osteoporosis. Ernesto Canalis*¹, Kristen Parker², Jian Feng³, Stefano Zanotti¹. ¹St. Francis Hospital & Medical Center, USA, ²Saint Francis Hospital & Medical Center, USA, ³Texas A&M Health Science Center, USA

Notch are transmembrane receptors that play a role in cell fate decisions, and regulate skeletal development and osteoblast differentiation. In osteoblasts, Notch inhibits cell differentiation and function, and causes osteopenia. However, in osteocytes the function of Notch is unknown. Since osteocytes are mechanosensing cells, we first determined whether Notch is responsive to mechanical signals in these cells. Fluid flow shear stress (2-16 dynes/cm²/2h) induced the expression of the Notch target genes hairy enhancer of split (Hes)1 and Hes related with YRPW motif (Hey)1 and 2 in MLOY4 osteocytes, confirming activation of Notch signaling by mechanical stress. To establish the function of Notch in osteocytes, *Rosa^{Notch}* mice, where the Notch intracellular domain (NICD) is expressed under the control of the *Rosa* promoter following the excision of an intervening *loxP*-flanked STOP cassette, were crossed with transgenics expressing Cre under the control of the *Dentin matrix protein 1* (*Dmp1*) promoter. *Dmp1-Cre;Rosa^{Notch}* mice exhibited a marked increase in cancellous bone volume, and suppressed bone resorption due to the induction of osteoprotegerin without an inhibition of receptor activator of nuclear factor κ B ligand (RANK-L). Since the unloading of the skeleton is characterized by decreased bone formation and increased resorption leading to bone loss, we postulated that Notch expression in mechanosensing osteocytes may preserve bone mass during unloading. To test this hypothesis, the quadriceps and triceps surae muscles of *Dmp1-Cre;Rosa^{Notch}* and control mice were paralyzed with botulinum toxin A and sacrificed after 3 weeks. Microarchitectural analysis revealed a decrease in trabecular bone volume/tissue volume from (means \pm SEM; n, 5-6) $5.6 \pm 0.4\%$ in control limbs to $1.6 \pm 0.2\%$ in botulinum paralyzed limbs of control mice. In contrast, the bone volume of *Dmp1-Cre;Rosa^{Notch}* mice was increased to $15.7 \pm 2.6\%$ in control limbs and did not change in paralyzed limbs, where it was $15.7 \pm 2.7\%$. Histomorphometry revealed that osteoclast surface was increased in paralyzed limbs of control mice, but not of *Dmp1-Cre;Rosa^{Notch}*. The results indicate that Notch is activated in osteocytes by mechanical stress and can prevent bone loss in an experimental model of disuse osteoporosis, and as a consequence protect the skeleton during unloading. Modulation of Notch in osteocytes may serve as a therapeutic approach in disuse osteoporosis.

RANKL Produced by Osteocytes Contributes to the Bone Loss Induced by Hyperparathyroidism. Jinhu Xiong*, Melda Onal, Stavros Manolagas, Charles O'Brien. Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Parathyroid hormone (PTH) regulates calcium homeostasis in part by stimulating the rate of bone remodeling; and it stimulates bone resorption in part by stimulating production of RANKL. Recently, osteocytes were shown to be a major source of RANKL for osteoclastogenesis in remodeling bone under normal conditions or for the loss of bone induced by unloading. However, it remains unclear whether osteocytes supply the RANKL responsible for the increase bone resorption during hyperparathyroidism. To address this question, mice lacking the RANKL gene specifically in osteocytes were placed on a calcium deficient diet which induces secondary hyperparathyroidism. Mice lacking RANKL in osteocytes, hereafter referred to as conditional knockout (KO) mice, were generated by crossing mice harboring a RANKL conditional allele with DMP1-Cre transgenic mice, which express the Cre recombinase in osteocytes. Five-month-old conditional KO mice and their control littermates were fed a calcium-deficient diet or a control diet for 4 weeks. Dietary calcium deficiency induced an increase in circulating PTH in both control and conditional KO mice; however, the increase in PTH was significantly greater in the conditional KO mice. As expected, dietary calcium deficiency induced bone loss in control mice as measured by DEXA. This bone loss was significantly attenuated in mice lacking RANKL in osteocytes. Micro-CT analysis revealed that there was a decrease in femoral cortical thickness and an increase in cortical porosity in control mice fed the calcium deficient diet compared with mice fed the normal diet, but both of these changes were completely abrogated in the conditional KO mice. Consistent with these findings, dietary calcium deficiency induced a significant increase in

RANKL expression in the bones of control mice but not in conditional KO mice. Moreover, osteoclast-specific gene expression was significantly elevated in the bone of control mice fed the calcium-deficient diet but this did not occur in the conditional KO mice, suggesting that dietary calcium deficiency induced a significant increase of bone resorption in control mice but not in the conditional KO mice. Taken together, these results demonstrate that RANKL produced by osteocytes is essential for the increase in bone resorption and the bone loss caused by hyperparathyroidism, thereby demonstrating that osteocytes are an important target cell for hormonal control of mineral homeostasis.

Direct Regulation of the RANKL Gene by PTH in Osteocytes Is Required to Stimulate Bone Resorption in the Adult Skeleton. Abdullah Ben-Awadh*, Naomie Olivos, Nicoletta Bivi, Matthew Allen, Lilian Plotkin, Xiaolin Tu, Teresita Bellido. Indiana University School of Medicine, USA

PTH increases osteoclasts by upregulating RANKL in osteoblastic cells, but the precise differentiation stage of the PTH target cell remains undefined. Recent findings demonstrate that PTH regulates gene expression in osteocytes and that these cells are an important source of RANKL. We therefore investigated whether direct regulation of the RANKL gene by PTH in osteocytes is required to stimulate bone resorption. To address this question, we examined resorption and RANKL expression in transgenic mice in which PTH receptor signaling is activated only in osteocytes (DMP1-caPTHRI) crossed with mice lacking the distal control region regulated by PTH in the RANKL gene (DCR^{-/-}). Longitudinal analysis of circulating CTX in male mice showed elevated resorption in growing mice of all genotypes that progressively decreased to plateau at 3-5 month of age. Resorption was significantly higher (~100%) in DMP1-caPTHRI mice and non-significantly lower (15-30%) in DCR^{-/-} mice, versus wild type littermates (wt) across all ages. CTX in compound DMP1-caPTHRI;DCR^{-/-} mice was similar to DMP1-caPTHRI mice at 1 and 2 months of age, but deletion of the DCR gradually corrected the increased resorption exhibited by DMP1-caPTHRI mice. By 3 months of age, CTX in compound mice was significantly lower compared to DMP1-caPTHRI mice (50% higher than wt), and by 5 months, it was undistinguishable from wt mice. Micro-CT analysis revealed lower material density in the distal femur of DMP1-caPTHRI mice, indicative of high remodeling, and this effect was partially corrected in compound mice. Consistent with previous results, the increased resorption exhibited by DMP1-caPTHRI mice was accompanied by elevated RANKL mRNA in bone at 1 and 5 months of age. RANKL closely matched resorption in DMP1-caPTHRI;DCR^{-/-} compound mice. Thus, RANKL levels were similar to DMP1-caPTHRI mice at 1 month and reduced to wt levels at 5 month of age. The same pattern of expression was observed for M-CSF, a survival factor for osteoclast progenitors and mature osteoclasts previously shown to be upregulated by RANKL *in vitro*. We conclude that resorption induced by PTH receptor signaling requires direct regulation of the RANKL gene in osteocytes. Moreover, whereas DCR-independent mechanisms operate in the growing skeleton, DCR-dependent, cAMP/PKA/CREB-activated mechanisms mediate resorption induced by PTH receptor signaling in the adult skeleton.

Gna13 as a Novel Negative Regulator of Osteoclast Differentiation and Activation Inhibits RANKL/AKT/NFATc1 Signaling. Mengrui Wu*¹, Wei Chen², Yi-Ping Li². ¹The University of Alabama at Birmingham, USA, ²University of Alabama at Birmingham, USA

Osteoclasts are the principle bone-resorbing cells, with its activity delicately modulated to maintain bone homeostasis. Osteoclast aberration results in diseases like osteoporosis and rheumatoid arthritis. Positive regulation of osteoclast by RANKL-axis signaling has been extensively studied during past decades, while negative regulation remains unclear. To explore the potential negative regulators of osteoclast differentiation and activation, we used microarray assay, RNAi knockdown and *in vitro* function analysis approaches, and identified Gna13 as the candidate molecule. To confirm the *in vitro* results, we generated mice specifically lacking Gna13 in the monocyte and osteoclast (CKO) by crossing Gna13^{fl/fl} mice with Lyz2-cre mice and Cathepsin K-Cre mice. The femur from a 2-month old CKO and wildtype (WT) mice were analyzed by X-ray, μ -CT, and histology (n \geq 4 per group). CKO mice demonstrated severe osteoporosis phenotype. TRAP staining of the femur sections showed that the osteoclast number in the CKO mice was increased two folds compared to those found in the WT mice. To study the bone resorption difference, CKO RANKL induced bone marrow cells were cultured on bone slides. CKO cells displayed increased osteoclast formation, larger cell size, larger actin ring on bone slides, and increased Cathepsin K secretion, compared with those of the WT cells. Bone resorption pit assay and medium CTX-I Elisa showed that bone resorption by CKO osteoclasts was increased (3-fold, p \leq 0.05) when compared with that of the WT osteoclasts. To study the regulatory mechanism of Gna13, the activity of BTK, ERK, p-38, JNK and AKT in response to RANKL was examined in the CKO and WT osteoclasts. AKT phosphorylation was largely increased in both pre-osteoclasts and osteoclasts in the absence of Gna13. Both mRNA and protein levels of NFATc1 were increased in CKO osteoclasts (2.5-fold, p \leq 0.05). Meanwhile, much more NFATc1 was observed in the nuclei of CKO osteoclasts. Interestingly, Src (upstream of PI3K/

AKT) inhibitor, pp2, rescued the CKO osteoclast aberration, indicating that Src may be involved in the Gna13 regulation pathway. In conclusion, our study demonstrated that Gna13, as a novel regulator of bone resorption, negatively regulates osteoclast differentiation and activation by inhibiting RANKL/AKT/NFATc1 signaling. Our results indicate that Gna13 may serve as a novel therapeutic approach for osteoporosis and other Osteoclast aberration related diseases.

VPS35 Haploinsufficiency Results in an Osteoporotic Pathology Due to an Impaired RANK Trafficking and Increased RANKL-induced Hyper-resorptive Osteoclast Formation. Wen-Cheng Xiong^{*1}, Wen-Fang Xia², Fulei Tang², Xu Feng³, Lin Mei². ¹Medical College of Georgia, USA, ²Georgia Health Sciences University, USA, ³University of Alabama at Birmingham, USA

Bone remodeling, a dynamic process coordinated by osteoblastic bone formation and osteoclastic bone resorption, is essential for maintenance of healthy bone mass and normal bone structure. It is regulated by multiple factors, including PTH (parathyroid hormone) or PTHrP (PTH related peptide), Wnt, and RANKL (receptor activator of nuclear factor- κ B ligand). Retromer, a complex consisting of a VPS35-VPS29-VPS26 trimer and a sortin nexin (SNX) dimer, mediates selective endosome-to-Golgi retrieval of numerous membrane receptors, including wtless (a "receptor" for Wnt secretion) and PTH1R (type I receptor for PTH/PTHrP). Whereas these retromer cargos are important modulators of bone remodeling, retromer's function in this event remains largely unknown. Here we provide evidence for VPS35, a major component of retromer, in regulating osteoclastogenesis and bone remodeling. Hemizygous deletion of Vps35 in mouse led to osteoporotic-like phenotype, including decreased trabecular and cortical bone volumes, reduced trabecular thickness and density, and enlarged bone marrow cavity in long bones. These deficits appeared to be largely due to the increase of hyper-resorptive osteoclastogenesis in the mutant mice. Further mechanistic studies demonstrate that VPS35 is highly expressed in osteoclasts and its progenitor cells, in addition to osteoblasts. VPS35 expression in osteoclastic progenitor cells (e.g., macrophages) is necessary for RANKL induced retrograde trafficking of RANK and RANK inactivation. Loss of VPS35 function in macrophages results in an enhanced RANKL sensitivity and sustained RANKL-driven signaling. These results thus reveal an unrecognized function of VPS35/retromer in controlling RANK receptor trafficking and signaling in time and space and demonstrate an important role for VPS35/retromer in preventing hyper-resorptive osteoclast formation and osteoporotic pathology.

The SH3BP2 Cherubism Mutation Promotes TNF Induction of Osteoclastogenesis Independent of RANKL. Tomoyuki Mukai^{*1}, Shu Ishida², Teruhito Yoshitaka³, Yasuyoshi Ueki⁴. ¹University of Missouri - Kansas City, USA, ²University Missouri-Kansas City School of Dentistry, USA, ³University Missouri-Kansas City School of Dentistry, USA, ⁴University of Missouri-Kansas City School of Dentistry, USA

TNF is an inflammatory cytokine known to play a key role in osteoclastogenesis. The precise mechanisms for TNF-induced osteoclast differentiation are not fully understood. While TNF has been reported to directly induce osteoclast differentiation, this is controversial as RANKL has been proposed to be responsible for all osteoclast formation. Gain-of-function mutations in SH3BP2, an adapter protein, are responsible for the craniofacial disorder, cherubism. In the mouse model of cherubism, elevated levels of systemic TNF and RANKL-induced osteoclastogenesis were observed compared to wild type. Since depletion of TNF in homozygous cherubism mice (KI/KI) corrects bone loss to control levels, we hypothesized that SH3BP2 plays a role in TNF direct induction of osteoclastogenesis. To test this hypothesis, primary bone marrow macrophages (BMMs) isolated from wild-type and SH3BP2 heterozygous mutant cherubism mice (KI/+) were cultured with M-CSF (25ng/ml) and TNF (100ng/ml) in the absence of RANKL for 4 days. We discovered that KI/+ BMMs form greater numbers of TRAP-positive multinucleated cells compared to wild-type BMMs (1143 \pm 58 vs 42 \pm 20 cells/well) and these TNF-induced osteoclasts resorb mineralized matrix. OPG-Fc failed to inhibit osteoclastogenesis, suggesting that TNF induces osteoclastogenesis independently of RANKL in KI/+ BMMs. Both type I and II TNF receptors (TNFRs) were required, as neutralizing antibodies against either receptor suppressed TNF-induced osteoclastogenesis. Specific inhibitors for Syk and Src also suppressed the osteoclastogenesis. Next we cultured NFATc1-deficient KI/+ BMMs with TNF and found that the NFATc1-deficient cells failed to differentiate into osteoclasts. Finally, to confirm the *in vivo* effect of the SH3BP2 mutation on TNF-induced osteoclastogenesis, recombinant TNF (1.5mg/mouse) was subcutaneously injected onto calvarial bones for 5 days in KI/+ mice, which unlike KI/KI mice, do not develop elevated systemic TNF. Histomorphometric analysis showed that osteoclast numbers per bone perimeter and eroded surface per bone surface are increased in TNF-treated KI/+ mice compared to TNF-treated wild-type mice (17.6 \pm 11.2 vs 6.5 \pm 4.6, 21.6 \pm 12.0 vs 9.2 \pm 9.4 %, respectively). In conclusion, the gain-of-function mutation in SH3BP2 enhanced TNF-induced osteoclastogenesis by mechanisms dependent on Syk, Src, and

NFATc1, and independent of RANKL. These data suggest that SH3BP2 is a novel regulator of inflammatory osteoclastogenesis.

Canonical and Non-Canonical BMP signaling Pathways Regulate Osteoclastogenesis. Aaron Broege^{*}, Lan Pham, Ann Emery, Melissa Stemig, Michael O'Connor, Anna Petrvk, Eric Jensen, Kim Mansky, Raj Gopalakrishnan. University of Minnesota, USA

We have previously shown that BMP2 acts directly on osteoclastic cells to enhance their differentiation. In the current study we further tested the requirement of BMP signaling for osteoclastogenesis by (a) characterizing the skeletal phenotype of mice carrying targeted deletion of *BMPRII* in osteoclasts using *LysM-Cre (BMPRII;LysM-Cre)* and (b) investigating the role of canonical and non-canonical BMP pathways during osteoclast differentiation. μ CT analysis of *BMPRII;LysM-Cre* showed increased trabecular bone volume fraction at 3 and 6 months compared to WT. Osteoclasts from *BMPRII;LysM-Cre* bone marrow monocyte (BMM) cultures were smaller than controls, and showed reduced expression of key genes involved in osteoclastogenesis including NFATc1, cathepsin K, OC-STAMP and Acp5. Investigation of the status of BMP signaling showed that phospho-Smad1/5/8 (P-SMAD1/5/8) levels were similar in osteoclasts from knockouts and WT controls. On the other hand, phospho-p38 (P-p38) levels were reduced in knockout osteoclasts compared to WT controls. These results suggest that reduced osteoclastogenesis and increased bone phenotypes in *BMPRII;LysM-Cre* are due to a reduced signaling through non-canonical BMP pathways. To further understand the mechanism of BMPs' regulation of osteoclastogenesis, we investigated both canonical and non-canonical BMP pathways at various time points in BMM cultures. In control cultures stimulated with RANKL, we detected P-p38 on day 1 and day 2 with a gradual decrease to undetectable levels at later time points, while P-SMAD 1/5/8 was not detected until osteoclasts began to fuse (day 3) and remained at detectable levels through day 5. Exposure of WT BMMs to Noggin on day 1 of the differentiation was sufficient to completely block osteoclast differentiation, indicating an early requirement for BMP signaling. At these early timepoints, treatment with exogenous BMP2 increased P-p38, whereas at late times P-SMAD1/5/8 was stimulated. Treatment with dorsomorphin or LDN193189, which preferentially inhibit the canonical pathway, inhibited osteoclast formation only when present on day 3 and later, suggesting that canonical BMP signaling is required for osteoclast fusion. Together, these results show that BMPs are required for osteoclastogenesis *in vivo* and that BMPs regulate osteoclast formation through distinct pathways at different phases of the differentiation process.

Deletion of Wnt Receptors Lrp5 and Lrp6 or β -catenin in Late Osteoclast Precursors Differentially Suppress Osteoclast Differentiation and Bone Metabolism. Ming Ruan¹, Larry Pederson¹, Christine Hachfeld¹, Michael Thomson², Y.S. Prakash³, Alan Howe⁴, Bart Williams⁵, Rachel Davey⁶, Sundeep Khosla⁷, Jennifer Westendorf⁸, Merry Jo Oursler^{*8}. ¹Endocrine Research Unit, Mayo Clinic, USA, ²Anesthesiology, Mayo Clinic, USA, ³Anesthesiology & Physiology, Mayo Clinic, USA, ⁴Department of Pharmacology, University of Vermont College of Medicine, USA, ⁵Van Andel Research Institute, USA, ⁶University of Melbourne, Australia, ⁷College of Medicine, Mayo Clinic, USA, ⁸Mayo Clinic, USA

The positive effects of canonical Wnt signaling on osteoblasts and bone formation are well known and have produced promising new anabolic therapies. However, little consideration has been given to other possible Wnt responding cells in the bone environment. It was recently shown that β -catenin suppression in osteoclasts causes osteopenia and increases osteoclast differentiation. Because β -catenin is involved in many Wnt-independent cellular processes this suggests but does not confirm a direct role for Wnts in osteoclast differentiation. In this study, we examined the bone microarchitecture of mice lacking the Wnt receptors, Lrp5 and Lrp6 (*Lrp5/6^{del}* mice) or β -catenin (β -cat^{del} mice) in cathepsin K-positive osteoclast precursors using *Cre/Lox* approaches. Trabecular bone density was reduced and osteoclast numbers were elevated in both models. One striking difference was the presence of large areas of cortical bone loss at the metaphyses of the β -cat^{del} bones, but not the *Lrp5/6^{del}* bones (see figure below). Histomorphometric analyses revealed a high turnover phenotype including increased bone formation in the β -cat^{del} bones, whereas the *Lrp5/6^{del}* bones exhibited a more muted phenotype and no increased bone formation compared to the β -cat^{del} bones. Deletion of either Lrp5 and Lrp6, or β -catenin increased osteoclast differentiation *in vitro* whereas Wnt3a suppressed differentiation in wildtype marrow cultures *in vitro*. Investigation of the mechanisms revealed that Wnt3a suppresses osteoclast differentiation by inducing the phosphorylation and inactivation of the crucial transcription factor NFATc1. Wnt3a also suppressed RANKL and M-CSF induced NFATc1 nuclear accumulation. Wnt3a rapidly activated Ca²⁺ influx through L type channels and activation of the AC/cAMP/PKA pathway in wildtype and β -cat^{del} precursors, but not in the *Lrp5/6^{del}* cells. Gene expression studies revealed that *Lrp5/6^{del}* precursors express high levels of the Wnt signaling inhibitors Dkk1,

Dkk2, and Sost compared to either control or β -cat^{del} precursors. Wnt3a also suppressed expression of these genes in wildtype osteoclast precursors. These data indicate that both canonical and non-canonical Wnt signaling suppress osteoclast differentiation whereas noncanonical signaling enhances coupling between bone resorption and bone formation.

The Calcium-activated Potassium Channel SK4 (KCNN4/ IKCa1/KCa3.1) Modulates Bone Homeostasis via Osteoclasts. Heeseog Kang^{*}, Xiaojing Xu¹, Qing Zhang¹, Michael Kim¹, Jodi Carlson Scholz¹, Aruna Behera², Donald Souza², Jie Zheng², James E Melvin³, Gerald Nabozny², Jun Li², Agnès Vignery¹. ¹Yale University, USA, ²Boehringer Ingelheim, USA, ³University of Rochester, USA

The formation of multinucleate osteoclasts requires the fusion of macrophages, which is an essential step for efficient resorption of bone as fusion failure leads to accumulation of brittle bone such as in osteopetrosis. Since macrophage fusion is a rare event, our hypothesis has been that the fusion machinery is transiently induced at the onset of fusion. To identify the molecular players of the macrophage fusion machinery, we previously subjected fusing macrophages from rat lungs and human monocytes to genome-wide oligonucleotide microarray analysis. We discovered the induced expression of the calcium-activated potassium channel SK4 (KCNN4/IKCa1/KCa3.1). The role of SK4 is to set the cell membrane potential at negative values so as to aid in the electrochemical transport of other ions such as Cl⁻ and Ca⁺⁺. By mediating the efflux of K⁺, SK4 helps maintain the cell membrane potential to allow sustained Ca⁺⁺ influx into cells. We observed that the SK4 inhibitors TRAM-34 and ICAGEN-17043 inhibit the fusion of human monocyte- and mouse bone marrow-derived macrophages in a dose-dependent manner. Using mice null in SK4, we found that SK4-deficient bone marrow-derived macrophages show a delay in fusion that is RANKL dose-, and time-dependent. To ask whether calcium plays a role in signaling downstream of SK4, we subjected fusing bone marrow macrophages to real time PCR, western blot analysis and immunofluorescence. We observed a decrease in NFAT2 protein expression and translocation to the nucleus in SK4 null osteoclasts. Using fura-2 to image intracellular calcium, osteoclasts deficient in SK4 demonstrated a decrease in the amplitude of calcium oscillations. SK4-null macrophages also showed a decrease in Akt (ser473) phosphorylation in response to activation by RANKL, and by LPS. We then compared the bones from SK4 null mice, male and female, to wild types. Mice deficient in SK4 had a high bone density (pQCT, microCT) when compared with wild type littermates, which was associated with a decrease in osteoclast number (histomorphometry). Finally, we observed that SK4 null mice were partially protected from LPS-induced calvarial bone resorption, and from inflammation in response to antibody-induced arthritis. Together, our data strongly suggest that the calcium-activated K channel SK4 plays a central role in the formation and activation of osteoclasts and participates in the physiological and inflammation-induced regulation of bone mass.

The Role of Osteal Macrophages in Anabolic Actions of PTH in Bone. Sun Wook Cho^{*}, Fabiana Soki², Amy Koh³, Matt Eber³, Pavam Entezam³, Laurie McCauley². ¹Seoul National University Hospital, South Korea, ²University of Michigan School of dentistry, USA, ³University of Michigan, USA

Bone marrow contains a population of resident macrophages termed osteomacs, which play a role in bone modeling, repair and hematopoietic stem cell niche maintenance. The purpose of this study was to determine the role of osteomacs in anabolic actions of PTH in bone. The macrophage fas-induced apoptosis (MAFIA) mouse model was utilized where the c-fms promoter activated by the synthetic dimerizer (AP20187) leads to Fas-mediated apoptosis of myeloid cells. AP20187 (AP) (10mg/kg) or vehicle was administered for 3d for initial macrophage depletion then every third day (1mg/kg) for 6wks to 16-22wk MAFIA mice, and intermittent PTH (50 mg/kg/d) was administered daily starting 4d after the initial AP dose until

ethanasia. AP-treated mice had ~80% depletion of macrophages (c-fms⁺F4/80⁺CD11b⁺Gr1⁺ or CD68⁺ via flow cytometric analysis) compared to vehicle treated mice. In bone, both trabecular and cortical bone volume and thickness were significantly reduced in AP-treated versus vehicle treated mice. PTH increased trabecular bone volume, number and thickness in vehicle-treated mice which was significantly attenuated in AP-treated mice. Consistently, PTH increased serum PINP and TRAP5b in vehicle but not AP-treated mice. To further investigate the function of late differentiated macrophages in PTH anabolism, clodronate-liposomes which induce apoptosis of phagocytic macrophages were utilized. Sixteen week old male wild-type C57Bl6 mice were treated with clodronate or PBS-loaded liposomes for 6 weeks, and intermittent PTH or vehicle control was administered from d4 until euthanasia resulting in 4 treatment groups. F4/80⁺CD11b⁺Gr1⁺ cells were significantly reduced (~50%) but CD68⁺ cells were increased (~15%) in the clodronate liposome groups. Increased trabecular bone volume and trabecular numbers were found in clodronate liposome-treated mice vs. PBS liposome mice. Intermittent PTH treatment to clodronate-treated mice resulted in prominent increases in trabecular bone mass, surpassing the PTH anabolic action observed in vehicle-treated mice. Taken together, depletion of c-fms⁺ myeloid-lineage cells resulted in osteopenic phenotypes with reduced effects of PTH anabolic actions in bone, whereas depletion of late-differentiated macrophages resulted in increased bone mass and anabolic PTH actions. These data suggest anabolic actions of PTH are associated with specific macrophage populations in bone.

Impaired Anabolic Action of PTH on Bone Formation in Fgf2 Knockout Mice is mediated by Attenuated Wnt Signaling. Yurong Fei^{*}, Liping Xiao², Marja Marie Hurley³. ¹New York University College of Dentistry, USA, ²University of Connecticut Health Center, USA, ³University of Connecticut Health Center School of Medicine, USA

Parathyroid hormone (PTH) is currently the only anabolic agent for treatment of osteoporosis in the U.S. However, the detailed mechanisms of its action are not fully defined. We previously showed that the anabolic bone effects of PTH require fibroblast growth factor 2 (FGF2). PTH treatment increases serum FGF2 in osteoporotic patients and PTH induces FGF2 and FGF receptor mRNA expression in osteoblasts. However, the anabolic effect of PTH on bone is impaired in *Fgf2*^{-/-} mice. Intermittent FGF2 treatment promotes osteoblast differentiation and bone formation *in vitro* and *in vivo*. However, bone formation is significantly reduced in *Fgf2*^{-/-} mice. PTH anabolic response also requires Wnt signaling and we recently reported that FGF2 modulates Wnt signaling in osteoblasts. We hypothesize that the impaired bone response to PTH in *Fgf2*^{-/-} mice is partially due to attenuated Wnt signaling. Three month-old *Fgf2*^{+/+} and *Fgf2*^{-/-} littermate male mice were treated with human rPTH (1-34) 20µg/kg body weight for 8 hours (n=3). Total RNA was extracted from tibia and protein was from femur. The data presented are pooled from two independent experiments. Ligand Wnt10b has been demonstrated to promote bone formation. We observed that PTH treatment markedly increased expression of Wnt10b mRNA and protein in *Fgf2*^{+/+} mice but not in *Fgf2*^{-/-} mice. Wnt antagonist SOST mRNA expression was significantly higher in *Fgf2*^{-/-} group, which may contribute to reduced bone formation. However, PTH treatment decreased SOST expression in *Fgf2*^{-/-} mice significantly. DKK2 is critical for osteoblast mineralization. PTH treatment significantly increased DKK2 mRNA in *Fgf2*^{+/+} mice but reduced DKK2 expression significantly in *Fgf2*^{-/-} mice. For Wnt receptor, we observed that PTH treatment significantly increased Lrp6 expression in *Fgf2*^{+/+} but not in *Fgf2*^{-/-} mice. β -catenin, an essential factor in Wnt signaling, is a positive regulator of bone formation. PTH treatment increased β -catenin mRNA expression significantly in *Fgf2*^{+/+} but not in *Fgf2*^{-/-} mice. Therefore, PTH treatment increased Wnt signaling in *Fgf2*^{+/+} mice, which is important for bone formation. However, attenuated Wnt signaling was observed in *Fgf2*^{-/-} mice, which may contribute to the impaired bone response of PTH. These data suggest that the impaired bone anabolic response to PTH in *Fgf2*^{-/-} mice is partially mediated by attenuated Wnt signaling.

The Sclerostin-Independent Bone Anabolic Activity of Intermittent PTH Treatment is Mediated by T Cell Produced Wnt10b. Jau-Yi Li^{*}, Jonathan Adams², Ming-Kang Chang³, M. Neale Weitzmann², Michaela Kneissel³, Roberto Pacifici². ¹Emory University, USA, ²Emory University School of Medicine, USA, ³Novartis Institutes for Biomedical Research, Switzerland

Blunted production of the Wnt inhibitor sclerostin (Scl) accounts for part of the bone anabolic activity of intermittent PTH (iPTH) treatment. However Scl-independent mechanisms of action of iPTH remain to be determined. iPTH promotes bone anabolism by increasing T cell production of the Wnt ligand Wnt10b. We thus investigated the contribution of T cell produced Wnt10b to the Scl-independent effects of iPTH. To avoid the confounding effect of the altered basal bone mass of Scl null mice have, we used an anti Scl mAb to neutralize Scl *in vivo*. 6 wk old WT mice, T cell deficient TCRb^{-/-} mice, TCRb^{-/-} mice previously reconstituted with WT T cells, and TCRb^{-/-} mice reconstituted with Wnt10b^{-/-} T cells were injected for 4 weeks with iPTH alone (hPTH1-34 at 80 µg/kg/day SC), Scl-ab alone (50 mg/kg once weekly IV),

or iPTH + Scl-Ab. PTH, vehicle and an isotype matched irrelevant Ab (Irr.Ig) were used as controls. Spine mCT measurements in WT mice revealed that bone volume (BV/TV) was increased 23.6 % by iPTH alone, 59.3 % by Scl-Ab alone, and 77.5 % by treatment with iPTH plus Scl-Ab. Combined treatment was more efficacious than Scl-Ab alone ($\Delta = 18.2\%$, $p < 0.05$), confirming that part of the anabolic activity of iPTH is Scl-independent. Identical results were obtained in TCRb^{-/-} mice reconstituted with WT T cells. By contrast, iPTH did not increase BV/TV nor potentiated the effect of Scl-Ab in TCRb^{-/-} mice and TCRb^{-/-} mice with Wnt10bKO T cells. Scl Ab alone had equal activity in all groups of mice. These findings indicate that T cell production of Wnt10 accounts for the Scl-independent anabolic effects of iPTH. iPTH alone increased serum levels of the bone formation marker PINP, and potentiated the increase in PINP induced by Scl Ab in T cell replete mice. By contrast, iPTH had no effects on serum bone formation markers in TCRb^{-/-} mice and TCRb^{-/-} mice with Wnt10bKO T cells. Moreover, iPTH and iPTH + Scl Ab increased ex vivo osteoblast (OB) differentiation and life span in T cell replete mice, but not in mice lacking T cells or T cell production of Wnt10b. By contrast, in vivo Scl-Ab treatment alone had no effects on OBs ex vivo, thus suggesting that iPTH regulates some aspects of OB differentiation and life span through a Wnt10b-dependent, Scl-independent mechanism. In summary, we show here that the Scl-independent activity of iPTH is completely accounted for by T cell produced Wnt10b.

PTH Induces Differentiation of Mesenchymal Stem Cells by Enhancing BMP Signaling. Bing Yu^{*1}, Xiaoli Zhao², Chaozhe Yang³, Janet Crane⁴, William Lu⁵, Mei Wan⁶, Xu Cao⁴. ¹Johns Hopkins School of Medicine, USA, ²The University of Hongkong, Hong Kong, ³The University of Alabama at Birmingham, USA, ⁴Johns Hopkins University, USA, ⁵The University of Hong Kong, Hong Kong, ⁶Johns Hopkins University School of Medicine, USA

Parathyroid hormone (PTH) stimulates bone remodeling and induces differentiation of bone marrow mesenchymal stem cells (MSCs) by orchestrating activities of local factors such as bone morphogenetic proteins (BMPs). The activity and specificity of different BMP ligands are controlled by various extracellular antagonists that prevent the binding of BMPs to their receptors. Low-density lipoprotein receptor-related protein 6 (LRP6) has been shown to interact with the extracellular signaling pathways of both PTH and BMP by forming a complex with PTH1R or sharing common antagonists with BMPs. Here we show that PTH induces the differentiation of MSCs into osteoblastic lineage through enhancement of BMP signaling by modifying the extracellular antagonist network assembled by LRP6. We found that single PTH injection increased the level of phosphorylated Smad1 (p-Smad1) in osteoblastic-like cells on the bone surface of 8-wk old mice, and the p-Smad1+ MSCs were elevated from 12.1% to 81.2% at 30 min after PTH injection. Importantly, PTH increased Smad1 phosphorylation and MSCs differentiation, antagonizing inhibitory effect of noggin, an BMP extracellular antagonist. Further, PTH enhanced pSmad1 was abolished in PTH1R^{-/-} OC59 cells, indicating that this effect is PTH1R-dependent. The results suggest that PTH enhances BMP signaling through regulation of extracellular antagonists.

We then examined whether PTH-induced PTH1R endocytosis plays a role in its effect on enhancing BMP signaling in MSCs. PTH-elevated phosphorylation of Smad1 was inhibited by blocking PTH1R endocytosis with β -arrestin knockdown or endocytosis inhibitor treatment. We also found that PTH enhances the phosphorylation of Smad1 through stimulating the endocytosis of the LRP6/PTH1R complex. Deletion of LRP6 with Ade-Cre in *lrp6* flox/flox MSCs elevated Smad1 phosphorylation to the level seen with PTH treatment in the presence of LRP6. However, in the LRP6-deficient cells, PTH did not further enhance the phosphorylation of Smad1, indicating that the PTH effect is LRP6-dependent. In addition, PTH stimulated 125I-BMP2 cell surface binding in a dose- and time-dependent manner by inducing the internalization of LRP6/PTH1R complex. Taken together, our results suggest that PTH enhances BMP signaling by inducing the endocytosis of LRP6-organized extracellular network of BMP antagonists and subsequent enhanced binding of BMPs to their receptors, leading to enhanced osteoblast differentiation of MSCs.

The p27 Pathway Modulates The Regulation of Skeletal Growth and Osteoblastic Bone Formation by Parathyroid Hormone-Related Peptide. Jing Zhang^{*1}, Min Zhu², David Goltzman³, Andrew Karaplis³, Dengshun Miao⁴. ¹Nanjing Medical University, China, ²Nanjing Medical University, China, ³McGill University, Canada, ⁴Nanjing Medical University, Peoples Republic of China

We previously demonstrated that parathyroid hormone-related peptide (PTHrP) 1-84 knockin (*Pthrp* KI) mice, in which the nuclear localization sequence and the C-terminal region of PTHrP are deleted, displayed skeletal growth retardation and defective osteoblastic bone formation, however, the mechanism is unclear. Microarray analyses of differential gene expression profiles were performed in long bone extracts from *Pthrp* KI mice and their WT littermates. Results revealed that the expression

levels of p27, p57 and p53 were up-regulated 8.3, 6.5 and 5.4 fold, respectively, whereas the expression levels of cyclin E, cyclin D1, CDK2, Runx2, Osterix and ALP were down-regulated 5.4, 5.4, 5.3, 5.1, 5.8 and 5.2 fold, respectively, in *Pthrp* KI mice relative to WT littermates. To determine whether the cell cycle inhibitor p27^{Kip1} was involved in the regulation by PTHrP of skeletal growth and development *in vivo*, we generated compound mutant mice which are homozygous for both p27 deletion and the *Pthrp* KI mutation (*p27^{-/-}Pthrp* KI), and compared *p27^{-/-}Pthrp* KI mice with *p27^{-/-}Pthrp* KI, and WT littermates. Phenotypes were analyzed by histopathological, immunohistochemical, cellular and molecular approaches. Deletion of p27^{Kip1} in *Pthrp* KI mice resulted in a longer lifespan, increased body weight and improvement in skeletal growth, although *Pthrp* KI mice were not normalized. At 2 weeks of age, skeletal growth parameters, including length of long bones, size of epiphyses and PCNA positive chondrocytes, BMD and BMC, trabecular bone volume, osteoblast numbers, and ALP, type I collagen and osteocalcin positive bone areas were increased in *p27^{-/-}* mice, and reduced in both *Pthrp* KI and *p27^{-/-}Pthrp* KI mice compared to WT mice; however these parameters were increased in *p27^{-/-}Pthrp* KI mice compared to *Pthrp* KI mice. As well, the mRNA expression levels of Runx2, ALP, and type I collagen and protein expression levels of osteocalcin and PTHR, IGF1 and Bmi-1, and the numbers of total CFU-f and ALP positive CFU-f generated from bone marrow cell cultures, were similarly increased in *p27^{-/-}Pthrp* KI mice compared to *Pthrp* KI mice. Our results demonstrate that deletion of p27^{Kip1} in *Pthrp* KI mice can partially rescue defects in skeletal growth and osteoblastic bone formation by enhancing endochondral bone formation and osteogenesis. These studies therefore indicate that the p27 pathway may function downstream in the action of PTHrP to regulate skeletal growth and development.

Bone Loss in Lactating Mice Requires RANKL Signaling. Laleh Ardeshirpour^{*1}, Pamela Dann², Cristina Dumitru², Marina Stolina³, Paul Kostenuik³, John Wysolmerski⁴. ¹Yale University, USA, ²Yale School of Medicine, USA, ³Amgen Inc., USA, ⁴Yale University School of Medicine, USA

Lactation is associated with rapid bone loss suggesting that the maternal skeleton is an important source of calcium for milk production. Previous studies have suggested that bone resorption during lactation is mediated by increased RANKL signaling. To test this concept, we treated 15-week-old, lactating CD-1 mice with saline or recombinant OPG (OPG-Fc; 10mg/kg) every 4th day for the first 12 days post-partum. As expected, OPG-Fc effectively reduced TRACP 5b, osteocalcin and type I procollagen levels. OPG-Fc also completely eliminated bone loss during lactation. In controls, serial DEXA scans revealed a decline in BMD of 20% \pm 0.9 at the spine, 13% \pm 1.4 at the femur and 13% \pm 0.8 for the total body. In contrast, OPG-Fc treatment led to increases in BMD of 10% \pm 1.9 at the spine, 3% \pm 2.4 at the femur and 5% \pm 1.7 for the total body. Similarly, in OPG-Fc-treated mice, micro-CT revealed higher trabecular BV/TV, thickness, number and density, and increased cortical thickness and decreased porosity. Histomorphometry confirmed the higher bone volumes, trabecular thickness and trabecular numbers in OPG-Fc-treated lactating animals compared to controls. Consistent with the turnover markers, OPG-Fc significantly lowered osteoblast numbers and surfaces as well as bone formation rates. However, in contrast to the TRACP 5b data, there were many osteoclasts still present in the OPG-Fc treated bone. These cells appeared larger than normal and were often near but not on bone surfaces. Finally, despite the complete abrogation of bone loss, OPG-Fc-treated mice exhibited no obvious impairment of lactation. Circulating calcium levels were within the normal range although circulating PTH levels were slightly elevated. There was no increase in the levels of circulating 1,25(OH)₂ Vit D in OPG-Fc-treated mice. OPG-Fc also had no effect on litter size or pup growth, demonstrating normal milk production. In contrast, preliminary studies show that the combination of a low calcium (0.01%) diet and OPG-Fc results in a 60% maternal mortality. In conclusion, osteoclastic bone resorption but not osteoclast survival depends on RANKL signaling during lactation. In addition, in the presence of adequate dietary calcium, skeletal calcium mobilization is not essential for normal lactation. Inhibiting RANKL signaling will allow us to better understand the normal interplay between skeletal and dietary sources of calcium during milk production.

The Risk of Hip Fracture after Initiating Antihypertensive Drugs in the Elderly. Debra Butt^{*1}, Muhammad Mamdani², Peter Austin³, Karen Tu³, Tara Gomes³, Richard Glazier³. ¹University of Toronto, Canada, ²Li Ka Shing Knowledge Institute, St. Michael's Hospital, Canada, ³Institute for Clinical Evaluative Sciences, Canada

Evidence indicates that initiating antihypertensive drugs in the elderly has been associated with an immediate increased risk of falls. However, it is unknown if initiation of antihypertensive drugs (thiazide diuretics, angiotensin II converting-enzyme inhibitors, angiotensin II receptor blockers, calcium channel blockers or beta-adrenergic blockers) is associated with an immediate increased risk of hip fractures. Our study examined the association between the initiation of monotherapy with any

of the five antihypertensive drug classes commonly used for the treatment of hypertension in the elderly and immediate increased risk of hip fracture.

A population-based, self-controlled case series design using healthcare administrative databases was conducted to identify patients initiating an antihypertensive drug from the over 1.6 million elderly residents in Ontario, Canada. A cohort of newly treated hypertensive elderly patients was linked to the occurrence of hip fractures from April 1, 2000 to March 31, 2009 to create exposed cases. The risk period was the first 45 days following antihypertensive therapy initiation with control periods before and after treatment in a 450-day observation period. The outcome measure was the first occurrence for a proximal femoral fracture during the risk period. The analysis determined the relative incidence (incidence rate ratio, IRR), defined as the hip fracture rate in the risk period compared to control periods.

Of the 301 591 newly treated hypertensive community-dwelling elderly, 1 463 hip fractures were identified during the observation period. Hypertensive elderly initiated on an antihypertensive drug had a 43% increased risk of having a hip fracture during the first 45 days following treatment initiation relative to the control periods, IRR 1.43 (95% confidence interval, CI 1.19 to 1.72). The IRR estimates were generally consistent amongst the five different classes of antihypertensive drugs, but only the angiotensin II converting-enzyme inhibitors (IRR 1.53, 95% CI 1.12 to 2.10) and beta-adrenergic blockers (IRR 1.58, 95% CI 1.01 to 2.48) demonstrated statistical significance.

Antihypertensive drugs were associated with an immediate increased hip fracture risk during the initiation of treatment in hypertensive community-dwelling elderly. Precautions should be undertaken to minimize the risk of hip fractures when initiating antihypertensive drugs in the elderly.

Risk of Hip Fracture Associated with Non-Benzodiazepine Hypnotics in Subgroups of Nursing Home Residents. Sarah Berry^{*1}, Yoojin Lee², Shubing Cai², Vincent Mor², David Dore². ¹Hebrew SeniorLife/Beth Israel Deaconess Medical Center, USA, ²Warren Alpert Medical School of Brown, USA

Purpose: It is important to identify subgroups of nursing home residents that are particularly vulnerable to injurious falls when using hypnotic drugs. We conducted a case-crossover study to estimate the association between non-benzodiazepine hypnotic drugs and risk of hip fracture among a nationwide sample of long-stay nursing home residents, overall and stratified by functional characteristics.

Methods: Participants included 26,618 long stay U.S. nursing home residents aged ≥ 50 years with a hip fracture (7/1/2007-12/31/2008) from a sample of over one million patients in fee-for-service Medicare Parts A & D. Hip fractures were defined using ICD-9 primary diagnostic and procedural codes. Dispensings of non-benzodiazepine hypnotic drugs (zolpidem, eszopiclone, zaleplon) were ascertained using Medicare Part D claims. Stratifying characteristics were ascertained using the Minimum Data Set. The odds ratios of hip fracture were estimated using conditional logistic regression models by comparing the prevalence of non-benzodiazepine hypnotic dispensings during the 0-15 days before the hip fracture (hazard period) with the prevalence of dispensings during the 30-45 and 60-75 days before the hip fracture (control periods). Analyses were stratified by cognition, bladder function, and ability to transfer.

Results: Among participants, 1,737 were dispensed a non-benzodiazepine hypnotic before the hip fracture, and 599 participants with exposure-discordant pairs were included in analyses. Mean age was 82 yrs (± 10 yrs), and 78% were female. The risk of hip fracture was elevated during the 0-15 days following dispensing of a non-benzodiazepine hypnotic (OR 1.49; 95% CI 1.26, 1.76). The association between non-benzodiazepine hypnotics and hip fracture was somewhat greater in residents with moderate or severe cognitive impairment, intermittent urinary incontinence, and among residents that were independent or severely impaired with transfers (Table 1); however, these differences remain consistent with chance.

Conclusions: In nursing home residents, risk of hip fracture was elevated following dispensing of a non-benzodiazepine hypnotic. There were no clear differences in risk by cognition, bladder function, and ability to transfer. Caution should be used when prescribing a non-benzodiazepine hypnotic to nursing home residents.

| Resident characteristic | Categories | Odds ratio | 95% confidence intervals |
|-------------------------|--|------------|--------------------------|
| Cognition | Intact or mild impairment | 1.39 | 1.13, 1.71 |
| | Moderate or severe impairment | 1.69 | 1.27, 2.26 |
| Bladder function | Always continent or always incontinent | 1.42 | 1.26, 1.75 |
| | Intermittently incontinent | 1.62 | 1.21, 2.15 |
| Ability to transfer | Independent | 1.63 | 1.13, 2.37 |
| | Mild impairment | 1.34 | 1.05, 1.71 |
| | Moderate or severe impairment | 1.62 | 1.21, 2.18 |

Implications of Expanding Indications for Initiation of Drug Treatment to Prevent Fracture in Older Men. Kristine Ensrud^{*1}, Kathy Wilt Peters², Brent Taylor³, Margaret Gourlay⁴, Meghan Donaldson², William Leslie⁵, Terri Blackwell⁶, Howard Fink⁷, Eric Orwoll⁸, John Schousboe⁹. ¹Minneapolis VA Medical Center / University of Minnesota, USA, ²San Francisco Coordinating Center, USA, ³University of Minnesota, USA, ⁴University of North Carolina, USA, ⁵University of Manitoba, Canada, ⁶CPMC RESEARCH INSTITUTE, USA, ⁷GRECC, Minneapolis VA Medical Center, USA, ⁸Oregon Health & Science University, USA, ⁹Park Nicollet Clinic/University of Minnesota, USA

Incremental effects of broadening the definition of osteoporosis (OP) and use of FRAX treatment thresholds on the proportion of older men identified as appropriate for initiation of drug treatment are uncertain. The extent to which observed-to-predicted fracture probability ratios differ across groups of untreated men identified using distinct criteria is also unknown. To address these questions, we sequentially applied the WHO OP definition, NOF OP definition, and FRAX treatment thresholds to 5882 men ≥65 years not taking bisphosphonates at the MrOS baseline exam. We then calculated observed 10-year probabilities for confirmed incident hip and major osteoporotic fracture events over time using cumulative incidence estimation, accounting for the competing risk of mortality. Predicted probabilities of hip and major osteoporotic fracture were calculated using FRAX with femoral neck BMD. Among the 5882 men, 130 (2.2%) were identified with OP using the WHO definition and an additional 422 were identified with OP using the NOF definition (total OP prevalence 9.4%). Applying FRAX treatment thresholds, 936 additional men were identified as eligible for treatment (i.e. high fracture risk) raising the total prevalence of men meeting indications for drug treatment to 25.3%. Observed fracture probabilities incrementally decreased across groups identified using different criteria (p<0.001), with highest probabilities among men identified with OP by the WHO definition (Table). Ratios of observed-to-predicted fracture probabilities were markedly greater than 1.0 among men with OP, especially those identified by WHO criteria, but were close to 1.0 among men without OP, including those at both high and low fracture risk. In conclusion, choice of definition of OP and use of FRAX treatment thresholds have major impacts on the proportion of men identified as warranting drug therapy to prevent fracture. Observed 10-year probabilities of hip and major osteoporotic fracture are highest among men identified with OP by the WHO definition, a group for which FRAX models with BMD underestimate actual risk. In the context of these findings and evidence suggesting lack of benefit of drug treatment in reducing nonvertebral fracture risk in the absence of OP, randomized trials are needed to evaluate efficacy of treatment in older men identified using criteria other than BMD-defined osteoporosis prior to expanding indications for initiation of drug treatment to prevent fracture.

Association of Stressful Life Events with Accelerated Bone Loss in Older Men: the Osteoporotic Fractures in Men (MrOS) Study. Howard Fink^{*1}, Michael Kuskowski¹, Jane Cauley², Brent Taylor³, John Schousboe⁴, Peggy Cawthon⁵, Kristine Ensrud⁶. ¹GRECC, Minneapolis VA Medical Center, USA, ²University of Pittsburgh Graduate School of Public Health, USA, ³University of Minnesota, USA, ⁴Park Nicollet Clinic/University of Minnesota, USA, ⁵California Pacific Medical Center Research Institute, USA, ⁶Minneapolis VA Medical Center / University of Minnesota, USA

According to the allostatic load hypothesis, stressful life events (LE) may lead to various adverse health outcomes. In prior prospective analyses, we found that LE were independently associated with an increased risk of falls and that an age-adjusted association of LE with an increased risk of clinical fractures was in part due to lower BMD among those with LE. The current analyses explore whether LE are associated with higher rates of bone loss.

We used data from MrOS, a longitudinal cohort study in community-dwelling men aged ≥65 yrs. Total hip (TH) BMD was collected at baseline (V1) and at a second clinic visit (V2), approximately 4.6 years later. Information on several types of LE (e.g. wife/partner serious illness, loss of/separation from other close relative or friend) during the past 12 months was collected in a mailed interim questionnaire (IQ)

mid-way between V1 and V2 and in another questionnaire at V2. We used age and multivariate (MV) linear regression to model the association of LE with annualized percent TH BMD loss between V1 and V2, and logistic regression to model the risk of accelerated TH BMD loss (>1 SD more loss than the mean annualized percent change, i.e. loss exceeding -1.24%/yr) between V1 and V2.

Of 5229 men with V2 data, 76% reported >1 type of LE at either IQ or V2, including 24% with 2 types of LE and 21% with 3 or more types of LE. Among 4388 men with TH BMD measurement at both V1 and V2, mean annualized TH BMD loss was -0.36% (SD 0.88) and 13.9% of men were defined as having accelerated TH BMD loss. After age-adjustment, any LE (vs. none) was not associated with a higher rate of TH BMD loss ($p=0.10$), but the number of types of LE was associated with a higher rate of TH BMD loss ($p<0.001$). Odds of accelerated TH BMD loss were higher among men with any type of LE (age-adjusted OR for any event vs. none, 1.4 [95% CI, 1.1-1.7]), and increased in a graded fashion, corresponding with an increased number of types of LE (vs. none) (Table). Associations were attenuated but remained significant after MV adjustment, including for percent weight change between V1 and V2 and mood symptoms.

In this older male cohort, stressful life events were associated with a dose-related, but modest increase in odds of concurrent accelerated TH bone loss independent of other explanatory factors. Future studies are needed to confirm these findings and to investigate the mechanism that may underlie this association.

Table: Stressful life events (LE) and odds of accelerated V1 to V2 TH BMD loss, OR (95% CI)

| Model | Any type of LE | Sum of types of LE | 1 type of LE | 2 types of LE | 3+ types of LE |
|---------------------------|----------------|--------------------|----------------|----------------|----------------|
| Age only | 1.4 (1.1-1.7) | 1.2 (1.1-1.3) | 1.2 (0.95-1.6) | 1.3 (1.01-1.7) | 1.7 (1.3-2.2) |
| Base MV model* | 1.3 (1.00-1.6) | 1.1 (1.03-1.2) | 1.1 (0.9-1.5) | 1.3 (0.97-1.7) | 1.4 (1.1-1.9) |
| MV* + wt change | 1.2 (0.96-1.5) | 1.1 (1.01-1.2) | 1.1 (0.9-1.5) | 1.2 (0.9-1.6) | 1.3 (1.00-1.8) |
| MV* + wt change + mood sx | 1.2 (0.96-1.5) | 1.1 (1.01-1.2) | 1.1 (0.8-1.5) | 1.2 (0.9-1.6) | 1.3 (1.00-1.8) |

*Base MV model adjusted for the following V1 measures: age, weight, education, history of fracture before age 50 yrs, diabetes, stroke, MI, Parkinson's disease, low mood symptoms, self-reported health status, IADL impairment, gait speed, and chair stand completion time.

Lower Fracture Risk in Older Men with Higher Sclerostin Concentration – A Prospective Analysis from the MINOS Study. Pawel Szulc^{*1}, Cindy Betholon², Olivier Borel³, Roland Chapurlat⁴. ¹INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France, ²INSERM UMR 1033, France, ³Inserm, France, ⁴E. Herriot Hospital, France

Sclerostin is a glycoprotein synthesized by osteocytes and it inhibits bone formation. Its relationship with fracture in older men has been rarely explored so far. We measured serum concentration of sclerostin (Quidel-TECOMEDICAL, San Diego, CA) in 711 men aged 50 and older. Bone mineral density (BMD) was measured at the lumbar spine, hip and distal forearm (HOLOGIC 1000W). Serum sclerostin increased with age ($r=0.30$, $p<0.001$). After adjustment for age, weight, height, current smoking, bioavailable estradiol and parathyroid hormone, BMD of all the skeletal sites correlated positively with serum sclerostin ($r=0.25$ to 0.30 , $p<0.001$) and increased by 0.27 to 0.51 SD /SD increase in sclerostin. In similar multivariable models, serum concentrations of osteocalcin, bone alkaline phosphatase, N-terminal propeptide of type I procollagen and C-terminal telopeptide of type I collagen (CTX-I) as well as urinary excretion of total and free deoxypyridinoline and CTX-I correlated negatively with serum sclerostin ($r=-0.09$ to -0.24 , $p<0.05$ to 0.001) and decreased by 0.10 to 0.25 SD per SD increase in sclerostin.

During 10 years of follow-up, 76 men sustained at least one fragility fracture. The distribution of fracture incidence per quintiles of sclerostin was as follows: 12.9% (lowest quintile), 15.2%, 13.1%, 6.7%, 5.3% (highest quintile) ($p<0.005$). We compared fracture risk in the two highest quintiles combined vs three lower quintiles combined using logistic regression adjusted for age, BMI, age and BMI interaction, BMD, bone width (for femoral neck and distal radius), prevalent fracture, prevalent falls, and severe abdominal aortic calcification. Men with higher sclerostin concentration had lower risk of fragility fracture (e.g., after adjustment for hipBMD, OR= 0.53, 95%CI: 0.29, 0.97; $p<0.05$). Similar results were obtained in the models adjusted for BMD and width of tubular bones (e.g., femoral neck, OR= 0.49, 95%CI: 0.27, 0.89; $p<0.05$). When the analysis was limited to 47 men who sustained major fragility fractures (vertebra, hip, femur, tibia, pelvis, proximal humerus, multiple ribs), the results were similar (e.g., lumbar spine: OR= 0.44, 95%CI: 0.19, 0.99, $p<0.05$).

In conclusion, in older men, higher serum levels of sclerostin are associated with lower risk of fracture, higher BMD and lower levels of biochemical bone turnover markers.

Disclosures: Pawel Szulc, None.

Bone Mineral Density and Mortality in Two Large Prospective Population-based Cohort Studies: Strongest Relation with Death due to Chronic Lung Disease. Natalia Campos-Obando^{*1}, Martha Castano-Betancourt², Ling Oei³, Oscar Franco⁴, Albert Hofman⁵, Bruno H. Ch. Stricker⁶, Fernando Rivadeneira⁷, Andre G. Uitterlinden⁸, M. Carola Zillikens². ¹Department of Internal Medicine, Erasmus University Medical Center, Netherlands, ²Department of Internal Medicine, Department of Epidemiology, Erasmus University Medical Center, Netherlands, ³Department of Internal Medicine, Erasmus University Medical Center, Netherlands, ⁴Cardiovascular Epidemiology Group, Erasmus University Medical Center, Netherlands, ⁵Department of Epidemiology, Erasmus University Medical Center, Netherlands, ⁶Department of Epidemiology, Department of Internal Medicine, Erasmus University Medical Center, Netherlands, ⁷Department of Epidemiology, Department of Internal Medicine, Erasmus University Medical Center, Netherlands, ⁸Department of Epidemiology, Department of Internal Medicine, Erasmus University Medical Center, Netherlands

Osteoporosis has been associated in some studies with cardiovascular disease (CVD) and all-cause and CVD mortality. Using two cohorts from the Rotterdam Study (RS-I and -II) we assessed the relation between femoral neck bone mineral density (FN BMD) and all-cause and cause-specific mortality divided into 7 groups based on ICD-10 codes: CVD, Cancer, Trauma, Infectious diseases, Dementia, Lung Diseases, and other causes. In 5,779 elderly participants from RS-I and 2,055 from RS-II BMD was measured at baseline and survival analyses were done using Cox proportional hazards models, adjusted for age, BMI and smoking, followed by meta-analysis. Hazard Ratios (HR; [95%CI]) are expressed for each standard deviation (SD) decrease in BMD. After mean follow-up of 14.5 (RS-I) and 9.0 (RS-II) years there were 2,832 and 220 deaths, respectively. An inverse relationship was found between BMD and all-cause mortality in males only: HR for RS-I: 1.09 [1.03-1.16] $P=0.004$; for RS-II: 1.30 [1.08-1.57] $P=0.005$; joint meta-analysis: 1.11 [1.05-1.17] $P=0.0003$. Adjustment for incident fractures did not essentially change these results. The strongest relation between BMD and cause-specific mortality was an inverse relation with mortality due to lung diseases (chronic obstructive pulmonary diseases (COPD)). This result was consistent in both cohorts and across genders (meta-analysis HR 1.90 [1.51-2.39], $P=4\times 10^{-8}$) and persisted after adjusting for steroid use and excluding prevalent COPD. There was an inverse association of BMD with trauma-related mortality in females only (HR: 1.71 [1.17-2.50], $P=0.006$). Also in females, there was a borderline significant trend for increased cancer-related mortality with increasing BMD. In both genders a decreased BMD was associated with increased dementia-related mortality only when prevalent cases were also included (meta-analysis HR: 1.23 [1.04-1.47], $P=0.018$). In RS-I but not in RS-II, there was a significant inverse relation between BMD and other causes of mortality in both genders (unattended-, unspecified- and sudden-death (HR 1.19 [1.08-1.31], $P=0.0003$)). We did not find a relation between BMD and mortality due to CVD or infections in either sex. In conclusion, FN BMD was inversely associated with all-cause mortality in elderly males but not females and strongly related to COPD mortality in both genders within two prospective population-based studies. No association was found between BMD and CVD mortality in either males or females.

Sclerostin Inhibition Improves Bone Mass, Bone Strength, and Bone Defect Regeneration in Rats with Type 2 Diabetes Mellitus. Christine Hamann^{*1}, Martina Rauner², Yvonne Hoehna³, Ricardo Bernhardt⁴, Jan Mettelsiefen³, Claudia Goettsch⁵, Klaus-Peter Guenther³, Franklin Asuncion⁶, Michael Ominsky⁶, Lorenz Hofbauer³. ¹Dresden Technical University Medical Center, Germany, ²Medical Faculty of the TU Dresden, Germany, ³Dresden University Medical Center, Germany, ⁴Technische Universität Dresden, Germany, ⁵Brigham & Women's Hospital Cardiovascular Division, USA, ⁶Amgen Inc., USA

Type 2 diabetes mellitus results in increased risk of fracture and delays in healing after a fracture has occurred. Better therapies are needed to prevent fractures and improve healing in these diabetic patients. ZDF fa/fa rats are an established model of type 2 diabetes mellitus and exhibit low bone mass and delayed bone defect healing. We tested whether antibodies against sclerostin (Scl-AbVI), an inhibitor of Wnt signaling, reverse the skeletal deficits of diabetic ZDF rats.

Gap defects of 3 mm were created at the femur of 11-week old diabetic ZDF fa/fa and non-diabetic ZDF +/- rats and stabilized by an internal plate. Saline or 25 mg/kg Scl-Ab was administered s.c. twice weekly for 12 weeks in diabetic and non-diabetic rats ($n=10$ /group). Bone mineral density (BMD), bone mass and strength were assessed using pQCT, μ CT, and biomechanical testing. Dynamic bone histomorphometry was used to assess bone formation, and the filling of the femur gap defect was analyzed by μ CT.

Diabetic rats displayed lower spinal and femoral bone mass compared to non-diabetic rats, and Scl-Ab treatment markedly enhanced bone mass of the femur and

the spine of diabetic rats. Scl-Ab also reversed the deficit in bone strength in the diabetic rats, with 65% and 89% increases in maximum load at the femoral shaft and neck, respectively. ZDF fa/fa rats had a 23% decrease in the material properties ultimate strength and modulus compared to +/+ rats, suggesting that bone quality was impaired by diabetes in this model. Scl-Ab modestly improved these parameters in diabetic rats, though its primary effect on whole bone strength was due to increased bone mass. The lower bone mass in diabetic rats was associated with a 65% decrease in vertebral bone formation rate, which Scl-Ab was able to increase by 6-fold, consistent with an anabolic effect. While non-diabetic rats filled 57% of the femoral defect, diabetic rats filled only 21%. Scl-Ab treatment significantly increased defect regeneration in both groups by 47% and 74%, respectively.

Sclerostin inhibition reverses the adverse effects of type 2 diabetes mellitus on bone mass and strength, and improves bone defect regeneration in rats.

Blosozumab, a Humanized Monoclonal Antibody, and A Chimeric Rodent Monoclonal Antibody Against Sclerostin Robustly Increase Bone Formation Activity in Intact Monkeys and Ovariectomized Rats. Yanfei Ma¹, Todd Page¹, Qianqiang Zeng¹, Mary D Adrian¹, David Halladay¹, Xuhao Yang¹, Masahiko Sato², Henry Bryant¹, Venkatesh Krishnan¹, David Waters¹, Rohn Millican¹, Jude Onyia¹, Stuart Kuhstoss¹. ¹Eli Lilly & Company, USA, ²Lilly Research Labs, USA

Loss-of-function mutations in the sclerostin gene result in a high bone mass phenotype in humans and knock-out mice. We examined the skeletal effects of a humanized anti-sclerostin antibody (blosozumab) in monkeys and a separate mouse/rat chimeric monoclonal anti-sclerostin antibody (sclerostin Ab) in rats. Rats were ovariectomized (OVX) at 6 months of age and permitted to lose bone for 1 month to establish osteopenia before initiation of treatment. A chimeric antibody was administered at doses up to 14 mg/kg once weekly (q7) or up to 28 mg/kg once every 2 weeks (q14) subcutaneously for 8 weeks (n=7/group). Compared to OVX IgG controls, bone mineral density (BMD) was increased with sclerostin Ab treatments in lumbar vertebrae (LV), and mid femur (MF) or distal femur at 14mg/kg q7 and at the 14 and 28 mg/kg q14 doses. Biomechanical load-to-failure analyses showed that LV, MF and femoral neck sites were strengthened to a similar extent with normalized time exposure between the q7 and q14 dosing regimens. Bone parameters increased in a dose dependent manner and compared favorably to PTH 1-38 (10µg/kg daily). Bone histomorphometry confirmed that sclerostin Ab increased trabecular area and thickness to sham- ovariectomy (Sham) levels in the proximal tibia metaphyses. Cortical area and thickness above Sham levels were observed in high dose groups in the mid shaft. The mineralizing surface and bone formation rate were higher in sclerostin Ab treated rats than those of IgG controls on trabecular, endocortical and periosteal surfaces. In the cynomolgus monkeys, blosozumab was administered up to 100 mg/kg weekly by intravenous injection to 3 year old males and females (n=4-6/dose/sex) for 9 months. The bone formation biomarker procollagen-1 N-terminal peptide (PINP) was increased at all dose levels and peaked at day 85. QCT analyses showed higher cortical bone mineral content (BMC), cortical area, thickness in tibial shaft, and trabecular BMC and BMD at the tibial metaphysis compared to vehicle controls in both genders at study termination. These results confirm the bone anabolic profile of sclerostin inhibition with selective monoclonal antibodies. The robustly enhanced bone microstructure and strength suggest therapeutic potential for blosozumab.

Despite rigorous nutritional and exercise countermeasures, astronauts lose bone mass at 10 times the rate of postmenopausal women. Sclerostin is a potent inhibitor of bone formation and expression levels of *SOST*, the gene producing sclerostin, increase

with unloading and may mediate disuse-induced bone loss. We tested the ability of a sclerostin antibody (SclAb) to improve bone mass, microarchitecture and strength in mice exposed to 13 days of microgravity on the space shuttle Atlantis (STS-135). Female C57Bl/6N mice (n=14-15/gr, 9 wks old) were assigned to flight vehicle (FL-VEH), flight SclAb (FL-SclAb), ground vehicle (GR-VEH), or ground SclAb (GR-SclAb), and injected with SclAb (100 mg/kg, SC, Amgen) or vehicle 1 day prior to launch. Ground-controls housed identically as the flight mice. Results: Spaceflight negatively influenced BMD, microarchitecture and strength. SclAb treatment markedly improved BMD, bone microarchitecture and mechanical properties in both GR and FL mice at multiple skeletal sites, such that bone properties in FL-SclAb were equal to or greater than GR-VEH (Table). Specifically, microgravity inhibited gains in total body BMD seen in these young mice (p<0.05 vs FL); whereas SclAb led to greater increases in total body BMD in both environments (p<0.01 vs VEH). Tibial and femoral Tb.BV/TV by µCT were 35% lower in FL-VEH than GR-VEH, and 2-3 fold higher in Scl-Ab treated mice, regardless of loading. Midshaft Ct.Th was 5-9% lower in FL-VEH vs GR-VEH, and increased by SclAb treatment, such that values in FL-SclAb were similar to ground controls. Three-point bending of the femoral diaphysis showed decreased stiffness (-16%, p<0.05) and failure load (-11%, p<0.05) in FL-V vs GR-V, while SclAb preserved these properties in FL-SclAb mice at GR-VEH levels. Bone formation, assessed by quantitative histomorphometry, was significantly reduced by spaceflight, and was 3-fold higher in SclAb treated mice. Consistent with this, serum PINP and osteocalcin were lower, and CTX1 higher in FL-VEH vs GR-VEH, while serum osteocalcin and PINP were significantly higher in SclAb-treated mice regardless of loading condition. In conclusion, a single injection of SclAb not only inhibits bone loss in mice exposed to microgravity, but improves bone mass and microarchitecture to levels similar to ground controls, demonstrating that the anabolic effect of sclerostin inhibition occurs even in the absence of normal mechanical loading.

Increased Bone Mass and Bone Strength by Sclerostin Antibody Is Maintained by a RANKL Inhibitor in Ovariectomized Rats with Established Osteopenia. Xiaodong Li¹, Kelly S. Warmington², Qing-Tian Niu², Frank J. Asuncion², Denise Dwyer², Mario Grisanti², Chun-Ya Han², Paul J. Kostenuik², Marina Stolina², Michael S. Ominsky², Hua Zhu Ke². ¹Amgen, Inc., USA, ²Amgen Inc., USA

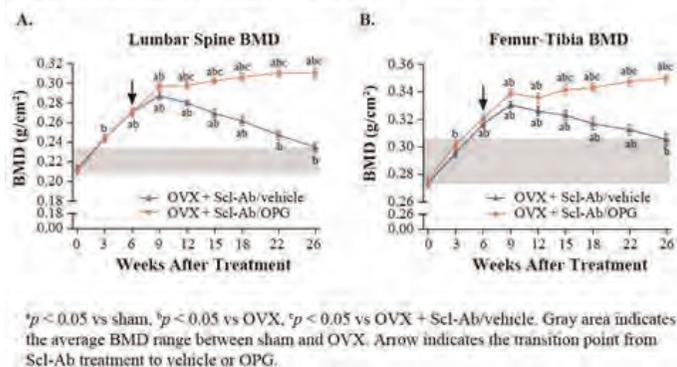

Our previous study demonstrated that some of the bone mass gained during sclerostin antibody (Scl-Ab) treatment is gradually lost after discontinuation of treatment. In the current study, we examined whether follow-up treatment with a RANKL inhibitor, OPG, would maintain the bone mass gains induced by Scl-Ab in ovariectomized (OVX) rats.

Six-month-old OVX rats (2 months post-ovariectomy) were treated with Scl-Ab (Scl-AbVI, 25 mg/kg, SC, 1x/week) for 6 weeks and then transitioned to vehicle or OPG-Fc (10 mg/kg, SC, 2x/week) for an additional 6 or 20 weeks (n=12-14/group). Vehicle-treated sham and OVX control rats were euthanized at weeks 0, 6, 12, and 26, and a group of Scl-Ab-treated OVX rats were euthanized at week 6 (n=10-12/group).

In vivo DXA analysis demonstrated that 6 weeks of Scl-Ab treatment in OVX rats increased lumbar spine and femur-tibia BMD to levels significantly above OVX and sham controls (Figure). Transition to vehicle resulted in gradual declines in BMD at both sites, to levels of sham controls, whereas transition to OPG-Fc maintained the increases in BMD at both sites. Histomorphometry revealed significant increases in vertebral trabecular bone volume (BV/TV) and tibial cortical thickness after 6 weeks of Scl-Ab treatment. Transition to vehicle led to gradual declines in these parameters, to levels that remained above OVX controls at week 26, whereas transition from Scl-Ab to OPG-Fc maintained BV/TV and cortical thickness at the peak levels achieved during Scl-Ab treatment. Six weeks of Scl-Ab treatment was associated with significant increases in trabecular, endocortical, and periosteal bone formation rates and significant decreases in trabecular and endocortical eroded surfaces. These changes were reversed upon transition to vehicle. Transition to OPG-Fc led to reductions in each of these bone resorption and formation parameters. At week 26, maximum load of lumbar vertebral bodies was significantly greater in the group transitioned to OPG-Fc than the group transitioned to vehicle.

In summary, after discontinuation of Scl-Ab treatment, bone formation returned to control levels and bone resorption increased, resulting in gradual bone loss. Transitioning to the RANKL inhibitor OPG-Fc effectively inhibited bone resorption and maintained bone mass and bone strength gains previously induced by Scl-Ab. These results support the strategy of using a RANKL inhibitor to maintain the bone mass and strength increases induced by sclerostin antibody.

Figure. OPG Maintained the Bone Mass Increased by Sclerostin Antibody

LLP2A-Alendronate, a Novel Anabolic Treatment to Reverse Bone Loss. Wei Yao¹, Min Guan², Junjing Jia³, Yu-An Evan Lay⁴, Ruiwu Liu⁵, Kit Lam⁵, Diana Olvera⁶, Robert Ritchie⁶, Jan Nolte⁷, Nancy Lane¹. ¹University of California, Davis Medical Center, USA, ²Johns Hopkins, USA, ³University of California, Davis, USA, ⁴Musculoskeletal Research Unit, Department of Medicine, University of California Davis Medical Center, USA, ⁵Department of Biochemistry & Molecular Medicine, University of California Davis Medical Center, USA, ⁶Materials Sciences Division, Lawrence Berkeley National Laboratory, USA, ⁷Stem Cell Program & Institute for Regenerative Cures, University of California Davis Medical Center, USA

Bone formation is reduced with aging due to fewer bone marrow MSCs and changes in the bone marrow microenvironment. Our research group has developed a synthetic peptidomimetic ligand (LLP2A) that has high affinity for activated $\alpha 4\beta 1$ integrin on the MSC surface, and linked it to a bisphosphonate (alendronate) that has high affinity for bone. We have previously shown that this hybrid compound, LLP2A-Alendronate (LLP2A-Ale), in vitro increased MSC migration and commitment of MSCs to osteoblast differentiation; in vivo it increased bone formation and bone mass in young immune-competent mice. In this study, we continued to evaluate the effects of LLP2A-Ale, with or without the MSC transplantation, in mice with established bone loss induced by ovariectomy or with advanced aging. Methods: C57BL/6 female mice were used in three efficacy studies. The first study used 10-week-old ovariectomized mice with established bone loss. The second study used 24-week-old adult mice and the third study used 24-month-old aged mice. LLP2A-Ale was given two monthly doses (0.9nmol IV) or in combination of mouse MSC (IV 5×10^5). Results: We found LLP2A-Ale partially prevented trabecular bone loss induced by estrogen deficiency by increasing the number of osteoblasts on the trabecular surface and the bone formation rate. MSC + LLP2A-Ale restored lost bone induced by estrogen deficiency by further increasing osteoblast surface and mineral apposition rate. The effects of LLP2A-Ale + transplanted MSCs was superior to LLP2A-Ale alone, especially at the cortical bone, where the combination treatment significantly increased cortical bone strength in all the three animal models we studied. Importantly, PTH or MSC alone failed to increase bone formation rate in 24-month-old mice. By contrast, BFR/BS was increased by 35% in LLP2A-Ale group, by 192% in MSC + LLP2A-Ale group in relative to the PBS-treated group. Only MSC + LLP2A-Ale treatment increased cortical bone maximum stress by 8% as compared to the PBS-treated group. In conclusion, LLP2A-Ale treatment increased bone mass and strength as measured by multiple outcomes in models of young adult mice, aged mice, and estrogen-deficient mice. The beneficial effects on bone formation resulted from the combination of increased homing of the transplanted MSCs to bone as well as the endogenous number of osteoblasts at the bone surface that together significantly increases the rate of bone formation. These results strongly support LLP2A-Ale as a novel therapeutic option for the treatment of bone loss related to age and hormone deficiency.

An Estrogen Dendrimer Conjugate Incapable of Stimulating the Nuclear-initiated Actions of Estrogen Receptors Prevents the Loss of Cortical Bone Mass in Estrogen Deficient Mice. Shoshana Bartell¹, Aaron Warren¹, Li Han¹, Srividhya Iyer¹, Sung Kim², Benita Katzenellenbogen², Ken Chambliss³, Philip Shaul³, John Katzenellenbogen², Paula Roberson¹, Robert Weinstein¹, Charles O'Brien¹, Robert Jilka¹, Maria Jose Almeida¹, Stavros Manolagas¹. ¹Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, ²University of Illinois, USA, ³University of Texas Southwestern Medical Center at Dallas, USA

Loss of bone mass following estrogen deficiency is caused by increased resorption of the cancellous compartment and of the endosteal surface of the cortex, but the cellular and molecular mechanisms of the effects of estrogens in these two compartments are apparently distinct. Indeed, published genetic evidence and work reported elsewhere in this meeting have revealed that the osteoclast ER α mediates the protective effects of estrogens in the cancellous, but not the cortical, compartment. On the other hand, the ER α of osteoblast progenitors is required for normal periosteal bone accrual as well as the maintenance of cortical bone mass, but plays no discernible role in the maintenance of cancellous bone. Based on this and additional evidence that some of the effects of estrogens on bone may be mediated via non-nuclear ER α signaling, we investigated the efficacy of an estrogen dendrimer conjugate (EDC) that is not capable of stimulating the nuclear-initiated actions of ER, in preventing the effects of estrogen loss in the two bone compartments. 17-week-old C57BL/6 mice were ovariectomized (OVX) or sham-operated and implanted with mini-pumps delivering vehicle, dendrimer control (DC), or equimolar concentrations of 17 β -estradiol (E2) or the EDC for 6 weeks. In two separate experiments, the EDC was as potent as E2 in preventing loss of DEXA BMD at the spine. By μ -CT, this effect was due to the preservation of cortical but not cancellous bone. In contrast, E2 was effective in both compartments. EDC also attenuated the loss of cortical bone, the enlargement of the endosteal perimeter, and the increased cortical porosity in femurs. In addition, the EDC prevented the OVX-induced oxidative stress (as determined by ROS and glutathione levels and p66^{bac} phosphorylation) to the same extent as E2. Most importantly, the OVX-induced decrease in uterine weight was unaltered by the EDC, but restored by E2. These results demonstrate that several effects of estrogens on bone, including their protective effect on cortical bone mass maintenance and their anti-oxidant properties, are mediated by a mechanism distinct from their classical genotropic action on reproductive organs. Nonetheless, attenuation of oxidative stress by EDC, unlike the use of E2 or anti-oxidants, is not sufficient to prevent loss of cancellous bone, suggesting that nuclear actions of the estrogen-activated osteoclast ER α are also involved in the protection of this compartment.

A Six Year Exercise Intervention Program in 7-9 Year Old Children Improves Bone Mass and Bone Structure without Increasing the Fracture Risk – A Population-Based Prospective Controlled Study in 2395 Children. Fredrik Deter¹, Bjorn Rosengren², Jan-Åke Nilsson³, Magnus Dencker⁴, Magnus Karlsson². ¹Clinical & Molecular Osteoporosis Research Unit, Lund University, Sweden, ²Skåne University Hospital Malmö, Lund University, Sweden, ³Department of Orthopedics, Sweden, ⁴Department of Physiology, Sweden

Purpose: Pediatric exercise intervention studies that evaluate if physical activity can decrease fracture risk span at most 36 months and use bone traits as a surrogate endpoint for fractures. It is however essential to include also fractures as reports infer that a high level of physical activity is associated with higher fracture risk. We have therefore during 6 years conducted a population based controlled exercise intervention study using both bone traits and fractures as endpoint variables.

Method: During 6 years children in the intervention group received 40 minutes of daily physical education (PE) in school while those in the control group continued with the Swedish standard 60 minutes PE per week. Incident fractures were continuously registered in the total sample size of 2395 children aged 7-9 years at baseline. There were 362 girls and 446 boys in the intervention group (3515 person-years) and 780 girls and 807 boys in the control group (7628 person-years). In 78 girls and 113 boys in the intervention group and 53 girls and 54 boys in the control group, skeletal development was followed annually by dual energy X-ray absorptiometry (DXA). As to evaluate bone area (mm²), peripheral computed tomography (pQCT) measurements were done in the forearm and tibia after 5 years. Slopes and annual changes were calculated for bone mineral density (BMD; g/cm³) and femoral neck (FN) area (mm²). Data are reported as mean group difference with 95% CI within brackets.

Results: There were 20.5 fractures/1000 person-years in the intervention group and 18.8 fractures/1000 person-years in the control group, resulting in a Rate Ratio (RR) of 1.09 (0.81, 1.45) (mean (95% CI)).

The annual gain in spine BMD was higher in both girls (0.007 (0.001, 0.013)) and boys (0.004 (0.001, 0.008)) in the intervention group compared to the control group. Girls with daily PE also had higher gain in femoral neck BMD (0.006 (0.001, 0.012)) and femoral neck area (0.04 (0.01, 0.07)) and after 5 years also a larger mid

radial cross sectional area (11 (0.6, 21)) and mid tibial cortical area (17 (2, 31)) than the control girls.

Conclusions: Increased physical activity for 6 years in a population based cohort of 7-9 year old children improve the gain in bone mass, and in girls also the bone structure, without increasing the fracture risk

Effect of Whole-Body Vibration Therapy (WBV) for Low Bone Mass in Adolescent Idiopathic Scoliosis Girls with Osteopenia: A Randomized, Controlled Trial. Tsz Ping Lam^{*1}, Bobby Kin Wah Ng², Louis Wing Hoi Cheung², Kwong Man Lee², Ling Qin³, Jack Chun Yiu Cheng².
¹Department of Orthopaedics & Traumatology, The Chinese University of Hong Kong, Peoples Republic of China, ²Department of Orthopaedics & Traumatology, The Chinese University of Hong Kong, China, ³Chinese University of Hong Kong, Hong Kong

Introduction: Adolescent idiopathic scoliosis (AIS) was associated with osteopenia which, apart from being an important health issue, was found to be a significant prognostic factor for curve progression in AIS. Although whole-body vibration (WBV) was shown to have anabolic effects on bone metabolism in animal studies, its effect on AIS subjects has not been studied before. The objective of this study was to determine whether WBV could improve low bone mineral density (BMD) and bone quality for AIS subjects with osteopenia.

Methods: This was a randomized, controlled trial with 2 parallel groups. 149 AIS girls of age 15 to 25 years old, with Cobb angle between 10 to 50 degrees and with BMD Z-scores < -1 were recruited. They were randomly assigned to either the Treatment or Control group under strict allocation concealment. In the Treatment group, subjects were treated with standing on a low-magnitude high-frequency WBV platform 20 mins a day, 5 days a week. Subjects in the Control group received observation alone. The study period was one year. Bone measurement was done at baseline and at 12-month: (1) areal BMD and BMC at bilateral femoral necks and lumbar spine using Dual-Energy X-ray Absorptiometry and (2) bone quality in terms of bone morphometry, volumetric BMD and trabecular bone micro-architecture using high-resolution peripheral quantitative computed tomography (HR-pQCT) for the non-dominant distal radius and bilateral distal tibiae according to standard protocols.

Results: The most significant findings were greater absolute and percentage increases in femoral neck areal BMD at the dominant leg (0.015 (SD=0.031)g/cm², 2.15 (SD=4.32)%) and greater absolute increase in lumbar spine BMC (1.17 (SD=2.05)g) in the Treatment group as compared with the Control group (0.00084 (SD=0.026)g/cm², 0.13 (SD=3.62)% and 0.47 (SD=1.88)g respectively, all with p < 0.05). No statistically significant difference was noted for other DXA parameters and bone quality parameters of the non-dominant distal radius and bilateral distal tibiae.

Discussion and Conclusions: WBV was effective for improving aBMD at the femoral neck of the dominant side and lumbar spine BMC in AIS subjects which might be of clinical significance in affecting curve progression in AIS. Further studies for defining the determinants that moderate the effect of WBV and its effect on curve progression in AIS subjects are warranted.

Effects of Aerobic Exercise on Carboxylated and Undercarboxylated Forms of Osteocalcin and their Relationship to Exercise-induced Changes in Insulin Sensitivity and Visceral and Total Body Fat in Overweight Children. Norman Pollock^{*1}, Barbara Gower², Karl Wenger¹, Jerry Allison¹, Catherine Davis¹.
¹Georgia Health Sciences University, USA, ²University of Alabama at Birmingham, USA

Although animal studies suggest that it is the undercarboxylated rather than carboxylated form of osteocalcin that affects glucose and fat metabolism, it is unclear which of the forms of osteocalcin is associated with better insulin sensitivity and fat loss in humans. This study investigated the effects of aerobic exercise on carboxylated and undercarboxylated forms of osteocalcin and their relationship to exercise-induced changes in insulin sensitivity and visceral and total body fat in children at risk for diabetes. Overweight children (n=222, aged 7-11 years, 56% female, 47% black, 86% obese) were randomly assigned to three experimental conditions: no-exercise control condition (n=78), low dose (20 min/d, n=71), or high-dose (40 min/d, n=73) aerobic exercise program for 12-weeks (5 d/wk). At baseline and posttest, an oral glucose tolerance test was used for assessment of insulin sensitivity (Matsuda index) and circulating forms of OC [total (OC_{total}), carboxylated (cOC), and undercarboxylated (ucOC)]. Given that the assay's capacity to identify ucOC depends on the concentration of OC_{total}, we also report ucOC as a percentage of OC_{total} (%ucOC). Percentage body fat (%fat) and visceral adipose tissue (VAT) were measured by DXA and MRI, respectively, at baseline and posttest. Absolute concentrations of all measures of OC showed a dose-response increase with exercise, whereas %ucOC showed a decrease (Figure). A dose-response benefit of exercise was also observed for insulin sensitivity, as indicated by a significant upward trend, and for %fat and VAT,

as indicated by significant downward trends (all P<0.04). Multiple linear regression adjusting for age, sex, and race revealed that changes in both OC_{total} and cOC were positively associated with changes in insulin sensitivity but negatively associated with changes in VAT (all p<0.05). Changes in ucOC and %ucOC were not associated with changes in insulin sensitivity, %fat, or VAT. In overweight children, circulating forms of osteocalcin are regulated by aerobic exercise in a dose-response manner. In addition, the exercise-induced changes in insulin sensitivity and visceral fat are associated with the carboxylated, rather than undercarboxylated, form of osteocalcin.

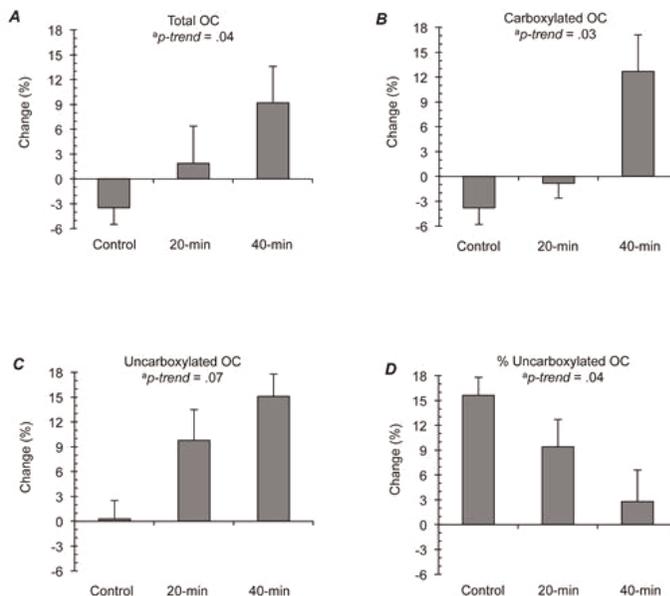

Figure. Change from baseline: total osteocalcin (A), carboxylated osteocalcin (B), undercarboxylated osteocalcin (C), and % undercarboxylated osteocalcin (D) in response to 12 weeks (5 day/wk) of either no exercise (n=78), 20 min/day of aerobic exercise (n=71), or 40 min/day of aerobic exercise (n=73). *Significant linear contrast indicates dose-response.

Disclosures: Norman Pollock, None.

Effects of a Specialized School Physical Education Program on Bone Structure and Strength: A 4-year Cluster Randomised Controlled Trial. Robin Daly^{*1}, Gaelle Ducher¹, Ross Cunningham², Briony Hill¹, Rohan Telford³, Prisca Eser⁴, Geraldine Naughton⁵, Markus Seibel⁶, Ahmad Javaid⁷, Richard Telford⁸.
¹Centre for Physical Activity & Nutrition Research, Deakin University, Australia, ²Fenner School of Environment & Society, Australian National University, Australia, ³Centre for Research & Action in Public Health, Department of Health, University of Canberra, Australia, ⁴Swiss Cardiovascular Centre Bern, University Hospital (Inselspital), Switzerland, ⁵Centre of Physical Activity Across the Lifespan, Australian Catholic University, Australia, ⁶Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, ⁷The Canberra Hospital, Australia, ⁸Clinical Trials Unit, The Canberra Hospital & Medical School, Australian National University, Australia

Physical activity programs incorporating specific weight-bearing exercises have proven effective for enhancing bone mineral accrual during growth, but the effects of more generalized school-based physical education (PE) on bone health remains unclear. In addition, few long-term studies have used pQCT to characterize changes in bone strength and its determinants (bone structure and volumetric BMD) in response to exercise during growth. This study investigated the effects of a specialist taught school PE program on bone mass, structure and strength and muscle mass and size in primary school aged children. This was a 4-year cluster RCT involving 365 boys and 362 girls in grade 2 aged 8 (SD 0.3) years from 29 primary schools in Canberra, Australia. All children received 150 min/week PE from classroom teachers but in 13 schools 100 min/week was replaced by two specialized PE classes that emphasized more vigorous exercise and games combined with static and dynamic postural activities involving muscle strength and function. Measurements in grades 2, 4, and 6 included DXA total body BMC and lean mass (LM), pQCT volumetric BMD, structure and strength at the radius and tibia (4% and 66% sites) and muscle CSA and pubertal development (Tanner stage). In girls, the 4-year gains in cortical area at the mid-radius and mid-tibia were on average, 9.6% (P<0.05) and 5.0% (P=0.08) greater in those who received the specialized compared to common-practice PE, with the relative increase being most apparent in the last 2 yrs. These results were independent of bone length, weight, pubertal status and the random effect of school. In boys, the only positive effect of the specialized PE was on cortical vBMD at the mid-tibia (2.4% vs 1.3%, P<0.05). However, neither of these benefits translated into significant

improvements in bone strength in the specialized PE group. There was also no evidence of any beneficial effects of specialized PE on trabecular vBMD at the distal radius or tibia or whole body LM or regional muscle CSA after 4-yrs. In conclusion, this study showed that generalized PE conducted twice weekly by specialist physical educators through grades 3-6 (age 8-12) of primary school can have some positive effects on cortical area and density, but these benefits did not translate into significant improvements in bone strength. This suggests that more specific bone loading activities may need to be incorporated into PE classes to maximize skeletal benefits during growth.

Disclosures: Robin Daly, None.

Sustained Effects of Physical Activity on Bone Health: Iowa Bone Development Study. Shelby Francis*, Elena Letuchy, Steven Levy, Kathleen Janz. University of Iowa, USA

Purpose: Previous studies of young athletes and children engaged in targeted interventions have shown some maintenance of bone mineral content (BMC; g) years after cessation of training, but less is known about the sustained effects in the average child population. Using a prospective cohort, this study examined the potential effect of early childhood physical activity (PA) on BMC in adolescence.

Methods: Participants (N=156 boys, 170 girls) in the Iowa Bone Development Study had clinical exams at ages 5, 8, 11, 13, and 15 yr. Body size and somatic maturity were measured using anthropometry. Moderate to vigorous physical activity (MVPA) and vigorous PA were measured using the Actigraph accelerometer. Due to the higher fitness level in children and adolescents compared to adults, cut points were set at ≥ 4 METs for MVPA and ≥ 7 METs for vigorous PA. BMC of the lumbar spine and hip was measured using dual-energy x-ray absorptiometry. Mixed regression models were used to test whether activity level at age 5 had an effect on BMC at ages 13 and 15 after adjustment for age 13 and 15 age (yr), height (cm), weight (kg), maturity ($0 = \text{pre-peak height velocity}/1 = \text{post}$), and activity level ($\text{min} \cdot \text{day}^{-1}$). The analysis was repeated to control for BMC at age 5.

Results: On average, boys participated in 59 min, 52 min, and 38 min of MVPA at ages 5, 13, and 15, respectively. They participated in 13 min, 17 min, and 11 min of vigorous PA at ages 5, 13, and 15, respectively. MVPA and vigorous PA at age 5 predicted spine BMC at ages 13 and 15 ($p < 0.05$). MVPA at age 5 predicted hip BMC. Girls participated in 47 min, 33 min, and 26 min of MVPA at ages 5, 13, and 15, respectively. They participated in 10 min, 9 min, and 7 min of vigorous PA at ages 5, 13, and 15, respectively. Neither MVPA nor vigorous PA predicted spine BMC at ages 13 and 15. MVPA at age 5 did predict hip BMC. When the analysis was repeated to control for BMC at age 5 as well as the other covariates, the effect of MVPA and vigorous PA at age 5 remained significant for boys at the spine. For girls, neither MVPA nor vigorous PA at age 5 predicted spine or hip BMC.

Conclusions: Everyday childhood activity provides bone benefits that can be sustained into adolescence. These results, especially in boys, suggest that bone strengthening physical activity programming should begin early in childhood.

Does Stage of Sexual Maturation Determine the Relationship of Calcium Intake and Physical Activity to Bone Mass Accrual. Joan Lappe*¹, Babette Zemel², Patrice Watson³, Xiang Fang³, Vicente Gilsanz⁴, Heidi Kalkwarf⁵, Sharon Oberfield⁶, John Shepherd⁷, Karen Winer⁸. ¹Creighton University Osteoporosis Research Center, USA, ²Children's Hospital of Philadelphia, USA, ³Creighton University, USA, ⁴Children's Hospital Los Angeles, USA, ⁵Cincinnati Children's Hospital Medical Center, USA, ⁶Columbia University Medical Center, USA, ⁷University of California, San Francisco, USA, ⁸National Institutes of Health, NICHD, USA

Background: Although it is accepted that dietary calcium (Ca) and physical activity (PA) increase bone mass accrual, evidence is lacking about whether Ca and/or PA might be more important for accrual during specific stages of sexual maturation.

Aim: To describe the relationship between Ca and PA and total body bone mineral content (TBBMC) accrual by Tanner stage (TS) in a large, multi-racial cohort of children followed prospectively from early childhood until sexual maturity.

Methods: Five U.S. centers recruited 2014 healthy children (ages 5 to 19 yr) and measured them annually for up to 7 yrs. Subjects with at least 2 visits are included in this analysis (915 males, 835 females). TBBMC was assessed by dual energy x-ray absorptiometry, height (ht) with a stadiometer, and TS by endocrinologist exam. PA and Ca were assessed by self-report using the modified Slemenda questionnaire and a food frequency questionnaire, respectively.

Analyses: The relationship between PA (hrs/wk) and Ca (mg/d) and TBBMC was assessed using linear regression in a mixed model. Specifically, annualized TBBMC change (from the prior visit) was modeled as a function of prior visit TBBMC, annualized ht change, TS, and PA/Ca. Separate regressions evaluated the significance of TS by PA/Ca interactions performed on gender and racial (black, B/nonblack, NB) subgroups.

Results: Males have significantly greater average PA and Ca than females, while B have greater PA and lower Ca than NB. PA was a significant predictor of TBBMC accrual in all subgroups except B males, but no differences were seen among TS. Ca

significantly predicted accrual in NB, but not in B. When analyzing by TS, Ca was a significantly better predictor of accrual in TS 3 and 4 in NB males, in TS4 in B males, and in TS4 and 5 in NB females. When controlling for Ca, PA was associated with TBBMC accrual in all subgroups except for B males ($p < 0.08$). When controlling for PA, Ca was significantly associated with accrual only for NB.

Conclusion: PA contributes significantly to bone mass accrual in this large cohort, but has no significant association with any specific stage of sexual maturation. Overall, Ca is significantly associated with accrual in NB only, both males and females. Within subgroups, Ca appears to be more important for accrual during specific stages of sexual maturation, ie, B males, TS4; NB males, TS3 and 4, and NB females, later stages of sexual maturation.

Disclosures: Joan Lappe, None.

Deletion of FoxO1, 3, and 4 from Osteoprogenitor Cells Increases Bone Mass throughout Life and Attenuates Adiposity in Aged Bone. Srividhya Iyer*¹, Elena Ambrogini¹, Li Han¹, Shoshana Bartell¹, Aaraon Warren², Julie Crawford², Paula Roberson², Robert Weinstein¹, Charles O'Brien¹, Maria Jose Almeida¹, Stavros Manolagas¹. ¹Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, ²Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

An important role of FoxO transcription factors in skeletal homeostasis has been established recently with studies of the loss or gain of FoxO function globally or selectively in osteoblasts and osteoclasts. In addition, it has been shown in many cell types, including osteoblasts, that FoxOs defend against oxidative stress or growth factor depletion and in the process divert β -catenin from Wnt/Tcf- to FoxO mediated transcription. Based on this and evidence that Wnt/ β -catenin signaling increases bone mass by promoting the progression of Osterix (Osx)-expressing cells to matrix synthesizing osteoblasts, we have deleted FoxO1,3,4 conditional alleles in committed osteoblast precursors expressing Osx1 (FoxO1,3,4flox;Osx1-Cre). At 3 months these mice exhibited a 20% increase in BMD at the spine and femur, an increase in cancellous bone volume, and increased periosteal apposition as compared to littermate controls. When the deletion was postponed until 3 months of age (by activating a Tet-off system incorporated into the Osx-Cre transgene), a very similar increase occurred in both femoral and spinal BMD, demonstrating that the phenotype was not due to developmental changes. The high bone mass was associated with increased BrdU incorporation, osteoblast number, and bone formation rate. Cultured Osx-GFP positive calvaria cells or periosteal cells from the femurs of FoxO1,3,4-flox;Osx-Cre mice exhibited higher proliferation and increased expression of the β -catenin/Tcf target genes cyclinD1, connexin43, coll6a1, and Mmp16. Consistent with the evidence that FoxOs antagonize Wnt/Tcf signaling, deletion of FoxOs by transfection of adeno-Cre in calvaria cells, increased cyclinD1 expression and proliferation, similar to treatment with Wnt3. Bone-marrow derived cells from FoxO1,3,4-flox;Osx-Cre mice also formed fewer adipocytes in response to rosiglitazone. Importantly, the high bone mass phenotype of the FoxO1,3,4-Flox;Osx-Cre mice was maintained up to 24 months of age. And at this age, FoxO1,3,4-Flox;Osx-Cre mice exhibited fewer marrow adipocytes in the femur as compared to controls. We conclude that throughout life activation of FoxOs restrains Wnt signaling by diverting β -catenin from Wnt/Tcf- to FoxO mediated transcription in osteoprogenitor cells. Thus, FoxO activation may contribute to the decreased bone mass and the increased bone marrow adiposity of the aging skeleton, perhaps while defending against oxidative stress.

Reciprocal Control of Osteogenic and Adipogenic Lineages by ERK/MAP Kinase Signaling and Transcription Factor Phosphorylation. Chunxi Ge*¹, William Cawthorn², Yan Li³, Guisheng Zhao³, Jennifer Westendorf⁴, Ormond MacDougald⁵, Renny Franceschi³. ¹Pom Univ of Michigan School of Dentistry, USA, ²Department of Molecular & Integrative Physiology University of Michigan, USA, ³University of Michigan, USA, ⁴Mayo Clinic, USA, ⁵Department of Molecular & Integrative Physiology University of Michigan School of Medicine, USA

Osteoblasts and adipocytes are thought to arise from a common mesenchymal stem cell. The ratio of marrow-derived osteoblasts to adipocytes decreases in osteoporosis and during skeletal unloading. Osteoblast differentiation is stimulated by ECM deposition and mechanical loading, events known to be accompanied by MAP kinase activation. Also, the osteoblast/adipocyte determination factors, RUNX2 and PPAR γ , exert reciprocal control over these 2 differentiation outcomes with RUNX2 suppressing adipogenesis and PPAR γ suppressing osteoblastogenesis. In this project, we test the hypothesis that the ERK/MAPK pathway is a major determinant of MSC lineage commitment to osteoblasts and an inhibitor of adipogenesis and that control of cell fate is achieved by phosphorylation of RUNX2 and PPAR γ transcription factors. ST2 murine MSC cells were grown in osteogenic or adipogenic medium and differentiation was measured by Alizarin Red or Oil Red O staining and expression of osteoblast and adipocyte markers. During osteoblast differentiation, ERK and

RUNX2-S319 phosphorylation increased. Interesting, PPAR γ -S112-P also increased and this was associated with decreased expression of adipocyte markers. During adipocyte differentiation, ERK activity and phosphorylation of both transcription factors decreased. Using RUNX2 and PPAR γ reporter constructs, MAPK phosphorylation was shown to directly stimulate RUNX2 transcriptional activity while inhibiting PPAR γ and this regulation was mediated by phosphorylation at S301,319 (RUNX2) and S112 (PPAR γ). Also, direct activation of MAPK signaling using an adenovirus encoding constitutively active MEK1 stimulated osteoblast differentiation and inhibited adipogenesis while DN MEK1 inhibited osteoblastogenesis and stimulated adipocyte formation. MAPK-dependent phosphorylation of RUNX2 was also shown to indirectly regulate Wnt signaling via down-regulation of the Wnt inhibitor, Axin2, leading to increased β -catenin during osteoblast differentiation. As previously reported, wild type RUNX2 is a potent stimulator of osteoblast differentiation when transfected into MSC-like cells while RUNX2 containing S301A, S319A mutations is inactive. Similarly, WT RUNX2 inhibits adipocyte differentiation while the S/A mutant is less active. Taken together, these studies show that levels of ERK/MAPK and RUNX2/PPAR γ phosphorylation are key determinants of osteoblast or adipocyte differentiation from MSCs.

Stem Cell Antigen-1 Positive (Sca-1+) Cell-based Gene Therapy with Fibroblast Growth Factor-2 (FGF2) Promotes Robust Recruitment of Osteoprogenitors in the Bone Marrow of Recipient Mice. Susan Hall*¹, Shin Tai Chen², Kristy Howard¹, Daila Gridley³, Subburaman Mohan¹, Kin-Hing William Lau¹. ¹Jerry L. Pettis Memorial VA Medical Center, USA, ²Jerry L. Pettis VA Medical Center, USA, ³Loma Linda University, USA

FGF2 is a potent mitogenic and angiogenic protein that when administered to rodents results in large increases in osteoblast and osteoid surface at bone sites. We have shown that transplantation of Sca1+ cells expressing a modified FGF2 gene (with improved secretion and stability) provides sustained, high dose FGF2 expression, and yields rapid and robust endosteal bone formation (BF) in recipient mice. In this study, to identify the mechanism for the increased BF, we evaluated the hypothesis that the FGF2 produced by engrafted Sca1+ cells in the bone marrow (BM) acts to promote recruitment and expansion of osteoprogenitors. We employed our *ex vivo* gene therapy model to determine the effect of transplanting FGF2 overexpressing cells on the mRNA levels of putative osteoprogenitor marker genes. Sublethally irradiated stem cell-deficient mice were injected IV with Sca1+ cells transduced with MLV-based vectors expressing FGF2 or β -gal (control). At 2 and 6 weeks post transplantation, RNA was isolated from BM cells of femurs of recipient mice and evaluated for transgene expression. Aliquots of individual samples were pooled according to level of FGF2 expression (high, medium, low or control) and the mRNA levels of candidate markers of osteoprogenitors (CD29, CD44, CD90, CXCR4, nestin, PDGFR- α , PDGFR- β , Sca1, SMA- α) were assessed by qRT-PCR. At 2 weeks post transplantation, compared to controls, dramatic dose-dependent increases were observed in PDGFR- β (12-, 19- and 35-fold), SMA- α (10-, 15- and 25-fold) and nestin (7-, 9- and 11-fold) mRNA levels in the low, medium and high FGF2 pooled samples, respectively. This dose-dependent trend was also seen at 6 weeks for all three genes. Other putative osteoprogenitor markers showed small changes and/or no dose-dependent pattern. mRNA level assessment of PDGFR- β , SMA- α and nestin was repeated on individual BM samples. Linear regression analysis confirmed strong positive correlations between FGF2 mRNA levels and PDGFR- β (R=0.77, p<0.0001), SMA- α (R=0.74, p<0.0002) and nestin (R=0.83, p<0.0001). To test if the increased recruitment of osteoprogenitors is caused by increased angiogenesis, we measured mRNA levels of angiogenic marker genes (Ang1, vWF, CD31) and failed to detect consistent changes in the expression of any of gene tested. In conclusion, our findings are consistent with a model in which engrafted FGF2 expressing Sca1+ cells leads to rapid recruitment of osteoprogenitors in the BM to induce robust endosteal BF.

Loss of Osteoblastic Connexin 43 Results in Delayed Bone Formation, Increased Sclerostin Expression and Attenuated Wnt Signaling During Fracture Repair. Alayna Loisel*¹, Emmanuel Paul¹, Gregory Lewis¹, Henry Donahue². ¹Penn State Hershey, USA, ²The Pennsylvania State University College of Medicine, USA

Connexin 43 (Cx43) is the predominant gap junction protein in bone, and is required for osteoblast differentiation, and bone homeostasis. We have generated mice with targeted deletion of Cx43 in osteoblasts using Col1-Cre (2.3Kb) to test the hypothesis that loss of Cx43 in osteoblasts results in decreased bone formation and mechanical properties as a result of increased Sclerostin expression, and diminished Wnt/ β -Catenin signaling. Cx43 conditional knockout mice (Cx43cKO) had significantly decreased Cx43 expression, as assessed by qPCR in the fracture callus, relative

to WT at all time-points post-fracture. Peak Cx43 expression occurred at 28 days in WT fractures (117-fold vs. WT day 3 expression, p=.001). Deletion of Cx43 in osteoblasts delayed expression of osteoblastic markers (*Col1a1*, *Osteocalcin*, *Bmp2*), suggesting a delay in the transition from cartilage to bony callus. Peak *Col1* expression occurred at 10 days (3.5-fold vs. day 3 WT, p=.02) in WT fractures, while peak *Col1* expression was delayed until 14 days in Cx43cKO fractures (3.7-fold, p=.04). Sclerostin (encoded by *Sost*), an inhibitor of bone formation and an antagonist of Wnt/ β -Catenin signaling, was significantly increased in Cx43cKO fractures at 21 days relative to WT (WT:129 \pm 13.5; Cx43cKO: 254 \pm 26.8, p=.002). Increased expression of *Wnt3a*, and Frizzled receptors were also observed, indicative of possible compensation for increased *Sost* expression. However, β -Catenin expression was significantly decreased in Cx43cKO fractures. This attenuation of β -Catenin signaling resulted in decreased BV/TV (WT:0.3 \pm 0.03 Cx43cKO:0.24 \pm 0.06 p=.03) and ultimate torque at failure (WT:21.66 \pm 4.9 N*mm, Cx43cKO:12.77 \pm 1.5, p=.009) of Cx43cKO fractures at 28 days post-repair. Loss of Cx43 during fracture healing also alters the remodeling phase of healing, with decreased *RankL* and increased *Opg* expression in Cx43cKO fractures, compared to WT at 21 days. This work identifies a novel mechanism of fracture callus mineralization via Cx43 regulation of Sclerostin and the Wnt/ β -Catenin pathway. These data suggest that targeted overexpression of Cx43 could decrease *Sost* expression, and enhance Wnt/ β -Catenin signaling to improve healing of fracture non-unions. This concept is a shift from the recognized paradigm of Cx43 as a down-stream functional target of Wnt signaling, to a role for Cx43 mediated regulation of Wnt/ β -Catenin and mineralization.

Bone as a Site of Insulin Resistance in Type 2 Diabetes. Jianwen Wei*, Gerard Karsenty. Columbia University, USA

Type 2 diabetes is characterized by insulin resistance in insulin target cells, the classical ones being the hepatocytes, myoblasts and adipocytes. The recent realization that the osteoblast is an insulin target cell involved in the control of whole-body glucose homeostasis suggests the possibility that impaired insulin signaling in osteoblasts might contribute to the development of type 2 diabetes. Consistent with this hypothesis, we first showed that insulin resistance occurred in osteoblasts in wild type mice rendered diabetic through a high-fat-diet (HFD). Molecular evidence of insulin resistance include reduced phosphorylation of AKT at Th308 and Ser347 in bones, a decrease of bone resorption due to an increase of *Opg* expression and a decrease of the active form of osteocalcin. Next, to test if insulin resistance in osteoblasts contributes to whole-body insulin resistance, we used loss-of (*InsR_{osb}+/-* mice) and gain-of function (*$\alpha 1(1)$ -InsR* transgenic mice) models of insulin signaling in osteoblasts. Glucose tolerance tests and insulin tolerance tests showed that *InsR_{osb}+/-* mice were more severely glucose intolerant and insulin resistant than control mice fed the same HFD, in contrast *$\alpha 1(1)$ -InsR* mice were protected from insulin resistance. Accordingly, *ex vivo* cell culture experiments and *in vivo* hyperinsulinemic euglycemic clamp experiments showed that osteoblasts uptake glucose in an insulin-regulated manner and that glucose uptake in osteoblasts is decreased in mice fed a HFD. Lastly, gene profiling analysis identified *Glut1* as the main glucose transporter in osteoblasts mediating both basal and insulin-dependent glucose uptake. Accordingly, gain and loss of function experiments in the mouse showed that *Glut1* is necessary for whole-body glucose homeostasis. Taken together, this study provides evidence that insulin resistance takes place in osteoblasts in diet-induced type 2 diabetes and identifies a molecular mechanism whereby insulin favors glucose uptake in osteoblasts.

Completing the Bone/Brain Circuit: Osteocalcin Signals within the Hypothalamus to Inhibit Bone Formation. Shu Lin¹, Ronaldo Enriquez¹, Herbert Herzog¹, John Eisman², Paul Baldock*². ¹Neuroscience Program, Garvan Institute of Medical Research, Australia, ²Garvan Institute of Medical Research, Australia

Osteocalcin (Ocn) is increasingly recognized for its endocrine actions to regulate energy homeostasis. However, despite its relatively osteoblast-specific expression, a major role for Ocn in bone has yet to be identified. Previous studies have reported a mild increase in bone mass in Ocn null mice, with elevated bone turnover and greater cortical bone formation. Thus the fundamental role of Ocn in bone is unclear.

We have examined the role of Neuropeptide Y family (NPY), which acts in the arcuate nucleus (Arc) of the hypothalamus to coordinate bone and energy homeostasis. The NPY pathway to bone is stimulated by circulating factors, such as leptin; which itself feeds back to the brain to regulate fat mass. We hypothesized that Ocn may also form a feedback loop within the brain, to regulate bone mass. Moreover, this loop may involve NPY action within the Arc of the hypothalamus.

We examined Ocn activation of hypothalamic neurons by determining c-fos expression. A Iug i.p. bolus of Ocn induced c-fos in neurons of the Arc, indicating that serum Ocn activates hypothalamic neurons. Injection of Ocn directly into the CSF circulation also activated neurons in the arcuate, as well as a number of other hypothalamic regions, indicating direct Ocn signalling in the brain.

To examine chronic Ocn supply to the hypothalamus, we injected a viral vector expressing Ocn (AAV-Ocn) into the Arc of 10 week old mice and examined bone 12 weeks later. This model mimics increased circulatory supply to the brain, as the Arc has a semi-permeable blood brain barrier. Consistent with increases in Ocn KO mice, AAV-Ocn injection significantly reduced cancellous bone volume of the distal femur (40%), compared to AAV-empty injected controls. This was associated with a significant reduction in mineral apposition rate (33%). These changes occur despite a fall in serum Ocn (AAV-empty 137 ± 7 ng/ml vs AAV-Ocn 115 ± 6 p<0.05), highlighting the importance of central signalling to the anti-anabolic effect.

This anti-anabolic Ocn effect requires intact NPY signalling, as AAV-Ocn injection did not alter bone in NPY KO or Y2 Receptor KO mice, both of which act through signalling in the Arc.

In conclusion, Ocn signals directly in neurons of the arcuate nucleus to control bone homeostasis. Chronic over supply of Ocn to these neurons inhibits bone formation and bone mass. This study defines, for the first time, a central feedback mechanism for bone mass, completing the bone-brain circuit.

No Additive Effects of In Vivo Loading and Sclerostin Antibody Treatment on Bone Anabolism in Elderly Mice. David Pflanz^{*1}, Etienne Berthet², Annette Birkhold³, Tobias Thiele², Chaoyang Li⁴, Hua Zhu Ke⁴, Georg Duda², Bettina Willie⁵. ¹Charité Universitätsmedizin Berlin, Germany, ²Julius Wolff Institute, Charité - Universitätsmedizin Berlin, Germany, ³Julius Wolff Institute, Charité Universitätsmedizin Berlin, Germany, ⁴Amgen Inc., USA, ⁵Charité- Universitätsmedizin Berlin, Germany

Bone adapts to mechanical stimuli to gain an optimized structure, although the exact mechanisms regulating this process remain unclear. The protein sclerostin, secreted by osteocytes, is thought to reduce bone formation by inhibiting Wnt signaling and decreasing osteoblast function. Recent data suggests SOST/sclerostin suppression may be at least partially responsible for the anabolic action of mechanical loading. We tested the effect of inhibition of sclerostin by sclerostin antibody (Scl-Ab) on elderly mice with or without in vivo loading.

We performed in vivo cyclic compressive loading to the left tibia of 78 week old female C57Bl/6J mice, half of which were treated with 25 mg/kg of Scl-Ab, twice a week (n=10/group). The right limb was an internal control. A peak load of -9N was applied at 4Hz for 432 cycles/day, 5days/week for 2 weeks engendering peak strains of 1200 μ e on the medial midshaft, measured by strain gauging. Longitudinal microCT at 10.5 μ m resolution was performed at day 0, 5, 10, and 15. Trabecular bone volume fraction (BV/TV), tissue mineral density (Tb vTMD, mg HA/cm³), thickness (TbTh, μ m) and separation (TbSp, μ m) were assessed in the proximal tibia. Principal moments of inertia (I_{MAX}, I_{MIN}), cortical bone area (CtAr, mm²), total cross-sectional area (TtAr, mm²), area fraction (CtAr/Tt.Ar), thickness (CtTh, μ m) and tissue mineral density (Ct vTMD, mg HA/cm³) were assessed at midshaft. An ANOVA was used to assess within-subject and between-subject effects and interactions.

By day 15, BV/TV increased significantly in Scl-Ab treated mice with (+89%) and without (+150%) loading compared to non-treated mice. Similarly, CtAr increased significantly in Scl-Ab treated mice with (+21%) and without (+27%) loading (Table 1). While Scl-Ab treated mice exhibited significant gains in bone mass, non-treated mice lost bone mass. Loading attenuated bone loss in non-treated mice; significantly greater BV/TV, TbTh, CtAr, and CtTh was measured at day 15 (loaded vs. control). No significant effect of loading was measured in Scl-Ab-treated mice at day 15. In summary, loading had a mild effect in maintaining bone mass in elderly mice, which was not observed when Scl-Ab was administered since Scl-Ab not only maintained but also increased bone mass from baseline controls. No additive effect of loading and Scl-Ab treatment on bone anabolism was observed, suggesting sclerostin may contribute to loading-induced bone gain in vivo.

Effects of Sclerostin Antibody on Tissue Level Strength in oim Mice. Jean-Pierre Devogelaer^{*1}, Patrick Ammann², Mike Ominsky³, Catherine Behets⁴, Daniel Manicourt⁵. ¹St. Luc University Hospital, Belgium, ²Division of Bone Diseases, Switzerland, ³Amgen, USA, ⁴Université Catholique de Louvain, Belgium, ⁵Université Catholique De Louvain, Belgium, Belgium

Available treatments fail to prevent the high rate of limb fractures in children with osteogenesis imperfecta (OI) type III, a severe genetic condition with poor bone quality. A sclerostin neutralizing monoclonal antibody (Scl-Ab) markedly reduced long bone fractures in oim/oim mice, a model of OI type III; therefore, tibiae of OI mice were analyzed to test the effects of Scl-Ab on bone strength at the level of the whole bone and for the bone matrix by nanoindentation.

Wildtype (WT) and OI mice (6-week-old) were treated with either Scl-Ab at 25 mg/kg or vehicle (PBS) twice per week for 10 weeks. Bone mechanical properties of tibia midshaft were assessed using a three-point bending test as well as by nanoindentation. Statistical analysis included parametric analysis of variance (ANOVA) followed by post hoc tests. Data are provided as mean \pm SEM.

As reported previously, Scl-Ab reduced the number of fractures in upper and lower limbs in OI mice by 60% (5.2 ± 0.3 versus 2.1 ± 0.2 per mouse; p<0.001). This effect corresponded to significant improvements in tibia midshaft cortical thickness (+50%), ultimate load (+53%), and stiffness (+112%) in Scl-Ab treated OI mice compared to PBS controls (Table). Similar effects of Scl-Ab were observed in WT mice. Plastic energy, which reflects tissue brittleness, was lower in the OI mice compared to WT mice, and significantly affected by Scl-Ab treatment. At the tissue level by nanoindentation, Scl-Ab increased slightly (+4%) the elastic modulus in both OI and WT bone whereas Scl-Ab increased modestly tissue hardness (+13% versus PBS) in WT bone, but not in OI bone.

Although it was unable to change the material properties of the bone matrix in OI mice, Scl-Ab was able to reduce the rate of long bone fractures by improving bone mass and whole bone strength. These results suggest that Scl-Ab may have the potential to reduce fractures in patients with OI.

| Tibia Shaft Parameter | OI mice | | WT mice | |
|-------------------------|-------------|--------------|-------------|--------------|

Mechanical Loading and Intermittent Parathyroid Hormone Promote Osteoblastogenesis, Inhibit Adipogenesis, and have Opposing Effects on Osteoclast Activity In Periprosthetic Bone. Matthew Grosso^{*1}, Hayden-William Courtland¹, Xu Yang¹, James Sutherland¹, Anna Fahlgren¹, Eduardo Suero¹, F. Patrick Ross¹, Marjolein Van Der Meulen², Mathias Bostrom¹. ¹Hospital For Special Surgery, USA, ²Cornell University, USA

Mechanical loading and parathyroid hormone (PTH) administration independently stimulate bone formation, and are strong candidates for enhancing osseointegration at the bone-implant surface. An understanding of the effects of these treatments on periprosthetic bone at the cellular level is crucial to developing targeted treatment strategies for implant stability. We hypothesized that the effects of loading and PTH on periprosthetic cancellous bone are anabolic and synergistic when combined, and that these effects are mediated by enhanced osteoblast differentiation and proliferation, control of bone turnover, and inhibition of adipogenesis.

Adult rabbits (n=96) underwent surgery to insert a porous titanium implant directly on the cancellous bone beneath a mechanical loading device on the right and left distal lateral femur. The right femur was loaded daily, and the left femur received a sham loading device. Half of the rabbits received daily PTH, and half received saline. Periprosthetic cancellous bone was processed at 3, 7, 14, and 28 days for gene expression and histology.

Runx2 mRNA, a transcription factor that promotes osteoblastogenesis, increased with loading (1.5 fold, p=0.007). PTH treatment decreased SOSTmRNA, an inhibitor of Wnt signaling, (-2 fold, p=0.01), and increased β -catenin levels (1.5 fold, p=0.009). SOSTmRNA decreased and β -catenin levels increased with loading (SOST: -1.5 fold, p=0.10, β -catenin: 1.5 fold, p=0.10) but did not reach significance. PPAR γ , a transcription factor that promotes adipogenesis, decreased with PTH treatment (-2.5 fold, p=0.021) and loading (-2 fold, p=0.023), but the effect was not additive or synergistic (Fig. 1). With loading, osteoclast number decreased (-1.5 fold, p=0.007), and was supported by increased OPG levels (2 fold, p=0.02). Conversely, PTH increased RANKL levels (1.5 fold, p=0.23), and osteoclast number (2.5 fold, p=0.03) (Fig. 2).

Mechanical loading and PTH exhibit similar effects in periprosthetic bone; they promote osteoblast activity and inhibit adipogenesis, acting at least in part through the Wnt signaling pathway. Although these pathways were similar, no synergistic effect between PTH and loading was seen at the molecular or cellular level. However, we found that mechanical loading reduces osteoclast number, in contrast to the pro-resorptive PTH effects, which may allow for a net additive effect on bone formation at the tissue level in this model of implant osseointegration.

Spatial Patterns of Src Activity Differ in Response to Mechanical Loading or EGF in Osteocytes. Julia Hum^{*1}, Suzanne Young², Richard Day¹, Fredrick Pavalko¹. ¹Indiana University School of Medicine, USA, ²Indiana University, USA

Mechanotransduction is the process by which a mechanical load is detected by osteocytes and osteoblasts at the cellular membrane and results in changes of gene transcription. However, the exact mechanism(s) of transmitting a physical stimulus to the nucleus is unknown. Src, a tyrosine kinase, is activated in response to mechanical loading and epidermal growth factor (EGF) treatment. We suggest that Src is an important mediator of mechanotransduction in osteocytes. To further investigate the role of Src during mechanical loading, we compared Src's pattern of activity in response to both oscillatory fluid shear stress (OFSS) and EGF treatment in live osteocytes using Förster Resonance Energy Transfer (FRET). A novel Src biosensor labeled with fluorescent probes (FP) at both C- and N-terminus was used. The activity of the Src biosensor was monitored via fluorescent lifetime imaging microscopy (FLIM). FLIM images dynamic real-time protein interactions and is capable of displaying sub-cellular locations of Src activity in live osteocytes. Src activity was assessed by measuring the FP's lifetime (nanoseconds). An inactivate Src mutant biosensor displayed no change in Src activity in response to OFSS or EGF treatment. However, in response to 5 minutes of OFSS, the Src biosensor displayed a distinct pattern of Src activity at 10, 15 and 20 minutes post OFSS. Src activity was significantly greater at the membrane after 10 minutes post OFSS as compared to static controls (p<.001). At 15 minutes post OFSS, Src activity was significantly greater in the cytoplasm (p<.001) and at 20 minutes post OFSS Src activity was significantly greater in the nuclear/perinuclear region (p<.001). In contrast, after 10 minutes of EGF treatment, Src activity significantly increased at the membrane (p<.001), but otherwise was uniformly increased throughout the osteocytes compared to static controls. Our data reveals, for the first time in live osteocytes, that OFSS and EGF treatment initially induces Src activity near the cell membrane, but with time OFSS increased Src activity in the cytoplasm and nuclear/perinuclear regions of the cell.

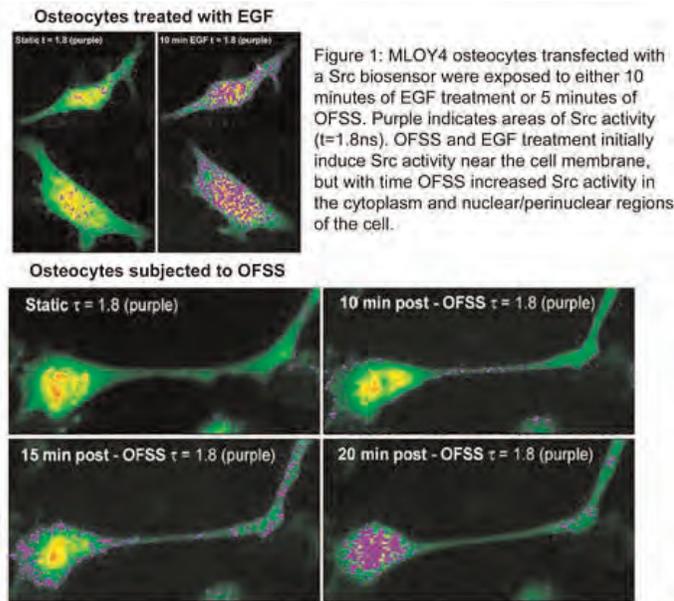

Figure 1: MLOY4 osteocytes transfected with a Src biosensor were exposed to either 10 minutes of EGF treatment or 5 minutes of OFSS. Purple indicates areas of Src activity ($\tau=1.8$ ns). OFSS and EGF treatment initially induce Src activity near the cell membrane, but with time OFSS increased Src activity in the cytoplasm and nuclear/perinuclear regions of the cell.

Spatial patterns of Src activity in osteocytes in response to mechanical loading or EGF

Deletion of Sirtuin 1 in Mature Osteoblasts Increases the Anabolic Response to Mechanical Loading *in vivo*, but Inhibits Wnt Signaling *in vitro*. Nicole Fleming¹, Jonathan Gali¹, Kellen Sakala¹, Katherine Matthews¹, Jeffrey Nyman², Daniel Perrien². ¹Vanderbilt University, USA, ²Vanderbilt University Medical Center, USA

Sirtuin 1 (Sirt1) is a Class III histone deacetylase that we and others have previously shown to regulate bone homeostasis via direct actions in both osteoblasts (Ob) and osteoclasts. Sirt1 is also expressed in osteocytes (Ot) in murine bone, but its role there is unknown. Inhibition of Sirt1 has been shown to inhibit β -catenin mediated Wnt signaling, a critical mediator of mechanical adaptation in bone, via decreased expression of multiple dishevelled proteins. Hence, we sought to understand the role of Sirt1 in the *in vivo* adaptation of bone to increased mechanical load. Sirt1^{Ob-/-} and Sirt1^{Ot-/-} mice were created by crossing 2.3kb-Col1 α 1-cre mice or 10kb-DMP-cre mice, respectively, with Sirt1^{lox} mice and inbreeding. As previously described, Sirt1^{Ob-/-} mice have mild but significant low bone volume phenotype. However, neither the trabecular nor cortical phenotypes were significantly altered in Sirt1^{Ot-/-} mice. Dynamic axial loading was performed on the left tibia of 3-month old male Sirt1^{Ob-/-}, Sirt1^{Ot-/-}, or respective Sirt1^{lox} littermates 3 days per week for 3 weeks. Mechanical loading significantly increased periosteal BFR and MS/BS in the tibial diaphysis compared to the non-loaded tibia in all genotypes. Surprisingly though, the load-induced increase in bone BFR and MS/BS was significantly greater Sirt1^{Ob-/-} mice compared to both Sirt1^{lox} and Sirt1^{Ot-/-} mice ($p<0.05$). The anabolic response in Sirt1^{lox} and Sirt1^{Ot-/-} mice was not significantly different. To determine the effect of Sirt1 deletion on Wnt signaling in Ob, wild type (WT) and Sirt1^{-/-} primary calvarial Ob were treated with vehicle, Wnt3a, or LiCl for 24 hours and the expression of sFrp2 was determined by RT-qPCR as an indicator of canonical Wnt signaling. As expected, both Wnt3a and LiCl significantly decreased the expression of sFrp2 in WT Ob ($p<0.01$). However, the ability of both factors to suppress sFrp2 expression was significantly reduced in the absence of Sirt1 ($p<0.05$). While Wnt signaling is largely associated with increased osteogenesis, others have shown that Wnts inhibit late stage differentiation of and mineralization by osteoblasts. These results suggest that deletion of Sirt1 in Col1 α 1-expressing, mature osteoblasts increases the anabolic response to mechanical loading by preventing the inhibitory effects of increased Wnt signaling in mature osteoblasts.

Lipocalin2 Is a New Osteoblast Mechano-Responding Gene That Regulates Osteoblast Differentiation and Osteoblast-Induced Osteoclastogenesis. Mattia Capulli¹, Nadia Rucci², Anna Teti². ¹Department of experimental Medicine, University of L'Aquila, Italy, ²University of L'Aquila, Italy

In a global transcriptome analysis of mouse calvarial osteoblasts subjected to simulated microgravity (0.008g), Lipocalin-2 (LCN2) was the most upregulated gene

(>8-fold) vs control (1g), suggesting a role in the response of osteoblasts to reduced mechanical loading. The enhanced expression of LCN2 correlated with an impaired osteoblast differentiation, as demonstrated by a decreased mRNA expression of Runx2, Sfrp2, Wisp2 and genes encoding for bone matrix proteins. Since the physiologic functions of LNC2 remain poorly understood and its role in bone is unknown, we transduced primary mouse osteoblasts with LCN2-expression-vector (Lcn2OBS) and investigated their phenotypic alterations. We observed that Runx2 and its downstream genes Osterix and Alp were downregulated in Lcn2OBS vs empty-vector transduced osteoblasts (emptyOBS) (-72%,-80% and -83%, respectively). Moreover, ALP activity was less prominent (-46%), thus indicating a less differentiated osteoblast phenotype. Lcn2OBS also exhibited an increase in Rankl/Opg ratio and IL-6 mRNA expression (8- and 5.3-fold increase, respectively), suggesting that LCN2 up-regulation could link poor osteoblast differentiation with enhanced osteoclastogenesis. Consistently, incubation of purified mouse bone marrow macrophages with conditioned media from Lcn2OBS, or their co-culture with Lcn2OBS, enhanced osteoclast formation compared to emptyOBS (5- and 2-fold increase, respectively). LCN2 could have an autocrine-paracrine effect given that osteoblasts expressed the LCN2 receptors, megalin and 24p3r, both at transcriptional and protein level. The mechano-responding properties of LCN2 were confirmed in three animal models of reduced mechanical loading-induced bone loss: tail suspension, treatment with the muscle paralysis inducer botox, and dystrophic MDX mice. Lcn2 mRNA was upregulated in the bones of all three models relative to controls (147-, 96- and 5.8-fold increase, respectively), with increased protein level confirmed in the botox-treated mice. Moreover, increase of mechanical loading in MDX mice, obtained by treadmill physical exercise, returned the LCN2 expression levels to those observed in WT mice. Our *in vivo* and *in vitro* data indicate that LCN2 could be a novel osteoblast mechano-responding gene and that its regulation appears to be central to the response of the bone tissue to low mechanical forces, inducing both poor osteoblast differentiation and increased osteoblast-mediated osteoclastogenesis.

Breast Cancer-induced Osteolytic Bone Lesions are Inhibited by TGF- β Signaling in Osteoclasts, but not Inhibited when Targeted to Osteoblasts. Xiaohong Li¹, Jeffrey Nyman², Alyssa Merkel¹, Kang-Hsien Fan¹, Neil Bhowmick³, Lynn Matrisian⁴, Julie Sterling⁵. ¹Vanderbilt University, USA, ²Vanderbilt University Medical Center, USA, ³Cedars-Sinai Medical Center, USA, ⁴The pancreatic cancer action network, USA, ⁵Department of Veterans Affairs (TVHS)/Vanderbilt University Medical Center, USA

TGF- β is abundant in the bone environment and plays a critical role in the "vicious cycle" of osteolytic bone metastasis; TGF- β stimulates the cancer cells to activate osteoclasts, causing bone degradation and the release of more TGF- β from the bone matrix. Systemic delivery of TGF- β inhibitors or neutralizing antibodies has been shown to reduce tumor burden and lytic bone lesions caused by breast cancer (BCa) and melanoma cells. However, TGF- β also directly effects the proliferation and differentiation of osteoblasts and osteoclasts, and we hypothesized that cell specific TGF- β signaling in the bone microenvironment has distinct and complex roles in BCa bone metastasis.

Through both gain-of-function and loss-of-function approaches, genetically engineered mouse (GEM) models were used to delineate the role of mesenchymal cell (Mes) or myeloid cell (Mye) specific TGF- β signaling on BCa-induced osteolytic bone lesion development. Lysozyme M promoter-driven Cre was used to induce the ablation of the TGF- β type II receptor (Tgfb2) or constitutively active TGF- β type I receptor (Tgfb1) in mature macrophages, granulocytes and osteoclasts [LysM^{cre}/Tgfb2^{loxE2/loxE2}/Rosa26/Rag2^{-/-} (Tgfb_off_Mye) and LysM^{cre}/Tgfb1^{T204D}/Rosa26/Rag2^{-/-} (Tgfb_on_Mye)]. Using the ER-regulated collagen promoter, the administration of tamoxifen activates Cre in fibroblasts, osteoblasts and chondrocytes [Col^{creER}/Tgfb2^{loxE2/loxE2}/Rosa26/Rag2^{-/-} (Tgfb_off_Mes) and Col^{creER}/Tgfb1^{T204D}/Rosa26/Rag2^{-/-} (Tgfb_on_Mes)]. MDA-MB-231 BCa cells were injected into the tibiae of the GEMs and their respective Cre- controlled, immunodeficient mice. Host mice tibiae were imaged by Faxitron weekly up to 4 weeks post injection and bone lesion number and area was analyzed using Metamorph.

We found that lytic bone lesion development was significantly reduced in Tgfb_on_Mye mice compared to control mice ($p=0.007$); and correspondingly a significant increase in lytic bone lesions was observed in the Tgfb_off_Mye mice compared to control mice ($p=0.009$). In contrast, MDA-MB-231 cells induced more lytic lesions in Tgfb_on_Mes mice compared to control mice, while fewer lesion number and lesion area were observed in Tgfb_off_Mes mice. All statistics were applied by mixed effect model analysis. The results suggest that TGF- β signaling activation in osteoblasts is pro-osteolytic, but TGF- β signaling in osteoclasts is anti-osteolytic in this model of breast-to-bone metastasis.

SOST Inhibits Prostate Cancer Invasion. Bryan Hudson*¹, Gabriela Loots², Nick Hum¹, Cindy Thomas¹. ¹Lawrence Livermore National Laboratory, USA, ²Lawrence Livermore National Laboratory, UC Merced, USA

In addition to its role in bone development, metabolism, and repair, the WNT signaling pathway is also implicated in cancer oncogenesis. Several inhibitors of WNT signaling, including dickkopf homolog 1 (DKK1), Wnt inhibitory factor 1 (WIF1), and secreted frizzled protein (sFRP), have been shown to be involved in prostate cancer (PC) metastasis; however the role of sclerostin (SOST) has not yet been explored. We examined human PC cells (PC3 and C4-2Bm) and healthy human prostate epithelial cells (HPrEC) to investigate the role of SOST in PC proliferation and invasion through the addition of recombinant proteins (rhSOST and rhDKK1) and in co-cultures with primary osteoblasts (OBs) isolated from mice lacking either the WNT co-receptor *Lrp5* (*Lrp5 KO*) or the WNT inhibitor *Sost* (*Sost KO*). We also conducted a whole-genome survey in PC3 to identify molecular changes as a function of PC3-OB co-culture. Here we report that rhSOST dramatically inhibits the invasive properties of both PC3 and C4-2Bm cells, without effecting cell proliferation or viability. In contrast, we found that rhDKK1 significantly increases invasion. Our data also shows that PC3 and C4-2Bm cells co-cultured with OBs derived from *Sost KO* mice exhibit increased invasion; an effect reversed in co-cultures with *Lrp5 KO* derived OBs. Gene expression analysis showed that major factors known to be involved in invasion, such as MMP2, are up-regulated in PC3 cells co-cultured with *Sost KO* OBs and down-regulated in *Lrp5 KO*, further implicating the direct involvement of WNT signaling in matrix degradation and cancer invasion. In support of this hypothesis, inhibition of MMP2 was sufficient to block the increased invasion of PC3 in PC3-OB/*Sost KO* co-cultures. These results were further examined *in vivo*, following intratumoral injections of PC3 cells in 8-week old control (WT), *Lrp5 KO*, and *Sost KO* mice, to determine if the host genotype alters the process of bone tumor formation. Consistent with the *in vitro* data, we found *Sost KO* mice to be more susceptible to tumor formation and growth while the *Lrp5 KO* mice showed a reduced susceptibility relative to WT. These findings support the hypothesis that the WNT signaling pathway is a critical component of prostate cancer metastasis to bone. In addition, we show that PC invasion is strongly reliant on SOST availability, where loss of SOST and hyperactive WNT activity in osteoblasts and bone tissue increases the ability of PC to invade and form tumors.

Metformin Targets Tumor Cells and the Microenvironment to Prevent Prostate Cancer Initiation and Growth in Bone. Tunde Akinyeke*¹, Tunde Akinyeke¹, Xinying Wang¹, Satoko Matsumura¹, Himaly Shinglot¹, Rupak Bhatt¹, Anjana Saxena², Wenbo Yan³, Xin Li¹. ¹New York University, USA, ²CUNY-Brooklyn College, USA, ³Nyack College, USA

Prostate cancer is the second leading cause of cancer-related death in American men and many prostate cancer patients develop bone metastasis. Current treatment modalities for metastatic prostate cancer are mostly palliative with poor prognosis. Epidemiological studies indicated that patients receiving diabetic drug metformin have lower prostate cancer risks and better prognosis, suggesting that the metformin may have anti-neoplastic effects. However, the mechanism by which metformin impedes prostate cancer initiation and progression is unknown. The amplification of *MYC* oncogene plays a key role in early prostate epithelia cell transformation and prostate cancer growth. The objective of this study is to investigate the effect of metformin on *MYC* expression and prostate cancer progression. Our results demonstrated that: (1) Metformin selectively inhibited the growth of prostate cancer cells by stimulating cell cycle arrest and apoptosis without affecting the normal prostatic epithelial cells (RWPE-1) growth. (2) In Myc-CaP mouse prostate cancer cells, metformin decreased *MYC* protein levels by 50% through protein degradation and inhibition of de novo protein synthesis. (3) In human prostate cancer cells that either develops osteoblastic lesion (C4-2b) or osteolytic lesion (PC-3), metformin significantly decreased *MYC* at mRNA and protein levels. (4) In Hi-Myc mice which display murine prostate neoplasia and cancer highly resembling the progression of human prostate tumors, metformin (250mg/kg/d, 4wks) reduced *MYC* protein levels in prostate glands and attenuated prostate intraepithelial neoplasia (PIN, the pre-cancerous lesion of prostate). (5) In athymic mice with tumors from intra-tibia injection of C4-2b cells, metformin treated group showed a significant reduction of tumor burden in the tibia with decreased levels of serum IGF-1 (a growth factor stimulates tumor growth) and TRAP5b (a bone resorption marker). Consistently, metformin suppressed RANKL expression in primary osteoblasts indicating inhibited osteoclastogenesis. In conclusion, our novel findings demonstrate that metformin inhibits prostate cancer growth associated with down-regulation of *MYC*. Importantly metformin also alters bone microenvironment to suppress bone resorption and IGF-1 levels. Taken together, our data strongly suggest that metformin may act as a chemopreventive agent to restrict prostate cancer initiation as well as a chemotherapy agent to inhibit its growth in bone.

PLCγ2/β-catenin Pathway Controls Myeloid-Derived Suppressor Cells to Promote Bone Metastasis Independent of the Osteoclasts. Aude-Helene CAPIETTO*¹, SEOKHO KIM², Deborah Novack³, Roberta Faccio². ¹Washington University School of Medicine, USA, ²Washington University in St. Louis School of Medicine, USA, ³Washington University in St. Louis School of Medicine, USA

Osteolytic bone metastases remain a clinical challenge even with anti-resorptive therapies. We have recently shown that *PLCγ2^{-/-}* mice have increased bone tumor burden despite defective osteoclasts. These findings suggest that skeletal metastases are modulated by other cells in addition to osteoclasts. Gr-1⁺CD11b⁺ Myeloid-Derived-Suppressor Cells (MDSC) promote tumor dissemination mainly by suppressing anti-tumor T-cell responses. We found aberrant expansion of MDSC and reduced T-cell activation in B16-melanoma-bearing *PLCγ2^{-/-}* mice. To determine whether MDSC promote tumorigenesis in *PLCγ2^{-/-}* mice, we adoptively transferred MDSC isolated from *PLCγ2^{-/-}* or WT mice into tumor-bearing WT mice. Animals receiving *PLCγ2^{-/-}*-MDSC displayed greater expansion of MDSC in the spleen and increased tumor burden compared to mice receiving WT-MDSC. Importantly, *PLCγ2^{-/-}*-MDSC were more efficient than WT cells to suppress CD8⁺ T-cell proliferation, via increased ROS and NO production. Thus, increased activation of MDSC promotes tumor growth in bone even in the absence of functional osteoclasts. Further confirming that MDSC expansion involves *PLCγ2* pathway, phosphorylation of PKC, a downstream target of *PLCγ2*, was decreased in MDSC isolated from tumor-bearing WT mice compared to non-tumor controls. PKC phosphorylation was further reduced in *PLCγ2^{-/-}* MDSC isolated from tumor-bearing mice. Since PKC has been shown to modulate β-catenin (β-cat) stabilization, we analyzed β-cat expression in WT and *PLCγ2^{-/-}* MDSC following tumor inoculation. *PLCγ2^{-/-}* MDSC displayed reduced β-catenin levels *in vivo* and *in vitro* compared to WT cells. Consistent with a functional role for this protein, deletion of β-catenin in myeloid cells (*LysMCre/β-cat.cKO*) led to a 2-fold increase in MDSC numbers and enhanced tumor burden. By contrast, mice expressing constitutive active β-catenin in myeloid cells (*LysMCre/β-cat.CA*) have reduced tumor growth compared to control mice.

In conclusion, our data indicate that *PLCγ2/β-catenin* pathway is critical for MDSC-mediated tumor escape from immune control. Because bone metastases are often refractory to current cancer therapies, including anti-resorptive agents, targeting MDSC and *PLCγ2/β-catenin* pathway may represent a new therapeutic avenue for bone metastases.

miR-192 Impairs Osteolysis and Metastatic Angiogenesis by Novel Microvesicular Transfer Mechanisms. Karmele Valencia*¹, Diego Luis-Ravelo², Nicolas Bovy³, Susana Martinez-Canarias², Carolina Zanduetta⁴, Iker Anton¹, Ingrid Struman³, Sebastien Tabruyn³, Eva Bandrés², Fernando Lecanda¹. ¹Foundation for Applied Medical Research, Spain, ²Center for Applied Medical Research, Spain, ³GIGA Research, Molecular Biology & Genetic Engineering Unit, University of Liège, Belgium, ⁴Fima University of Navarra, Spain

Emerging evidence suggests that miRNAs (miR) can modulate a complex gene network in cell-intrinsic and extrinsic manner through their secretion into microvesicles (MV) and cargo transfer to target tissues. We previously identified miR192 as heavily downregulated in different highly metastatic subpopulations (HMS) isolated from bone metastases, but its mechanistic contribution remains unknown.

Overexpression of miR192 in HMS led to stunted decrease invasiveness and metalloproteolytic activity as compared to mock transduced cells whereas cell growth kinetics was unaltered. To delineate the pleiotropic functions of miR192 in metastatic activity, after intracardiac inoculation in nude mice, bioluminescence imaging (BLI) showed a dramatic decrease in skeletal tumor burden in mice injected with miR192 and a marked reduction in osteolytic lesions assessed by X-rays and μ CT scans. To explore its role in bone colonization, we intratibially injected (i.t.) miR192 cells. Significant decrease in BLI was associated with a decrease in osseous tumor burden in mice injected with miR192 cells. Growth kinetics and apoptosis of tumor cells were unaffected *in vivo*. Interestingly, the number TRAP⁺ cells were impaired in mice injected with miR192 cells. Transcriptomic analysis identified proosteoclastogenic factors repressed in miR192 derived tumors. Incubation with conditioned medium derived from miR192 tumor cells, but not with MV, showed a decrease TRAP⁺ cells *in vitro*. Furthermore, metastasis-induced angiogenesis was also severely deranged in mice i.t. with miR192 cells. To assess the contribution of miR192 released in MV, we isolated MV from mock and miR-192 overexpressing cells. Interestingly, miR192 was detected by qPCR in CD63-rich MV of ~100 nm in size by electron microscopy. MV transfer to endothelial cells (HUVEC) was demonstrated after MV-fluorescent labelled incubation. Cargo transfer to HUVEC was demonstrated by incubation with MV-derived from cells overexpressing a non-human miR. Incubation of HUVEC with miR192-derived MV led to decreased endothelial proliferation, migration and tubulogenesis. Moreover, miR192 in HUVEC repressed key proangiogenic IL8, CXCL1 and ICAM1 factors leading to impaired angiogenesis.

Thus, bone metastatic colonization is achieved by novel multimodal mechanisms mediated by miR192 governing tumor cell dependent functions, and non-cell

autonomously regulated tumor-induced osteolysis and angiogenesis by microvesicular transfer.

Measles Virus Nucleocapsid Protein (MVNP) Induction of TANK Binding Kinase 1 (TBK1) Activity Contributes to the Development of Pagetic Osteoclasts. Quanhong Sun^{*1}, Feng-Ming Wang², Benedicte Sammut³, Jolene Windle⁴, G. David Roodman², Deborah Galson¹. ¹University of Pittsburgh, USA, ²Indiana University, USA, ³University of Pittsburgh Hillman Cancer Center, USA, ⁴Virginia Commonwealth University, USA

Paget's disease (PD) is characterized by abnormal osteoclasts (OCL) with a pagetic phenotype that includes: increased sensitivity of OCL progenitors to 1,25(OH)₂D₃, RANKL and TNF α , increased OCL and nuclei/OCL, enhanced resorption capacity, increased expression of IL-6 and the transcription factors TAF12 and ATF7. We have recently reported that MVNP plays a key role in the development of abnormal OCL in PD patients expressing p62^{P392L}, the key mutation linked to PD. Further, we have also shown that MVNP can induce the pagetic OCL phenotype in vitro and in vivo in TRAP-MVNP transgenic mice. However, the molecular mechanisms by which MVNP induces a pagetic OCL phenotype have not been determined. TBK1 and IKK ϵ are IKK-related family members which physically interact with MVNP and can activate both the IRF3 and NF κ B pathways. We found that both TBK1 and IKK ϵ were increased early in OCL differentiation, suggesting a possible role in normal osteoclastogenesis. However, only TBK1 is further increased in OCL precursors from TRAP-MVNP mice compared to wildtype (WT) mice. TBK1 overexpression induced IL-6 reporter expression in both HEK293 and NIH3T3 cells, and even elevated endogenous IL-6 mRNA in both NIH3T3 and the pre-osteoclastogenic cell line RAW264.7. Knockdown of TBK1 with shRNA lentivirus impaired MVNP-induced IL-6 secretion as well as decreased TAF12 and ATF7 levels in NIH3T3 cells. The pharmacological TBK1/IKK ϵ catalytic activity inhibitor BX795 dose-dependently inhibited IL-6 RNA production in MVNP-NIH3T3 much more than in EV-NIH3T3. Further, BX795 administered after 1 day of RANKL treatment of bone marrow monocytes (BMM) also blocked the MVNP-induced increased IL-6 expression in cells from TRAP-MVNP mice compared with cells from WT mice when assayed 24 hr later. Importantly, knockdown of TBK1 in BMM from TRAP-MVNP and WT mice prior to RANKL addition impaired development of the MVNP-induced OCL pagetic phenotype, including altered IL-6 expression, TRAP-positive OCL numbers, and expression of OCL differentiation markers. Further, our study also indicated that MVNP modulates TBK1 expression by affecting the stability of both TBK1 mRNA and protein, which is dependent on IL-6, indicating a positive feedback loop. These results demonstrate that TBK1 plays a critical role in mediating the effects of MVNP on the expression of TAF12, ATF7, and IL-6, key contributors to the pagetic OCL phenotype.

Ten-Year Cumulative Incidence of Second Hip fracture in Women and Men. The Norwegian Epidemiologic Osteoporosis Studies (NOREPOS). Tone Omsland^{*1}, Nina Emaus², Grethe S. Tell³, Luai Ahmed⁴, Jacqueline Center⁵, Clara Gjesdal⁶, Siri Forsmo⁷, Berit Schei⁷, Anne Johanne Sogaard⁸, Haakon Meyer⁸. ¹University of Oslo, Norway, ²University of Tromsø, 9037 Tromsø, Norway, ³University of Bergen, Norway, ⁴Faculty of Health Sciences, University of Tromsø, Norway, ⁵Garvan Institute of Medical Research, Australia, ⁶Haukeland University Hospital, Norway, ⁷Norwegian University of Science & Technology, Norway, ⁸Norwegian Institute of Public Health, Norway

Purpose: The purpose of the present population study was to examine the 10-year risk of second hip fracture by gender and investigate the impact of mortality in relation to second hip fracture risk.

Methods: All hip fractures (cervical, trochanteric or sub-trochanteric) treated in Norwegian hospitals between 1994 and 2008 were retrieved through patient administrative systems. Hip fractures sustained between 1994 and 1998 were excluded to minimize misclassifications of the second hip fractures. Thus, all subjects with a first hip fracture between 1999 and 2008 were included (n=81,867). Data were analyzed with standard Cox proportional hazard regression and re-analyzed with competing risks regression with death as the competing event of second hip fracture. Mortality following first hip fracture was analyzed by Cox regression adjusted for age. Time in the survival analyses was calculated as date of first fracture to date of event (second hip fracture or death) or censoring (emigration, end of study, (death)). Cumulative incidences were obtained from competing risks analyzes adjusted for age.

Results: A total of 6,161 women and 1,782 men, sustained a second hip fracture during the 10 years after the first hip fracture. Median time between first and second hip fracture, was 1.5 years in women and 1.2 years in men. The crude incidence rate per 10,000 person years of second hip fracture was 379 (95% Confidence Interval (CI): 370-389) in women and 333 (95% CI: 318-349) in men. The overall age-adjusted hazard

ratio (HR) of sustaining a second hip fracture in women versus men was not significant (HR = 1.03 (95% CI: 0.98-1.09)). The age-adjusted overall mortality after a first hip fracture was 77% (95% CI: 73-80) higher in men compared to women. When accounting for competing risk of death, the age-adjusted HR of a second hip fracture was 1.40 (95% CI: 1.33-1.48) in women versus men. The 10-year cumulative incidence of second hip fracture was 15% in women and 11% in men.

Conclusions: Although incidence rates of second hip fractures were almost similar in women and men, the 10-year risk of a second hip fracture was 40% higher in women compared to men when competing risk of death was taken into account. The gender difference was explained by a higher mortality in men.

Contribution of Refracture to Early Fracture-Associated Mortality. Dana Bliuc^{*}, Nguyen Nguyen, Tuan Nguyen, John Eisman, Jacqueline Center. Garvan Institute of Medical Research, Australia

Background: Following an initial fracture, there is a 2-fold increased risk of re-fracture and an increased risk of premature mortality not just restricted to hip and vertebral fractures. However, the extent to which the re-fracture contributes to, and timing of, excess mortality is unknown. This study examined the additional premature mortality associated with re-fracture following all osteoporotic fractures.

Methods: 1295 subjects aged 60+ from the Dubbo Osteoporosis Epidemiology Study with initial fractures were followed for re-fracture and mortality (1989-2010). Competing risk analysis was used to examine re-fracture, mortality and mortality following re-fracture for hip, vertebral and non hip non vertebral fractures.

Results: There were 358 re-fractures and 487 deaths in women and 90 re-fractures and 206 deaths in men over 5779 p-yrs in women and 1886 p-yrs in men. Following a non-hip non-vertebral fracture in women, 52% of all subsequent fractures were either hip or vertebral. In men this fraction was 49%. Most of the re-fractures and premature mortality occurred in the first 5 years post initial fracture. Excess mortality in the first 5 yrs (above that expected for age and sex) was highest for hip fractures (8.1/100 p-yrs in women and 16.7/100 p-yrs for men). Of all the excess deaths, 25% in women and 20% in men occurred after a re-fracture. Following a vertebral fracture, excess deaths were 2.8/100p-yrs for women and 8.4/100 p-yrs for men. However, over 30% of all deaths for both women and men followed a re-fracture. For non-hip non-vertebral fractures, excess deaths were 1.8/100 p-yrs in women and 3.7/100 p-yrs in men with 30% of these deaths in women and 25% in men following a re-fracture. Population attributable risk of mortality was similar for all fracture types due to the larger number of non-hip non-vertebral fractures (13-18% in women and 25-29% in men).

Conclusion: There is a high premature mortality associated with all osteoporotic fractures occurring predominantly in the first 5 years post initial fracture. However, up to 20-30% of this early premature mortality occurs after a re-fracture with higher percentages following re-fractures after initial non hip fractures. This highlights the vital importance of re-fracture in overall fracture-associated mortality particularly in the immediate post fracture period and thus underscores the urgency for early intervention for all fracture types.

Background: Variations in risk factors associated with femoral neck (FN) and intertrochanteric (IT) fractures have been well described. Similar characterization has not been carried out in individuals who sustain subtrochanteric (ST), diaphyseal (D) or periprosthetic (PP) femur fractures.

Objectives

We compared clinical and densitometric predictors associated with subtypes of femur fractures in the prospective population-based Canadian Multicentre Osteoporosis Study (CaMos).

Method: We identified all CaMos participants age 50 years and older, who sustained an incident femur fracture, as confirmed by a radiologist's report. We assessed differences in clinical variables and in bone mineral density (BMD) between

groups (FN- IT vs ST- D fractures, and PP vs non-periprosthetic (NPP)) recurrent femur fractures after initial repair. We used logistic regression analyses to determine predictors for ST-D compared to FN-IT fractures and for PP compared to NPP recurrent femur fractures.

Results: We identified 270 femur fractures in 246 participants (women: 79%; low trauma: 85%) during 14 years of follow-up. Initial fractures of the ST and D regions were infrequent (8%). There were 16 PP fractures (17%), 6 of which were D. Age, body mass index (BMI), BMD and FRAX scores at baseline were similar between groups. However, when compared to participants with FN-IT fractures, those with ST-D fractures tended to be less sedentary (1.2 hours/day less; 95% Confidence Interval [CI]: -0.1; 2.4), have lower intakes of supplemental calcium (113 mg/day less; 95% CI: -24; 249) and vitamin D (260 IU/day less; 95% CI: 35; 486) and more frequent use of bisphosphonates (Table). Among the 24 subjects with recurrent femur fractures (women: 79%, low trauma: 100%), 9 were PP (5 D) with 5 re-fractures occurring within 12 months of the index fracture. In logistic regression analyses, bisphosphonate use at the time of fracture and bisphosphonate use between cohort entry and index fracture were associated with a higher risk of ST-D fractures (Odds Ratio [OR] 3.8; 95% CI: 1.4; 10.4 and OR 3.1; 95% CI: 1.1; 9.0, respectively) compared to FN-IT fractures. Higher BMD at the femoral neck was associated with higher risk PP fracture vs NPP recurrent fractures.

Conclusion: ST-D femur fractures are infrequent but are associated with different predictors than FN-IT fractures. PP fractures, particularly of the diaphyseal region, frequently follow a recent hip fracture repair.

Table Characteristic in participants with a first femur FN- IT, D-ST fractures (isolated fractures of greater trochanter, lesser trochanter, distal femur not included: N=19)

Change in Bone Mineral Density (BMD) Does Not Improve Fracture Prediction Beyond Baseline BMD. Sarah Berry*¹, Elizabeth Samelson², Robert McLean³, Kerry Broe⁴, L. Adrienne Cupples⁵, Douglas Kiel⁶.

¹Hebrew SeniorLife/Beth Israel Deaconess Medical Center, USA, ²Hebrew SeniorLife, Harvard Medical School, USA, ³Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ⁴Institute for Aging Research/Hebrew SeniorLife, USA, ⁵Boston University School of Medicine, USA, ⁶Hebrew SeniorLife, USA

Purpose: Recent studies question whether a repeat BMD screening test is beneficial in older women. The purpose of our study was to examine whether change in BMD, independent of baseline BMD, predicts fracture in a population based cohort of older men and women. We further examined whether certain subgroups are more vulnerable to fracture in the setting of bone loss.

Methods: Participants included 492 women and 310 men in the Framingham Study with baseline and 4-yr follow-up BMD at the femoral neck (1987-1999) and no prior hip fracture. Hip fractures were confirmed with medical records, and non-hip fractures were self-reported. Follow-up time was calculated from time of the second BMD assessment until fracture, death, or 10 yrs. Cox regression models were used to calculate hazard ratios (HR) for the association between annual percent BMD loss and risk of fracture adjusting for baseline BMD and other covariates. We used logistic regression to calculate areas under the curve (AUCs) to determine whether a model with baseline BMD was improved by including BMD change. In secondary analyses, models were stratified by baseline age, sex, BMI, T-score, weight loss, and FRAX hip fracture risk.

Results: Mean age was 75 yrs (± 4 yrs). Twenty-one percent had a T-score >-1.0, and 54% had a T-score between -1.0 and -2.4. Mean BMD loss was 0.7% annually (± 1.8%). During follow-up, 64 hip and 121 non-hip fractures occurred. After adjusting for baseline BMD, one SD loss of BMD was associated with a 50% increased risk of hip fracture (95% CI, 1.2, 1.9; Table 1), but did not increase the risk of non-hip fracture (HR 1.0, 95% CI 0.8, 1.2). Models including baseline BMD were

not improved by including BMD change (Table 1; AUC 0.72 versus 0.73). Stratified results were similar to the overall results.

Conclusion: In community dwelling older men and women without a hip fracture, BMD loss over four years increases the risk of hip fracture, but not non-hip fracture. BMD loss did not substantially contribute to the 10 yr prediction of hip or non-hip fracture beyond baseline BMD. The contribution of BMD change to risk of fracture was similar regardless of age, sex, BMI, T-score, weight loss, or FRAX risk. Our results confirm and extend previous findings demonstrating that repeating a bone density test every two years to improve risk stratification may not be necessary in older adults provided they have a baseline assessment.

Trajectories of change in physical function: Effects on Fractures and Mortality. Kamil Barbour*¹, Li-Yung Lui², Deborah Barnes³, Kristine Ensrud⁴, Ann Newman⁵, Kristine Yaffe³, Steven Cummings⁶, Jane Cauley⁷. ¹CDC, USA, ²California Pacific Medical Center Research Institute, USA, ³University of California San Francisco, USA, ⁴Minneapolis VA Medical Center / University of Minnesota, USA, ⁵Department of Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, ⁶San Francisco Coordinating Center, USA, ⁷University of Pittsburgh Graduate School of Public Health, USA

Prior studies have identified poor physical function as a risk factor for fractures and mortality. However, these studies did not consider change in physical function over time. We hypothesized that women who maintain their physical function would have a lower risk of non-traumatic fracture (hip and any non-vertebral) and death. We followed 9704 women enrolled into the Study of Osteoporotic Fractures at four U.S. clinical centers. Physical function was measured a maximum of 8 times over 19 years. The median (range) number of measurements for walking (m/s) and chair stand speed (time/s) were 6 (1-8) and 5 (1-8), respectively. Random slope and intercept models were used to determine a walking and chair stand speed slope for each woman, and for the entire population. Three groups were formed for walking speed: “maintainers” (slope ≥ -1 SD from 0, n=773, 8%); “average decliners” (1 SD below mean ≤ slope < -1 SD from 0, n=7676, 79%); “accelerated decliners” (slope > 1 SD below mean, n=1255, 13%). Cox proportional hazards models were used to estimate hazard ratios (HRs; 95% CI) of fracture and mortality and control for age, BMI, physical activity, falls, fracture after age 50, diabetes, stroke, hypertension, calcium intake, health status, weight change, smoking, estrogen use, and hip BMD. The HR of hip and any non-vertebral fracture was 0.64 (0.50, 0.81) and 0.76 (0.67, 0.86) for maintainers of walking speed and 1.52 (1.31, 1.76) and 1.24 (1.13, 1.36) among accelerated decliners of walking speed when compared with the average decliner group. Similar results were shown for chair stand speed. The HR of mortality was 0.49 (0.43, 0.56) for maintainers of walking speed and 0.56 (0.50, 0.64) for maintainers of chair stand speed compared with average decliner group. The HR of mortality was null for accelerated decliners of walking speed, but surprisingly 0.75 (0.70, 0.81) for accelerated decliners for chair stand speed compared with average decliners. In conclusion, women who maintained physical function up to 19 years experienced a lower risk of fractures and mortality than average decliners of physical function, suggesting that maintaining physical function may be a marker for healthy aging.

Fracture rate per 1000 women-year

Direct Healthcare Costs for 5 Years Post Fracture in Canada: A Population-Based Assessment. William Leslie^{*1}, Lisa Lix², Greg Finlayson¹, Colleen Metge¹, Suzanne Morin³, Sumit Majumdar⁴. ¹University of Manitoba, Canada, ²University of Saskatchewan, Canada, ³McGill University, Canada, ⁴University of Alberta, Canada

Background: High healthcare costs in the 1st year post fracture are well known, but long term costs are less well studied. We estimated direct incremental healthcare costs of fracture (post- minus pre-fracture costs) in Manitoba, Canada, up to 5 years after incident fractures.

Methods: We used the comprehensive Population Health Research Data Repository for the 1.2 million residents of Manitoba, Canada, to identify incident fractures in 1997-2002 and direct healthcare costs in the year pre-fracture and 5 years post-fracture. Non-traumatic fractures (hip n=2814, spine n=1030, wrist n=3145, humerus n=1652, other n=7557) and high-trauma fractures (n=444) were identified in continuously-insured residents aged >50 years. Healthcare costs (physician visits, hospitalizations, drugs, homecare and nursing home) were converted to 2009 Canadian dollars. Data were analyzed using median values, which are less sensitive to outliers and extreme costs.

Results: Healthcare costs for all incident fractures combined showed a large increase over pre-fracture costs in the 1st year (\$120M women, \$57M men), but fell below pre-fracture costs in years 2-5 (Figure). This was attributed to higher short term mortality among higher users of healthcare. Incremental median costs (adjusted for age-related cost increases using age- and sex-matched fracture-free controls) for a hip fracture were highest in the 1st year (\$24757 women, \$20927 men), lower in the 2nd year (\$2167 women, \$844 men) and declined below pre-fracture costs by 5 years consistent with healthy survivor effect. In those who survived 5 years following a hip fracture, incremental median costs were again highest in the 1st year (\$26102 women, \$20735 men) but remained above pre-fracture costs at 5 years (\$5091 women, \$3269 men). A similar pattern was seen in 5 year survivors after non-hip fracture with the highest median incremental costs in the 1st year and costs remaining above baseline at 5 years (for women/men: spine \$2802/\$524, wrist \$259/\$382, humerus \$595/\$684, other \$206/\$529, high trauma \$667/\$805).

Conclusions: Direct healthcare costs attributable to fracture peak in the 1st year, but total costs fall below pre-fracture levels for the next 4 years. Our findings suggest that, from a societal perspective, many previous economic analyses have systematically over-estimated the economic burden of fracture. Among those who survive 5 years, however, costs remain above pre-fracture levels, especially for hip fractures.

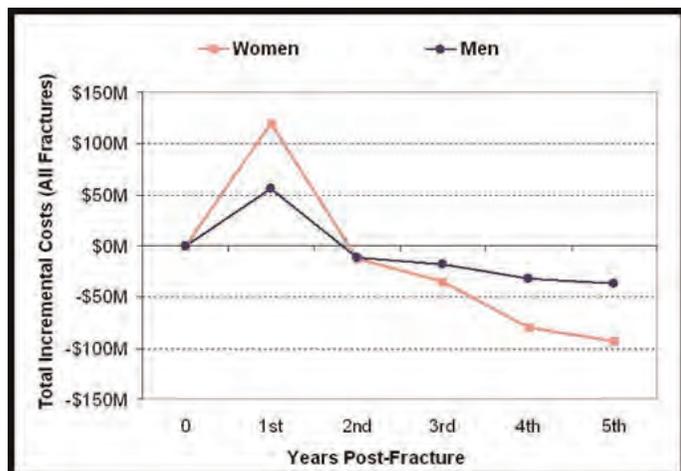

Figure: Incremental healthcare costs over pre-fracture costs for all fracture cases (million SCDN).

The Effects of Combined Denosumab and Teriparatide Administration on Bone Mineral Density in Postmenopausal Women: The DATA (Denosumab And Teriparatide Administration) Study. Benjamin Leder^{*1}, Alexander Uihlein², Robert Neer³, Ruchit Kumbhani⁴, Erica Siwila-Sackman⁵, Sherri-Ann Burnett-Bowie³. ¹Massachusetts General Hospital Harvard Medical School, USA, ²Massachusetts General Hospital, USA, ³Massachusetts General Hospital, USA, ⁴Massachusetts General Hospital, USA, ⁵Massachusetts General Hospital, USA

Background: Currently approved osteoporosis medications increase BMD modestly and reduce, but do not eliminate, fractures. Combining the most commonly prescribed class of antiresorptive agents, bisphosphonates (BPs), and the anabolic agent, teriparatide (TPTD), does not increase BMD more than the respective individual therapies. Animal models suggest that the combination of the newly approved antiresorptive denosumab (DMAB) and TPTD might increase BMD more than either drug alone.

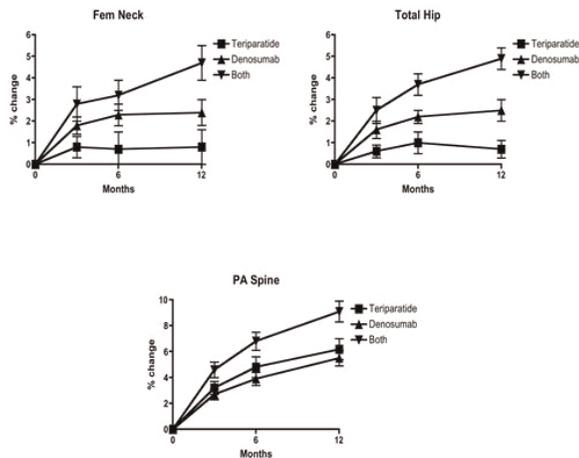

Methods: We enrolled 92 postmenopausal women at high risk of fracture (age 51-91) in a 12-month open-label RCT comparing the effects of TPTD (20 mcg SC daily, n=31), DMAB (60 mg SC Q6 mo, n=33), or both medications (n=30) on hip, spine and 1/3 radius DXA BMD. Subjects were excluded if they had used oral BPs in the past 6 months or had any prior use of strontium or IV BPs. Subjects were stratified by age and prior BP use. Between-group changes in BMD were compared by mixed-model ANCOVA.

Results: No significant between-group differences were observed at baseline (table). As shown in the figure, at 12-months, total hip BMD (mean ± SD) increased more in the combo group (4.9% ± 2.9%) than in either the TPTD (0.7% ± 2.7%), P<0.0001) or DMAB (2.5% ± 2.6%, P=0.0001) groups. Femoral Neck BMD also increased more in the combo group (4.7% ± 4.3%) than in the TPTD (0.8% ± 4.1%, P<0.001) and DMAB (2.1% ± 3.8%, P=0.013) groups. Similarly, spine BMD increased more in the combo group (9.1% ± 3.9%) than in either the TPTD (6.2% ± 4.6%, P=0.0005) or DMAB (5.5% ± 3.3%, P<0.0001) groups whereas BMD at the 1/3 radius increased similarly in the DMAB (1.7% ± 3.2%) and combo groups (2.5% ± 2.8%). These increases in radius BMD were significantly different than the decrease observed in the TPTD group (-1.8% ± 3.6%, P <0.001). DMAB alone increased BMD more than TPTD alone at the total hip (p=0.003) but TPTD and DMAB produced similar gains in the spine (P=0.7) and femoral neck (p=0.09).

Summary: Unlike the combination of TPTD and BPs, the combination of TPTD and DMAB increased BMD at the hip and spine more than either drug alone. Moreover, as DMAB-TPTD co-administration resulted in greater increases in femoral neck, total hip and spine BMD than any currently available alternatives, combined therapy with these agents may prove to be an important treatment option in patients at high risk of fracture.

| | TPTD | DMAB | Both |
|------------------------------------|------------|------------|------------|
| Age | 66 ± 8 | 66 ± 8 | 66 ± 9 |
| Previous BP use | 42% | 36% | 33% |
| Fem Neck BMD (g/cm ²) | 0.64 ± .10 | 0.64 ± .08 | 0.64 ± .07 |
| Total Hip BMD (g/cm ²) | 0.76 ± .10 | 0.77 ± .10 | 0.76 ± .07 |
| Spine BMD (g/cm ²) | 0.82 ± .10 | 0.86 ± .09 | 0.85 ± .12 |

Effects of Denosumab on Fracture Risk in Japanese Patients with Osteoporosis - Results of 2-year Data from the Denosumab fracture Intervention RandomizEd placebo Controlled Trial (DIRECT). Toshitaka Nakamura^{*1}, Toshio Matsumoto², Toshitsugu Sugimoto³, Takayuki Hosoi⁴, Takami Miki⁵, Itsuo Gorai⁶, Hideki Yoshikawa⁷, Yoshiya Tanaka⁸, Sakae Tanaka⁹, Tetsuo Nakano¹⁰, Masako Ito¹¹, Teruki Sone¹², Toshiyuki Yoneda¹³, Shigeyuki Matsui¹⁴, Hideo Takami¹⁵, Masao Fukunaga¹². ¹University of Occupational & Environmental Health, Japan, ²University of Tokushima Graduate School of Medical Sciences, Japan, ³Shimane University School of Medicine, Japan, ⁴National Center for Geriatrics & Gerontology, Japan, ⁵Osaka City University Medical School, Japan, ⁶Hori Hospital, Japan, ⁷Osaka University Graduate School of Medicine, Japan, ⁸University of Occupational & Environmental Health, Japan, Japan, ⁹The University of Tokyo, Japan, ¹⁰Tamana Central Hospital, Japan, ¹¹Nagasaki University Hospital, Japan, ¹²Kawasaki Medical School, Japan, ¹³Osaka University Graduate School of Dentistry, Japan, ¹⁴The Institute of Statistical Mathematics, Japan, ¹⁵Daiichi Sankyo Co., LTD., Japan

Introduction: Denosumab increases bone mineral density (BMD) in both Japanese and Caucasian postmenopausal women with osteoporosis and was shown to reduce fracture risk in a large international study. However, the effect of denosumab on fracture risk in Japanese patients has not been evaluated.

Methods: To examine the anti-fracture efficacy and safety of denosumab (60 mg subcutaneous injection every 6 months [Q6M]) in Japanese patients with primary osteoporosis, a randomized, double-blind, placebo-controlled trial with an open-label referential comparator arm was conducted. The main eligibility criteria were age \geq 50 years, 1-4 prevalent vertebral fractures, and low BMD (L1-L4 or total hip BMD $<$ 80% of young adult mean [T-score $<$ -1.7 (L1-L4) or $<$ -1.6 (total hip)]). A total of 1262 patients were randomly assigned in a 2:2:1 ratio to the following treatment groups, respectively: double-blind denosumab injection (N=500; 25 men), double-blind placebo (N=511; 26 men), or open-label oral alendronate 35 mg weekly (N=251; 12 men) for 2 years. All patients received daily supplements of at least 600 mg calcium and 400 IU vitamin D.

Results: Denosumab significantly reduced the risk of new or worsening vertebral fractures, with incidences of 3.6% in the denosumab group and 10.3% in the placebo group at 2 years (HR, 0.343; 95%CI 0.194-0.606, P=0.0001). The alendronate group showed an incidence of 7.2% at 2 years. Denosumab also significantly reduced the risk of new vertebral fracture and multiple new vertebral fractures, compared to placebo, by 74% (P<0.0001) and 90% (P=0.0113), respectively. Denosumab significantly increased BMD compared to placebo at L1-L4, total hip, femoral neck and distal 1/3 radius by 9.04%, 5.72%, 5.11%, and 2.32%, respectively, at 2 years (all P< 0.0001). Serum CTX-1 and bone ALP levels decreased significantly in the denosumab group at month 1 and these suppression sustained throughout the study period. The incidences of hypocalcemia, cancer, infection, cardiovascular disease and hypersensitivity in the denosumab group were well balanced compared to those of the placebo group. No cases of delayed fracture healing, atypical femoral fracture or osteonecrosis of the jaw (ONJ) were observed. No patients developed a neutralizing antibody to denosumab.

Conclusion: Denosumab 60 mg Q6M for 2 years is safe and effective in reducing vertebral fracture risk in Japanese patients with primary osteoporosis.

Relationship Between Changes in Bone Mineral Density and Incidence of Fracture With 6 Years of Denosumab Treatment. Paul D. Miller^{*1}, Steven Cummings², Jean-Yves Reginster³, Nathalie Franchimont⁴, Gerolamo Bianchi⁵, Michael A. Bolognese⁶, Roland Chapurlat⁷, Federico Hawkins⁸, David L. Kendler⁹, Beatriz Oliveri¹⁰, Jose R. Zanchetta¹¹, Nadia Daizadeh⁴, Andrea Wang⁴, Rachel B. Wagman⁴, Socrates Papapoulos¹². ¹University of Colorado Health Sciences Center & Colorado Center for Bone Research, USA, ²San Francisco Coordinating Center, USA, ³University of Liège, Belgium, ⁴Amgen Inc., USA, ⁵Azienda Sanitaria Genovese, Italy, ⁶Bethesda Health Research Center, USA, ⁷Hôpital Edouard Herriot, France, ⁸Hospital Universitario, Spain, ⁹University of British Columbia, Canada, ¹⁰Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Argentina, ¹¹Instituto de Investigaciones Metabólicas & University of Salvador, Argentina, ¹²Leiden University Medical Center, Netherlands

Purpose: During the first 3 years of denosumab (DMAb) treatment in FREEDOM, there were continued increases in bone mineral density (BMD) and a robust reduction in fracture risk (Cummings et al., *NEJM* 2009). The changes in total hip BMD explained a considerable proportion of the reduction in new or worsening vertebral and nonvertebral fracture risk (Austin et al., *JBM* 2011). Here, we conducted a BMD responder analysis and explored if the progressive BMD gains with 6 years of DMAb therapy continued to relate to the observed fracture incidence.

Methods: The long-term efficacy and safety of DMAb for up to 10 years is being investigated in the open-label extension of the 3-year FREEDOM trial. During the extension, all participants receive 60 mg DMAb every 6 months. For the analyses presented here, women from the FREEDOM DMAb group received 3 more years of DMAb for a total of 6 years. The percentages of women treated with DMAb who achieved BMD increases from FREEDOM baseline at the lumbar spine, total hip, and femoral neck were determined. A logistic regression model was used to examine the relationship between change in total hip BMD and new or worsening vertebral fracture. A comparable approach was employed for nonvertebral fracture using the Cox proportional hazards model.

Results: For women who received 3 additional years of DMAb treatment (N=2343 enrolled), further significant increases in BMD occurred for cumulative 6-year mean gains of 15.2% (lumbar spine), 7.5% (total hip), and 6.7% (femoral neck). At year 6, almost all women treated with DMAb had gains in BMD at the lumbar spine (98%), total hip (96%), and femoral neck (91%). Additionally, 99% of women had gains in BMD at any of these sites, and of these, the gains were $>$ 3% in 98% of women and $>$ 6% in 95% of women. Fracture incidence remained low during the extension. The relationships between total hip BMD gains and new or worsening vertebral and nonvertebral fractures with 6 years of DMAb treatment are shown in Figures 1 and 2, respectively.

Conclusion: Almost all women who received 6 years of DMAb treatment had gains in BMD at the lumbar spine, total hip, or femoral neck; and those gains were $>$ 6% in 95% of them. While on denosumab treatment, the risk of new or worsening vertebral fracture and nonvertebral fracture decreased with increasing percentage change in total hip BMD over 6 years. This association provides clinical relevance to the progressive and continued BMD gains reported with DMAb over time.

Figure 1.

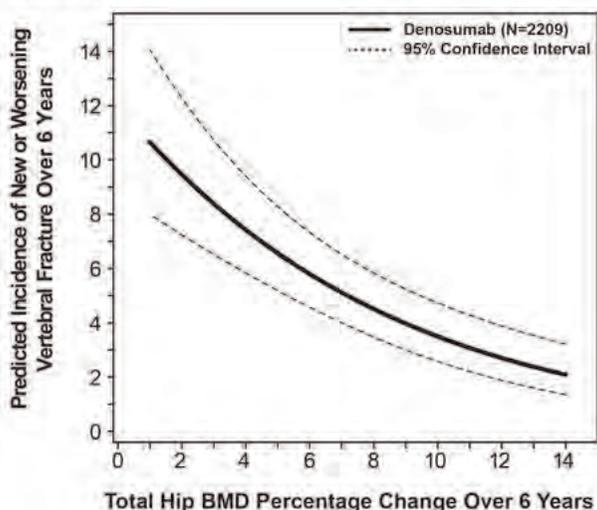

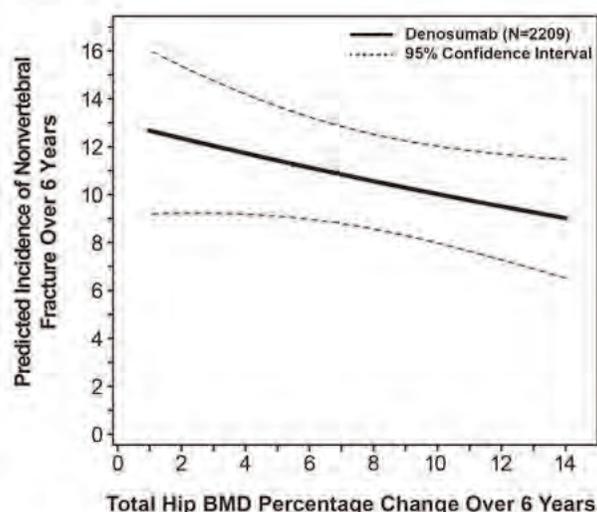

Figure 2.

Aims: To determine if strength of the spine and hip is increased from baseline by Adding and Switching to teriparatide in women on ALN and RLX and to compare the magnitude of the strength effects with these 2 approaches.

Methods: Postmenopausal women with osteoporosis pretreated for at least 18 months with ALN 70 mg/week or RLX 60 mg/day were randomized to Add or Switch to teriparatide 20 mcg administered once daily by sc injection. Quantitative computed tomography scans at baseline, 6 and 18 months were used to assess changes in volumetric BMD and estimated strength by nonlinear finite element analysis (FEA) in a blinded fashion. A plan approved prior to the completion of the assessments specified the analyses.

Results: At the spine, strength and volumetric BMD increased in all groups, and there were no significant differences between Adding and Switching (Table). In the ALN stratum, at the hip, Adding teriparatide significantly increased volumetric BMD relative to Switching at month 6 (0.9% vs -0.5%, $P=0.004$) and month 18 (2.2% vs 0.0%, $P=0.002$). Furthermore, at 18 months in the hip, significant increases in strength were only observed in the Add group (2.7%, $P<0.001$ vs baseline; between-group comparison $P=0.076$). In the RLX stratum, at the hip, both volumetric BMD and strength increased significantly at 6 and 18 months in the Add group, but only at 18 months in the Switch group.

Summary/conclusion: In postmenopausal women with osteoporosis previously treated with ALN or RLX, Adding and Switching to teriparatide conferred similar effects on the spine. In the ALN stratum at 18 months, hip strength increased significantly in the Add but not the Switch group, although the between-group difference was not significant. At 18 months, hip strength increased similarly in both RLX groups. As limitations, the study duration was 18 rather than 24 months, the study lacked power to compare fracture outcomes, and the treatment effects of prior antiresorptives on the bone tissue material properties affecting the estimation of FEA-based strength are unknown.

Median change (%) from baseline (25th, 75th IQR) for volumetric BMD (vBMD) and strength (hip for a sideways fall; spine for uniform compression) in postmenopausal women with osteoporosis previously treated with alendronate (ALN) or raloxifene (RLX) then randomized to Add or Switch to teriparatide (TPTD).

| Outcome | ALN + TPTD (Add) | ALN → TPTD (Switch) | P value ^a | RLX + TPTD (Add) | RLX → TPTD (Switch) | P value ^a |

A Phase 2 Randomized Trial of Orally Administered PTH(1-31)NH₂ Tablets in Postmenopausal Women with Osteoporosis. Nozer Mehta¹, Morten Karsdal^{2*}, Roxanne Tavakkol³, William Stern³, Amy Sturmer¹, Sheela Mitta³, Kim Henriksen², Jeppe Andersen⁴, Bente Riis⁴, Peter Alexandersen⁵, Ivo Valter⁶, Bettina Nedergaard⁷, Christence Teglbiaerg⁷, Antonio Nino⁸, Lorraine Fitzpatrick⁸, Claus Christiansen², Felicia Cosman⁹. ¹Unigene Laboratories, USA, ²Nordic Bioscience A/S, Denmark, ³Unigene Laboratories, Inc., USA, ⁴Nordic Bioscience, Denmark, ⁵Center for Clinical & Basic Research A/S, Denmark, ⁶Center for Clinical & Basic Research, Estonia, ⁷Center for Clinical & Basic Research, Denmark, ⁸GlaxosmithKline Pharmaceuticals, USA, ⁹Helen Hayes Hospital, USA

Purpose: A phase 2 study was designed to test an oral tablet formulation of PTH(1-31)NH₂ as a bone anabolic agent. Background: A solid dosage enteric-coated formulation has been developed that enables oral delivery by a unique mechanism that includes an organic acid as a protease inhibitor and an acylcarnitine as a permeation enhancer. Based on results from phase 1 studies, we tested a 5 mg oral tablet dose of a

The predicted fracture incidence was estimated corresponding to the 5th through the 95th percentiles of the observed total hip BMD percentage changes over 6 years. N=number of subjects with an observed BMD value at FREEDOM extension baseline and at ≥1 follow-up visit.

Hip and Spine Strength Effects of Adding Versus Switching to Teriparatide in Postmenopausal Women with Osteoporosis Treated with Prior Alendronate or Raloxifene. Felicia Cosman^{1*}, Tony Keaveny², David Kopperdahl³, Robert Wermers⁴, Xiaohai Wan⁵, Kelly Krohn⁶, John Krege⁵. ¹Helen Hayes Hospital, USA, ²University of California, Berkeley, USA, ³O.N. Diagnostics, USA, ⁴Mayo Clinic, USA, ⁵Eli Lilly & Company, USA, ⁶Lilly USA, LLC, USA

Background: Many women treated with teriparatide for osteoporosis have previously received antiresorptive therapies. For postmenopausal women with osteoporosis previously treated with alendronate (ALN) or raloxifene (RLX), Adding versus Switching to teriparatide caused different responses in areal BMD and biochemistry (JCEM 94: 3772–3780, 2009). The effects of these approaches on bone strength are unknown.

differentiated PTH(1-31)NH₂ analog in a phase 2 proof-of-concept study. Methods: The study was a 24-week double blind, randomized, repeat dose parallel group study of rhPTH(1-31)NH₂, or placebo tablets, compared to open label Forsteo® (teriparatide) in 97 postmenopausal women with osteoporosis. The primary endpoint was to characterize percent change from baseline in BMD at lumbar spine (LS) after 24 weeks of once daily oral treatment of PTH(1-31)NH₂. Secondary endpoints included the measurement of bone markers, and measuring the exposure of oral PTH(1-31)NH₂ and teriparatide at the first and last dose. Results and Conclusions: The trial met the primary endpoint with an increase of 2.2% in LS BMD with PTH(1-31)NH₂ compared to baseline (p=0.004). Placebo had a -0.17% decrease (p=NS) and teriparatide increased LS BMD by 5.1% (p<0.001). After an initial lag, the rate of increase in BMD for oral PTH between week 12 and week 24 was comparable to teriparatide. There were statistically significant increases from baseline in the total hip BMD for PTH(1-31)NH₂ and teriparatide, with no significant differences between these two groups. In the PTH(1-31)NH₂ group, there was a minimal increase of 12.7% (p=NS) in CTx-1, a marker of bone resorption compared to a significant increase of 124.6% in the teriparatide group at week 24. Increase in the bone formation marker PINP was fairly modest in the PTH(1-31)NH₂ group, however, osteocalcin was increased 23.3% (p=0.015) compared to baseline. This is in contrast to 4.9% (p=0.87) in placebo and 172% (p<0.0001) in the teriparatide group at week 24. No clinically significant hypercalcemic events or elevated urine calcium were seen in the oral PTH(1-31)NH₂ arm. The most common adverse event in the oral PTH and placebo arms was GI pain or distress, and these events were mostly mild or moderate. The efficacy data and safety profile seen in this study demonstrate that this orally delivered PTH(1-31)NH₂ analog warrants evaluation in further late stage clinical studies.

Absence of the Anabolic Window Characterizes Premenopausal Women with Idiopathic Osteoporosis Who Do Not Respond to Teriparatide. Adi Cohen^{*1}, Polly Young², Emily Stein³, David Dempster², Hua Zhou⁴, Robert Recker⁵, Joan Lappe⁵, Chiyuan Zhang², Donald McMahon³, Serge Cremers², Alexander Zwahlen⁶, Ralph Müller⁶, Elizabeth Shane³.
¹Columbia University Medical Center, USA, ²Columbia University, USA, ³Columbia University College of Physicians & Surgeons, USA, ⁴Helen Hayes Hospital, USA, ⁵Creighton University Osteoporosis Research Center, USA, ⁶ETH Zurich, Switzerland

Idiopathic osteoporosis (IOP) in premenopausal women is characterized by cortical and trabecular microarchitectural deterioration and heterogeneous remodeling. We hypothesized that the osteoanabolic agent, teriparatide (TPTD), would improve BMD in IOP. We enrolled 21 premenopausal women with IOP (17 with fractures, age 39±6 yrs) in an open-label, 24-month pilot study of TPTD 20 mcg daily. We measured areal BMD by DXA, bone turnover markers (BTMs), and transiliac biopsy parameters. On average, there were substantial and significant (all p<0.05) 24M increases in areal BMD (±SD) at the spine (LS; 12.2±8.3%), total hip (6.4±5.6%) and femoral neck (FN; 7.8±3.4%). However, four women did not respond to TPTD (Fig 1; NonRES) defined as 12M change in BMD below least significant change at all sites). At baseline, NonRES and Responders (RES) were similar in terms of age, BMI, BMD, calciotropic and gonadal hormones, and iliac crest bone volume fraction (BV/TV). However, bone remodeling activity was lower in NonRES than RES, as evidenced by lower serum C-telopeptide (CTX; 201±160 vs 431±170 pg/mL;p=0.001), osteocalcin (OC; 12.0±1.5 vs 19.5±8.5 ng/mL;p=0.003), N-terminal propeptides of procollagen type 1 (PINP; 32±13 vs 46±17;p=0.1) and iliac crest bone formation rate (BFR/BS; 0.002±0.001 vs 0.011±0.006 mm²/mm/yr;p<0.0001). After TPTD initiation, PINP increased in RES (Fig 2A) by 1M, peaked at 180% above baseline by 6M and returned to baseline by 24M. In NonRES (Fig 2B), the PINP peak was blunted (108% above baseline) and delayed (12M). CTX rose comparably in RES (Fig 2A) and NonRES (Fig 2B) but peaked earlier in RES (6M vs 12M). In all subjects, 1M change in BTMs significantly predicted percent change in LS BMD at 12M (OC: r=0.55,p=0.02; PINP: r=0.50,p=0.04; CTX: r=0.46,p=0.046) and 24M (OC: 0.58,p=0.02; PINP: r=0.52,p=0.046) but not changes in hip BMD or BV/TV.

In summary, most premenopausal women with IOP responded to TPTD with marked increases in BMD. Those with attenuated and delayed responses to TPTD had low bone turnover at baseline and no evidence of an anabolic window, the early rise in formation markers that usually characterizes TPTD therapy. Early changes in bone formation markers predict response to TPTD in premenopausal women with IOP and may detect premenopausal women with IOP who will not experience substantial improvements in BMD in response to TPTD.

Vitamin D Activation of Functionally Distinct Regulatory MicroRNAs in Primary Human Osteoblasts. Thomas Lisse^{*1}, Rene Chun², Sandra Rieger³, John Adams⁴, Martin Hewison⁴.
¹Massachusetts General Hospital, USA, ²UCLA/Orthopedic Hospital Research Center, USA, ³Mount Desert Island Biological Laboratory, Institute for Regenerative Medicine, USA, ⁴University of California, Los Angeles, USA

When bound to the nuclear vitamin D receptor (VDR), the active form of vitamin D, 1,25-dihydroxyvitamin D (1,25(OH)₂D) is a potent regulator of transcription in bone-forming osteoblasts. Less clear is the impact of 1,25(OH)₂D on post-transcriptional events in osteoblasts, such as the generation and action of microRNAs (miRNAs). Microarray analysis using replicate (n = 3) primary cultures of human osteoblasts (HOB) identified 5 human miRNAs (either registered [www.sanger.ac.uk/Software/Rfam/mirna] or proprietary) that were differentially regulated following treatment with 1,25(OH)₂D (10 nM, 6 hrs). Of these two non-proprietary miRNAs, miR-637 and miR-1228, were significantly increased following treatment with 1,25(OH)₂D. RT-PCR analyses showed that the host gene for miR-1228, low density lipoprotein receptor-related protein 1 (LRP1), was co-induced with miR-1228 in a dose-dependent fashion following treatment with 1,25(OH)₂D (0.1 – 10 nM, 6hrs). By contrast, the endogenous host gene for miR-637, death-associated protein kinase 3 (DAPK3), was transcriptionally repressed following treatment with 1,25(OH)₂D, indicating host-gene-independent regulation of miR-637. Analysis of two potential targets for miR-637 and miR-1228 in HOB, type 4 collagen (COL4A1) and bone matrix protein-2-inducible kinase (BMP2K), respectively, showed that 1,25(OH)₂D mediates suppression of these targets via distinct mechanisms. In the case of miR-637, suppression of COL4A1 appears to occur via decreased levels of COL4A1 mRNA. By contrast, miR-1228 showed no significant effect on BMP2K mRNA expression but appears to act instead by inhibition of BMP2K protein translation. In mature HOBs, siRNA inactivation of miR-1228 alone was sufficient to abrogate 1,25(OH)₂D-mediated down regulation of BMP2K protein expression. This event was associated with suppression of pro-differentiation responses to 1,25(OH)₂D in HOB, as represented by simultaneous decreases in osteocalcin and alkaline phosphatase expression. These data show for the first time that the effects of 1,25(OH)₂D on human bone cells are not restricted to classical VDR-mediated transcriptional responses but also involve miRNA-directed post-transcriptional mechanisms for regulation of gene expression.

Transgenic Expression of the Vitamin D Receptor (VDR) Restricted to the Ileum, Cecum and Colon of VDR Knockout Mice Rescues VDR Dependent Rickets. Puneet Dhawan^{*1}, Connie Hasio¹, Ghassan Yehia¹, Liesbet Lieben², Geert Carmeliet³, Sylvia Christakos⁴.
¹UMDNJ-New Jersey Medical School, USA, ²KU Leuven, Belgium, ³Katholieke Universiteit Leuven, Belgium, ⁴University of Medicine & Dentistry & New Jersey - New Jersey Medical School, USA

The intestine plays the major role in 1,25(OH)₂D₃ action on calcium homeostasis. Yet the mechanisms involved remain incompletely understood. The established model of 1,25(OH)₂D₃ regulated intestinal calcium absorption postulates a critical role for

the duodenum. However it is the distal intestine where 70-80% of the ingested calcium is absorbed. In order to test directly the role of 1,25(OH)₂D₃ and VDR in the distal intestine, we generated mice expressing VDR exclusively in the ileum, cecum and colon by breeding VDR knockout (KO) mice with transgenic (TG) mice expressing hVDR under the control of the 9.5kb *cdx2* promoter. In adult mice from 3 independent KO/TG lines, expression of VDR was restricted to ileum, cecum and colon (highest expression was in cecum and colon). Mice from one TG line (TG [3]) showed low VDR expression in distal intestine (<30% of the levels observed in TG [1] and TG [2]). In the KO/TG mice hVDR was not expressed in duodenum, jejunum, kidney or other tissues. KO/TG mice from all 3 TG lines and VDR KO mice had alopecia. Growth arrest and hypocalcemia of the VDR KO mice were prevented in mice from KO/TG lines 1 and 2. 1,25(OH)₂D₃ treatment significantly increased serum calcium in mice from all 3 TG lines and in wild type (WT) mice (*p* < 0.05 compared to vehicle) but not in VDR KO mice. Renal calbindin-D_{9k} was similarly reduced 5-6 fold in VDR KO mice and in all 3 KO/TG lines (compared to WT). 1,25(OH)₂D₃ treatment had no effect on renal calbindin-D_{9k} expression in the KO or KO/TG mice. Although calbindin-D_{9k} was undetectable in the distal intestine of the VDR KO mice, calbindin-D_{9k} was expressed in the KO/TG [1] and [2] mice at levels equivalent to WT (in ileum and colon) or was 1.5 fold upregulated compared to WT (in cecum). In addition, μ CT analysis revealed that the expression of high levels of hVDR in the distal intestine (KO/TG mice [1] and [2]) rescued the bone defects associated with systemic VDR deficiency, including the rachitic growth plate abnormalities and the abnormal increase of bone mass in the primary spongiosa. Also, the decreased cortical thickness and increased cortical porosity were completely prevented. TG line 3 showed rickets, yet less severely compared to VDR KO mice. These findings provide evidence for the first time using VDR transgenic mice for the importance of the distal intestinal segments in vitamin D mediated calcium and bone homeostasis.

Blocking Osteogenic Differentiation and Mineralization: a Struggle between VDR and RUNX2 in the Mouse Mesenchymal Stem Cells. Mark Meyer^{*1}, Chang-Hun Lee², Nancy Benkuskay¹, Buer Sen³, Janet Rubin⁴, J. Pike¹. ¹University of Wisconsin-Madison, USA, ²University of Wisconsin at Madison, USA, ³University of North Carolina At Chapel Hill, USA, ⁴University of North Carolina, Chapel Hill, School of Medicine, USA

Osteogenic differentiation is believed to be primarily controlled by a master regulating transcription factor, RUNX2, and mice deficient of RUNX2 have severe skeletal defects. In the mouse, 1,25(OH)₂D₃ activates the VDR to reduce levels of RUNX2 and this in turn reduces the levels of several important osteogenic genes, blocking differentiation as well as mineralization in osteoblasts and their precursors, the multi-potential mesenchymal stem cells (MSCs). We studied this mechanism through ChIP-seq and RNA-seq of MSC cells (and MC3T3 cells) over 2 weeks of differentiation. Overlap of epigenetic markers implicated in activated enhancers, promoters and elongation (H4K5ac, H3K9ac, H3K4me1, H3K4me3, H3K36me3) revealed a modest shift in chromatin occupancy between the activated genes in the differentiation states, which may indicate a certain level of plasticity in cells with osteogenic potential. Therefore, we sought to understand the coordinated genome-wide efforts of VDR/RXR and RUNX2 (and C/EBP β) during this transition. VDR/RXR and RUNX2 overlapped significantly at 36% of sites, many of which are located within loci harboring osteogenic gene markers. Interestingly, C/EBP β , which may facilitate lineage determination, was found to be overlapped with VDR/RXR and RUNX2 binding, 52% and 45%, respectively. 1,25(OH)₂D₃ severely inhibited this differentiation and down-regulated key genes such as *Runx2* and *Osterix* (*Sp7*). We found VDR/RXR, RUNX2 and C/EBP β enhancer regions at +104kb in *Runx2* and -11kb in *Sp7* and a RUNX2 specific enhancer at +6kb within *Sp7*. siRNA knockdown of VDR reversed the 1,25(OH)₂D₃-mediated repression of these cloned enhancers and the *Runx2* mRNA. We found 1,25(OH)₂D₃ regulation of genes that modulate mineralization through the balance of pyrophosphate such as *Enpp1*, *Enpp3* and *Ank*. These genes contained intronic or intergenic distal VDR/RXR, RUNX2 and C/EBP β binding that demonstrated transcriptional response to 1,25(OH)₂D₃ after subsequent cloning and mutagenesis. Most interestingly, the regions responsive to 1,25(OH)₂D₃ in *Enpp1/3* and *Ank* were not conserved or present in our human osteoblast model lines (hOB and MG63) which may contribute to the inability of 1,25(OH)₂D₃ to inhibit *in vitro* mineralization in these cells. Overall, our studies help to define the complex arrangement of RUNX2 and VDR/RXR during the process of osteogenic differentiation and help clarify part of the mechanism by which mineralization can be blocked.

Glucocorticoid-Induced Leucine Zipper (GILZ): An Anabolic Effect Mediator of Glucocorticoids. Guodong Pan^{*1}, Kehong Ding¹, Nianlan Yang¹, Mark Hamrick¹, Carlos Isaales², Xing-Ming Shi¹. ¹Georgia Health Sciences University, USA, ²Medical College of Georgia, USA

Glucocorticoids (GCs) have both anabolic and catabolic effects on bone. However, the clinical outcome of GC therapy is a net loss of bone. Recent studies in mice have shown that the GC receptor (GR) mediates the catabolic effect and is responsible for GC-induced bone loss. However, no anabolic GC effect mediator has been identified to date. We showed previously that overexpression of glucocorticoid-induced leucine zipper (GILZ), a GC-inducible anti-inflammatory mediator, significantly enhances bone marrow mesenchymal stem cell (MSC) osteogenic differentiation *in vitro*. But the *in vivo* function of GILZ in bone is unknown. In this study we aimed to test the hypothesis that GILZ is an endogenous GC anabolic effect mediator and that bone-specific overexpression of GILZ increases bone formation in mice. We generated GILZ transgenic mice (GILZ^{Tg}) in which the expression of GILZ is under the control of a 3.6Kb type I collagen promoter. Bone-specific GILZ transgene expression was confirmed at the mRNA and protein expression levels by RT-PCR and Western blot, respectively. Bone analyses were performed using femurs of 3-month-old mice with standard bone parameter measurements. Results show that compared with their wild-type (Wt.) littermate controls, both DXA and μ CT results showed a significant bone mineral density (BMD) increase in GILZ^{Tg} mice (Tg vs. Wt: 9%, *p* < 0.05). Histology and histomorphology analyses show that the bone volume (BV/TV) and trabecular thickness (Tb.Th.) were increased significantly in GILZ^{Tg} mice (Tg vs. Wt: BV/TV 20% and Tb.Th 39% increase, respectively, *p* < 0.05). Most strikingly, the bone mineral apposition rate (MAR) was doubled in GILZ^{Tg} mice compared with the control mice (*p* < 0.01). In conclusion, our data have shown that bone-specific overexpression of GILZ can significantly increase bone formation *in vivo*, demonstrating that GILZ is an endogenous GC anabolic effect mediator and a very prominent bone anabolic drug candidate.

Osteoblast-specific Estrogen Receptor Alpha Knockout Mice Have Compromised Bone Mass and Architecture. Katherine Melville^{*1}, Timothy Bruhn¹, Sohaib Khan², John Schimenti¹, F. Patrick Ross³, Russell Main⁴, Marjolein Van Der Meulen¹. ¹Cornell University, USA, ²University of Cincinnati, USA, ³Hospital for Special Surgery, USA, ⁴Purdue University, USA

Estrogen signaling through estrogen receptor alpha (ER α) is critical to maintenance of bone mass and normal bone growth. Lack of ER α in global ER α KO female mice increases cortical and cancellous BMD in the tibia, but is accompanied by systemic increases in body mass and serum estrogen (E2) levels and decreases in uterine mass and IGF-I levels. We hypothesized that the phenotype of an osteoblast-specific ER α knockout mouse would differ from the global ER α KO mouse due to lack of systemic effects. Therefore, we generated an osteoblast-specific ER α knockout mouse (cKO) to investigate the role of ER α in osteoblasts and osteocytes in determining body and bone phenotype, while limiting the confounding hormonal systemic effects present in the global ER α KO.

Mice with a floxed ER α gene (*fl/fl*; +/+) and mice with an osteocalcin-promoter cre recombinase (+/+; oc-cre/+) were bred to generate female osteoblast-specific ER α conditional knockout mice (cKO, *fl/fl*; oc-cre/+) and littermate controls (LC, *fl/fl*; +/+). Skeletal phenotype was characterized at 12 weeks (n=7 cKO, n=6 LC) and 18 weeks (n=10/genotype). Body, ovary, and uterus mass were measured. Serum was assayed for E2, testosterone (T), IGF-I, TRACP5b, and osteocalcin (OC) levels. Cancellous and cortical regions in the tibiae and L5 vertebrae were analyzed by microcomputed tomography. Tibiae were stained for ER α immunohistochemistry. Vertebral stiffness and strength were measured in compression to failure.

ER α staining was absent from osteoblasts in cKO. In the proximal tibia, cancellous bone mass was decreased (-36%) and tissue mineral density (+5%) and trabecular separation (+54%) increased in cKO compared to LC at 12w and 18w. L5 cancellous bone volume fraction (-43%) was decreased due to decreased trabecular thickness (-11%) and increased trabecular separation (+32%) in cKO vs LC at 12w. Tibial cortical area (-7%) and tissue mineral density (-2%) were decreased in cKO vs LC at both ages. L5 strength was reduced in cKO vs LC at 12w (-11%). Body, ovary, and uterus mass, and serum E2, T, IGF-I, and OC serum levels were similar between genotypes. In contrast to the global ER α KO, cancellous and cortical mass were decreased in cKO vs LC, which likely reflects the lack of altered hormone levels in the cKO that are present in the global ER α KO.

Bivariate Genome-wide Association Analysis Identifies Novel Candidate Genes for Cross-sectional Bone Geometry and Appendicular Lean Mass: The GEFOS and CHARGE Consortia. Yi-Hsiang Hsu¹, Xing Chen², Karol Estrada³, Serkalem Demissie⁴, Tamara Harris⁵, Thomas Beck⁶, Alireza Moayyeri⁷, Candace Kammerer⁸, Carolina Medina-Gomez⁹, Vilmundur Gudnason¹⁰, Tim Spector⁷, Maria Zillikens¹¹, L. Adrienne Cupples⁴, Andre Uitterlinden¹², Fernando Rivadeneira³, Douglas Kiel¹³, David Karasik^{*13}. ¹Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ²Harvard University, USA, ³Erasmus University Medical Center, The Netherlands, ⁴Boston Uni Sch Pub Health, USA, ⁵Intramural Research Program, National Institute on Aging, USA, ⁶Quantum Medical Metrics, LLC, USA, ⁷King's College London, United Kingdom, ⁸University of Pittsburgh Graduate School of Public Health, USA, ⁹Erasmus Medical Center, The Netherlands, ¹⁰Icelandic Heart Association Research Institute, Iceland, ¹¹Erasmus Mc, The Netherlands, ¹²Rm Ee 575, Genetic Laboratory, The Netherlands, ¹³Hebrew SeniorLife, USA

Hip geometry and lean (muscle) mass have significant genetic correlation, indicating that genetic determinants may be shared by both bone and muscle. To identify genes with pleiotropic effects on bone and muscle traits, we performed a bivariate genome-wide association analysis (GWAS) using data from two consortia.

The Hip Structural Analysis program was used to measure the femoral neck length (FNL), neck-shaft angle (NSA), narrowest width of the femoral neck (NNW) and calculate its section modulus (NNZ), from DXA scans of GEFOS consortium participants (17,528 men and women from 10 mostly Caucasian studies). Appendicular lean mass (aLM), combining upper and lower extremities, was measured in participants of the CHARGE Musculoskeletal Consortium (22,360 Caucasian men and women from 15 cohorts).

Univariate GWAS meta-analyses of ~2.5 million autosomal SNPs (imputed based on CEU HapMap phase II panel) were first performed for hip geometry and aLM, separately. An additive genetic effect model was applied with adjustment for age, sex, height, ancestral genetic background, as well as age² and fat mass (for aLM only). We then used the univariate GWAS results to perform a bivariate analysis for each pair of HSA-aLM traits. We used the linear combination of test statistics approach with estimated variance-covariance structure, to take into account the phenotypical correlation between HSA and aLM. We considered SNPs as potentially pleiotropic if (a) they achieved genome-wide significance threshold (bivariate p-value $\leq 5 \times 10^{-8}$) and (b) the bivariate p-value was an order of magnitude lower than both univariate p-values.

For a combination NSA-aLM, there were no SNPs with genome-wide significant bivariate signal; for other pairs of phenotypes, potentially pleiotropic SNPs were mapped to regions in/near *SORCS1* (on 10q23-q25) and *C6orf223* (6p21.2) for FNL-aLM; *PPP6R3/LRP5* (11q13) for NNZ-aLM, and *ADAMTSL3* (15q25.2) for NNW-aLM pair. The potential pleiotropic genetic variants had associations in the same directions for both HSA and aLM. Notably, the same variant in *PPP6R3/LRP5* is associated at genome significant level in a bivariate GWAS of total body lean mass and BMD in children (ASBMR 2012). *LRP5*, a member of the Wnt signaling pathway, is an established locus associated with BMD and fracture risk; in contrast the role in musculoskeletal biology is less clear for *PPP6R3* (ubiquitously expressed in bone and muscle), *SORCS1*, belonging to a neuropeptide signaling pathway, and for *ADAMTSL3*, previously associated with adult height but whose *in-vivo* function is unknown.

In conclusion, using the bivariate GWAS approach, we discovered loci potentially regulating the hip geometry and muscle mass. Additional replication in independent cohorts and functional follow-up in relevant musculoskeletal tissues is needed to confirm the pleiotropic effects of these gene variants.

PTHrP Regulates the Modeling of Enteses During Linear Growth. Meina Wang^{*1}, Joshua VanHouten², Randy Johnson³, Arthur Broadus². ¹Yale University, USA, ²Yale University School of Medicine, USA, ³M.D. Anderson Cancer Center, USA

PTHrP is widely expressed in the fibrous periosteum (PO) and in tendon and ligament insertion sites (entheses, ENTs). In most such sites, PTHrP is mechanically-induced and is temporally associated with subjacent osteoclast (OC) and/or osteoblast (OB) populations. We tested the working hypothesis that PTHrP might regulate the modeling of cortical bone and/or ENTs using *Scx-Cre*-driven ENT-specific *PTHrP* cKO mice. Scleraxis (*Scx*) is a transcription factor that is widely expressed in the connective tissue of bone.

The *PTHrP* cKO mice display a dozen or so surface abnormalities that reflect failed development and/or modeling of ENT or PO sites. Here, we will focus on three ENTs that represent variations on a theme of load-driven PTHrP induction of ENT OCs. First, the medial collateral ligament (MCL) insertion into the proximal tibial metaphysis must migrate to accommodate linear growth, a process that is driven by OCs at the migrating edge. This process fails in the cKO mouse and is replaced by a

Endocrine Actions of Parathyroid Cyp27b1 in The Ca²⁺ and Skeletal Homeostasis: Studies of Parathyroid-Specific Knockout Mice. Zhiqiang Cheng, Chia-Ling Tu, Alfred Li, Christian Santa-Maria, Hanson Ho, Michael You, Nathan Liang, Tsui-Hua Chen, Rachel Roston, Dolores Shoback, Daniel Bikle, Wenhan Chang^{*}. Endocrine Unit, VA Medical Center, University of California, San Francisco, USA

The renal 25-hydroxyvitamin D₃ 1-alpha-hydroxylase (Cyp27b1) is thought to be the major enzyme producing 1,25 (OH)₂ vitamin D₃ (1,25D), which critically modulates mineral and skeletal homeostasis. The role of extra-renal Cyp27b1 is, however, unclear. We demonstrated previously that Cyp27b1 and vitamin D receptor (VDR) constitute an autocrine/paracrine pathway to suppress PTH secretion by studying parathyroid glands from mice with homozygous Cyp27b1 (PT-Cyp27b1-KO) or VDR (PT-VDR-KO) gene KO targeted to their parathyroid cells (PTCs). In the current study, we used those mice to determine whether parathyroid Cyp27b1 contributes to circulating 1,25D levels and modulates mineral and skeletal homeostasis. Serum 1,25D (s1,25D), Ca²⁺ (sCa), phosphate (sPi), and PTH (sPTH) levels in the PT-Cyp27b1-KO and PT-VDR-KO mice and control littermates (Cont), which carry floxed alleles but no Cre, were compared as were their bone mass and structural parameters by micro-computed tomography (μCT). The specificity of excision of VDR and Cyp27b1 gene in PTCs was confirmed by PCR analyses of genomic DNA and RNA extracted from different tissues. sPTH levels increased modestly by ~80% in PT-VDR-KO mice and profoundly by ~250% in the PT-Cyp27b1-KO mice, compared to Cont mice. While sCa and sPi levels were unchanged in the PT-VDR-KO mice, PT-Cyp27b1-KO mice developed hypocalcemia and hyperphosphatemia, despite markedly elevated sPTH levels. We further found that s1,25D levels in PT-Cyp27b1-KO mice were reduced to ~30% of the level in Cont mice, even though renal Cyp27b1 RNA levels were increased by 2-3 fold (likely due to the elevated sPTH levels) along with a decrease (by ~50%) in renal Cyp24 RNA expression. These results suggest that Cyp27b1 activity in PTCs is a source of s1,25D. We examined the skeletal effects of PTC-specific gene KO on trabecular bone (Tb) parameters in the distal femurs of PT-VDR-KO and PT-Cyp27b1-KO mice. VDR KO in PTCs produced an increased Tb bone volume (BV) over total tissue volume (TV) ratio (Tb.BV/TV) and Tb number (Tb.N). These anabolic effects were, however, not evident in the Cyp27b1 KO mice, suggesting that different calcemic and phosphatemic states affect skeletal actions of PTH. Our data suggest that PTC Cyp27b1 not only exerts autocrine/paracrine actions to modulate PTH secretion but also provides an important source of s1,25D essential either directly or indirectly for maintaining mineral and skeletal homeostasis.

massive traction tuberosity comprising mostly mineralizing fibrochondrocytes (FCs). Second, the teres major (TM) inserts into the proximomedial humerus via a major cord-like tendon at a near-90° angle; this is anchored into a deep OC-driven cortical cave, the strength of this ENT being in the depth of its root system. Here too, OCs fail entirely in the cKO mouse, and a major FC-associated traction tuberosity forms that distorts the entire proximal humerus. Third, the latissimus dorsi (LD) inserts over a lengthy portion of the anteromedial humerus at a gentle (about 10°) angle, and its OC-driven root system resembles a saw-tooth pattern of minimal depth; here strength depends upon breadth and surface rather than depth. This ENT also fails in the cKO mouse but without a traction deformity.

The traction tuberosities are pathological structures that form because of the continued load in the absence of the normal OC modeling that the load should induce. The FCs here originate from both the tendon and cambial ENT layers as an apparent consequence of heavy loading.

These data provide the initial genetic evidence that PTHrP regulates the formation and function of membranous bone cell populations at the surface of long bones. These functions reflect the use of PTHrP as a modeling tool, in this case at three so-called fibrous insertion sites that represent forms frusts of a common strategy, presumably differing from each other as a consequence of differences in biomechanical inputs.

Interactions between Periosteal Cells and Muscle-Derived Blood Vessels are Essential for Bone Autograft Healing. Nick Van Gastel*¹, Maarten Depypere², Karen Moermans¹, Ingrid Stockmans¹, Jan Schrooten³, Frederik Maes², Frank Luyten⁴, Geert Carmeliet⁵. ¹Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, ²Department of Electrical Engineering (ESAT/PSI), KU Leuven, Belgium, ³Department of Metallurgy & Materials Engineering, KU Leuven & Prometheus, Division of Skeletal Tissue Engineering, KU Leuven, Belgium, ⁴University Hospitals KU Leuven, Belgium, ⁵Katholieke Universiteit Leuven, Belgium

Despite major drawbacks, autologous bone transplantation remains the therapy of choice to treat large bone defects. Cell-based bone tissue engineering seems a promising alternative, but one of the key challenges is the timely formation of blood vessels to promote survival of the cells in the implant. To gain more insight in this critical process, we examined how periosteal cells orchestrate blood vessel formation during bone autograft healing.

Using a murine segmental bone defect model, we confirmed the importance of periosteal cells in bone healing by showing that removal of the periosteum reduced the healing of autografts to the level of devitalized allografts. Implantation of autografts derived from GFP-mice further revealed that the donor periosteal cells were the main source of chondrocytes and osteoblasts in the callus. *In vitro* analysis of murine periosteum-derived cells (mPDC) indicated that they may contribute to healing not only by differentiating to osteoblasts and chondrocytes, but also by promoting endothelial cell (EC) proliferation and survival through the production of angiogenic factors such as VEGF. Ectopic co-implantation of mPDC and EC in mice proved that periosteal cells can enhance both angiogenesis and vasculogenesis *in vivo*.

The role of periosteal cells in blood vessel formation during bone repair was further shown by the observation that autografts were surrounded by a significantly higher number of blood vessels compared to allografts. In contrast to the bone-forming cells, the blood vessel network in the autograft callus was derived almost entirely from the host and was at numerous sites connected to the vessels of the adjacent muscle. The importance of the muscle vascular bed was confirmed by insertion of a membrane in between the graft and the muscle, which completely abrogated the periosteal reaction. While an angiogenic response from the host was still observed, the blood vessels could not reach the periosteum, preventing cell proliferation and callus formation.

In conclusion, our results demonstrate that periosteal cells may provide an ideal cell source for bone regeneration, not only because of their strong osteogenic and chondrogenic potential, but also by their pro-angiogenic features. In addition, we show that during bone healing the survival and function of periosteal cells drastically relies on timely interactions with blood vessels from the nearby muscle, which emphasizes the importance of the local environment.

Muscle Atrophy Enhances Bone Anabolism. Ted Gross*¹, Brandon Ausk¹, Steven Bain¹, Leah Downey¹, Edith Gardner¹, Ronald Kwon¹, Leah Worton², Sundar Srinivasan¹. ¹University of Washington, USA, ²The University of Washington, USA

Simultaneous atrophy or hypertrophy of muscle and bone is observed throughout life. In direct contrast to this relation, we recently observed that superimposing transient muscle paralysis upon external tibia loading elevated periosteal bone formation 2-fold compared to what the loading regimen induced without muscle paralysis. Following on this unexpected result, we designed an *in vivo* experiment to test the hypothesis that the enhanced bone anabolism associated with combined

muscle paralysis and mechanical loading requires spatial proximity between the atrophied muscle and mechanically stimulated bone. Adult female C57 mice (16 wk) each underwent a 3d/wk, 3wk external cantilever bending regimen of the right tibia (1600 µε normal strain, 100 cycles/loading bout). Mice randomly received a 0 saline injection in the right calf (R. Calf S, n=6), or BTxA (2U/100g) in the right calf (R. Calf B, n=6), left calf (L. Calf B, n=5), or the right triceps (R. Triceps B, n=5). All mice received calcein labels (d 10, 19) with p.MS, p.MAR, and p.BFR determined for the periosteal surface of left and right tibiae. No differences were noted in the contralateral left tibiae across groups. The R. Calf S tibiae demonstrated significant increases in p.MS (p<0.05), p.MAR (p<0.01), and p.BFR (<0.01) vs contralateral tibiae. Likewise, each BTxA group demonstrated significant increases in p.MS, p.MAR, and p.BFR vs contralateral tibiae (all p<0.01). p.BFR in each of the BTxA groups was significantly elevated vs the Saline group (p<0.05) but did not differ with the site of muscle paralysis. The enhanced anabolism was achieved almost entirely via enhanced p.MAR, as p.MS did not differ across groups. The lack of response in the contralateral tibiae indicate that muscle paralysis alone is not sufficient to activate a quiescent periosteum. The surprisingly equivalent anabolic benefit of L. Calf and R. Triceps muscle paralysis vs R. Calf paralysis (directly adjacent to the externally loaded tibia) demonstrates that spatial adjacency is not required as hypothesized and that reduced mechanical loading of the right tibia (which did not occur in L. Calf and R. Triceps paralysis) is not a primary underlying influence for the enhanced response. In summary, these data suggest that transient muscle paralysis results in activation of signaling pathways that, via systemic distribution, are capable of enhancing osteoblast function.

Trabecular Mineralization and Muscle Fiber Growth in Response to Dynamic Fluid Flow Stimulation. Minyi Hu*¹, Robbin Yeh¹, Morgan Teeratananon¹, Yi-Xian Qin². ¹Stony Brook University, USA, ²State University of New York at Stony Brook, USA

Intramedullary pressure (ImP)-driven bone fluid flow acts as a mediator between an external load and bone cells, which then regulate bone remodeling. It is hypothesized that muscle compressions may increase vessel pressure gradient that can directly increase ImP. To establish the translational potential of ImP-induced fluid flow stimuli in bone, a dynamic hydraulic stimulation (DHS) approach has been developed to evaluate trabecular mineralization and muscle fiber growth in response to non-invasive, direct muscle compressions in a disuse osteopenia rat model. Sprague-Dawley virgin rats were randomly assigned to 5 groups: baseline control (n=15), age-matched control (n=12), hindlimb suspended (HLS, n=10), HLS+static pressure (n=10), HLS+DHS (n=14). Stimulation were given to right tibia by an inflatable cuff with 2Hz, 30mmHg static+30mmHg dynamic pressures, for 10min on-5 min off-10min on, 5d/wk for 4 wks. Two injections of calcein (10mg/kg) were given to the animals in two weeks apart during the study. The right tibiae, soleus and gastrocnemius were obtained at the animal sacrifice. The proximal tibiae were embedded with PMMA. Longitudinal sections were made to 5µm. Histomorphometric measurements were done by tracing calcein labels in the trabecular bone in the metaphyseal region using the Osteomeasure software. Muscle samples were snap-frozen, and cross-sections were made to 8µm followed by H&E staining. Muscle fiber areas were determined by the Image J software. The histomorphometry data indicated that HLS significantly reduced BV/TV, MS/BS, MAR, BFR/BS and BFR/BV compared to age-matched controls (Table 1). HLS+static pressure alone did not show a significant difference compared to HLS, except for MS/BS. However, HLS+DHS rats showed significant increases in BV/TV and all other bone formation indices, except for MAR. HLS+DHS had increases compared to the HLS group by 34% in BV/TV, 121% in MS/BS, 190% in BFR/BS, and 146% in BFR/BV. On the other hand, stimulation-induced improvements on muscle fiber growth were not shown (Figure 1). DHS did not seem to rescue muscle atrophy due to HLS. While dynamic fluid flow stimulation by DHS significantly mitigate bone loss in disuse, the current effective DHS stimuli may be suitable for bone cell responses but not for muscle fiber alterations.

| | BV/TV (Hise, %) | MS/BS (%) | MAR (mm/day) | BFR/BS (mm ³ /mm ² /day) | BFR/BV (mm ³ /mm ³ /day) |
|-------------|-----------------|-------------|--------------|--|--|
| Age-matched | 46.61±7.32 | 10.75±2.24 | 0.73±0.15 | 0.04±0.03 | 0.23±0.07 |
| HLS | 31.22±9.91* | 4.12±0.64** | 0.53±0.16* | 0.02±0.01** | 0.07±0.03** |
| HLS+Static | 40.99±18.04 | 6.53±1.18** | 0.59±0.19 | 0.04±0.01** | 0.12±0.03** |

Ryanodine receptor 1 Remodeling in Cancer Associated Muscle Dysfunction. David Waning^{*1}, Khalid Mohammad², Daniel Andersson³, Sutha John⁴, Patricia Juarez-Camacho⁴, Steven Reiken³, Andrew Marks⁵, Theresa Guise². ¹Indiana University School of Medicine, USA, ²Indiana University, USA, ³Department of Physiology & Cellular Biophysics, College of Physicians & Surgeons of Columbia University, USA, ⁴Indiana University Simon Cancer Center & Indiana University School of Medicine, USA, ⁵Columbia University, USA

Muscle weakness is common in advanced cancers and is a cause of significant cancer-related morbidity and mortality. The mechanisms of cancer-associated muscle dysfunction are unknown and no effective treatment exists. Ryanodine receptor 1 (RyR1) is the skeletal muscle sarcoplasmic reticulum calcium release channel required for excitation-contraction coupling. The RyR1 channel is a macromolecular complex that is comprised of 4 RyR1 monomers and regulatory proteins that modulate channel function. RyR1 undergoes remodeling in disease states, such as muscular dystrophy and ageing, characterized by oxidation and nitrosylation of the channel and loss of the stabilizing subunit, calstabin1 resulting in leaky channels. We hypothesized that muscle weakness in cancer could be due to remodeling of RyR1 resulting in intracellular calcium leak that causes impaired muscle function.

We used a mouse model of breast cancer metastases to bone during which mice develop significant cachexia. Five-week-old female nude mice were inoculated with MDA-MB-231 breast cancer cells via intra-cardiac inoculation and compared to non-tumor bearing controls. Mice developed osteolytic lesions 12 days after inoculation. Tumor bearing mice lost significant weight by 4 weeks compared to controls (20.5±0.6 vs. 23.2±0.4; p<0.0002). This was associated with a significant reduction in total body tissue, lean mass and fat in tumor bearing mice, as assessed by DXA (P<0.01), with no difference in total body %lean mass or %fat. Muscle specific force production of the extensor digitorum longus (EDL) muscle was significantly decreased in tumor bearing mice compared to controls (p<0.001). The reduction in muscle force correlated with larger osteolytic lesions (p<0.05). Immunoprecipitation and immunoblotting of RyR1 from EDL of tumor bearing mice showed that RyR1 were oxidized, nitrosylated and depleted of calstabin1, consistent with leaky channels. Transmission electron microscopy showed dysmorphic mitochondria in tumor bearing mice.

Our data show that MDA-MB-231 bone metastases are accompanied by loss of muscle function and remodeling of RyR1 channel complex resulting in leaky channels. Similar remodeling of RyR1 has been shown to cause muscle weakness in muscular dystrophies and sarcopenia. Targeted therapy against leaky RyR1 channels improves muscle function and exercise capacity in murine models of muscular dystrophy and sarcopenia and may be an effective therapy for cancer-associated muscle weakness.

Injury-Activated TGFβ Controls Mobilization of MSCs for Tissue Remodeling. CHANGJUN LI^{*1}, GEHUA ZHEN¹, WENYING HE¹, KAI JIAO¹, YIU-FAI CHEN², XIAOFENG JIA¹, Bing Yu³, Xu Cao⁴, Mei Wan¹. ¹Johns Hopkins University School of Medicine, USA, ²University of Alabama at Birmingham, USA, ³Johns Hopkins School of Medicine, USA, ⁴Johns Hopkins University, USA

Upon secretion, TGFβ is maintained in a sequestered state in extracellular matrix as a latent form, which is considered as a molecular sensor that releases active TGFβ in response to mechanical stress, wound repair and tissue injury. The biological implication of the temporal discontinuity of TGFβ storage in the matrix and its activation is obscure. Here, using rat and mouse models in which latent TGFβ is activated in vascular matrix in response to injury of arteries, we show that active TGFβ1 controls the mobilization and recruitment of MSCs for tissue remodeling. Active TGFβ1 was elevated in both vasculature and peripheral blood at 8 hrs after injury in both models, and the elevation sustained for 2 wks. At the same time points, Sca1⁺CD29⁺CD11b⁺CD45⁺ MSCs, in which 91% are nestin⁺ cells, were mobilized to peripheral blood and recruited to the remodeling arteries. Inhibitor of TGFβ type I receptor (TβRI) blocked the mobilization and recruitment of MSCs to the remodeling arteries. Notably, intravenously injection of rhTGFβ1 in uninjured mice rapidly mobilized MSCs into circulating blood. To confirm the MSCs feature of the mobilized cells, biotinylated rhTGFβ1 was injected i.v. and its binding to bone marrow cells was analyzed. Biotinylated rhTGFβ1 binds to bone marrow nestin⁺Sca1⁺CD29⁺CD11b⁺ cells, which have multilineage differentiation capacity and can differentiate into myofibroblast-like cells. To further investigate how injury-induced activation of TGFβ1 in vascular matrix stimulates migration of MSCs, we developed an injured aorta-conditioned medium (Aorta-CM)-based cell migration assay, in which MSCs were placed in the upper chamber and the Aorta-CM was placed in the lower chamber of a transwell. Aorta-CM prepared from *ex vivo* injured aorta significantly enhanced cell migration, and the neutralizing antibody of TGFβ1 blocked the migration. Consistently, active TGFβ1 level was significantly elevated in the injured Aorta-CM, and addition of inhibitors of either TβRI or MCP-1 in the CM blocked the migration, indicating that active TGFβ1 released from the injured vessels is a primary factor in induction of the migration of MSCs, and cascade expression of MCP1 stimulated by TGFβ amplifies the signal for migration. Collectively, the results suggest that TGFβ1

is an injury-activated messenger essential for the recruitment of MSCs to participate in vascular remodeling.

Hyperactive Transforming Growth Factor-beta1 Signaling Potentiates Fracture Non-union in Neurofibromatosis Type 1. Steven Rhodes^{*1}, Yongzheng He¹, Xiaohua Wu², Ping Zhang³, Shi Chen¹, Chang Jiang¹, Hiroki Yokota⁴, Xianlin Yang¹, Xianghong Peng¹, Sreemala Murthy¹, Khalid Mohammad¹, Theresa Guise¹, Feng-Chun Yang¹. ¹Indiana University, USA, ²Indiana University School of Medicine, USA, ³Indiana University – Purdue University Indianapolis, USA, ⁴Indiana University Purdue University Indianapolis, USA

Tibial pseudarthrosis, in up to 90% of cases, is associated with Neurofibromatosis type 1 (NF1). Tibial pseudarthrosis is a rare yet debilitating pediatric orthopedic condition, progressing to spontaneous fracture and subsequent fibrous nonunion. Treatment of tibial pseudarthrosis has been notoriously difficult, ultimately requiring amputation of the affected limb in many cases. Still, the molecular etiology of these pathological defects remains unclear.

Transforming growth factor-beta1 (TGF-β1) is known to be a critical factor regulating the spatiotemporal coupling of bone resorption and bone formation. Intriguingly, haploinsufficiency of *Nf1* in myeloid cells has been shown to result in hypersecretion of TGF-β1 *in vitro*. Given the fact that disruption of TGF-β signaling gradients is associated with a spectrum of osseous defects in both patients and mouse models, we sought to investigate the impact of TGF-β1 signaling in NF1 associated skeletal manifestations.

Here, we show that compared to WT mice, TGF-β1 serum levels are 5.7 fold higher in *Nf1*^{flx/flx}; *Col2.3Cre* mice, a murine model that closely recapitulates multiple NF1 skeletal defects including, short stature, osteoporosis, and mechanically induced nonunion fracture. We further found that *Nf1* deficient osteoblasts, the principal source of TGF-β1 in bone, overexpressed TGF-β1 in a gene dosage dependent fashion at both the mRNA and protein levels. Moreover, *Nf1* deficient osteoclasts and osteoblasts were hyperresponsive to TGF-β1 in tissue culture, preferentially augmenting *Nf1*^{+/-} osteoclast bone resorptive activity, while inhibiting *Nf1*^{-/-} osteoblast differentiation. These cellular phenotypes were accompanied by biochemical hyperactivation of the TGF-β1-Smad pathway. As an *in vivo* proof of concept, we found that administration of the pharmacologic TGF-β type I receptor inhibitor, SD-208, can rescue both osteoporotic and non-union fracture phenotypes in *Nf1*^{flx/flx}; *Col2.3Cre* mice, restoring bone mass and callus bone volume to WT levels. This study provides direct preclinical evidence for the critical role of *Nf1* dependent TGF-β1 signaling in the pathogenesis of NF1 associated osteoporosis and pseudarthrosis, thus implicating the TGF-β signaling pathway as a potential therapeutic target in the treatment for NF1 osseous defects.

Metabolically Active Brown Adipose Tissue (BAT) Has Anabolic Effects on Bone Through Endocrine/Paracrine Activity Including Production of IGFBP2. Sima Rahman^{*1}, Yalin Lu², Sven Enerback³, Clifford Rosen⁴, Beata Lecka-Czernik⁵. ¹University of Toledo Health Sciences Campus, USA, ²University of Toledo Medical Center, USA, ³University of Goteborg, Sweden, ⁴Maine Medical Center, USA, ⁵University of Toledo College of Medicine, USA

Energy metabolism is tied to bone acquisition; however the role of adipose tissue in this process has not been well defined. Recently, it has been reported that in young women the volume of preformed brown adipose tissue (pBAT) directly correlated with BMD. In a mouse model, *Misty*, pBAT dysfunction was associated with very low bone mass. Forkhead protein FoxC2 represents a transcription factor which regulates mitochondrial function and increases energy production in adipose tissue. Ectopic expression of FoxC2 in adipose tissue leads to increased energy expenditure, protection from high fat-diet induced obesity and insulin resistance, and a high bone mass phenotype. At 5 mo of age, trabecular BV/TV in *aP2-FoxC2*^{Tg} mice is 3-fold higher vs. WT mice and correlates with increased osteoblast number (4-fold), increased MAR and high BFR (2- and 3- fold, respectively). The high bone mass in *aP2-FoxC2*^{Tg} mice is accompanied by increased marrow adipose tissue (MAT) which is juxtaposed in the tibia and femur. Ectopically expressed FoxC2 increases expression of UCPI, Dio2, and Prdm16 in both peripheral and marrow adipocytes suggesting acquisition of a brown-like (iBAT) phenotype. To investigate the hypothesis that iBAT has endocrine/paracrine function in the regulation of bone remodeling, the effects of conditioned media (CM) derived from iBAT represented by either epididymal fat of *aP2-FoxC2*^{Tg} mice or marrow adipocytes expressing FoxC2 on markers of osteoblast phenotype were tested. CM from iBAT significantly increased alkaline phosphatase (ALP) activity, expression of osteoblast-specific gene markers (Dlx5, osteocalcin and cyclin D), and levels of pAkt. Proteomic analysis of the secretome of FoxC2-3T3-L1 adipocytes revealed increased IGFBP2, a protein known for its insulin sensitizing properties as well as its IGF-1-independent effects on osteoblast differentiation. Serum levels of IGFBP2 protein are elevated and the

expression of IGFBP2 transcripts in WAT and MAT are also increased in aP2-FoxC2^{fl} mice. Furthermore, depletion of IGFBP2 from CM using an IGFBP2-specific antibody abrogated FoxC2-mediated increases in ALP activity in the recipient osteoblastic cells. These data suggest a role for IGFBP2 in mediating BAT's endocrine/paracrine regulation of bone mass. The role of pBAT and iBAT in the pathogenesis of osteoporosis requires further studies.

Overexpression of Bmi-1 in Mouse Lymphocytes Stimulates Osteogenesis by Improving the Osteogenic Microenvironment. Xichao Zhou^{*1}, Wen Sun², David Goltzman³, Andrew Karaplis³, Xiang-Jiao Yang³, Dengshun Miao⁴. ¹Nanjing Medical University, China, ²Nanjing Medical University The Research Center for Bone & Stem Cells, Peoples Republic of China, ³McGill University, Canada, ⁴Nanjing Medical University, Peoples Republic of China

Overexpression of Bmi1 in mouse lymphocytes has been shown to be important for the specification of the identity of the vertebral column, but it is unclear whether such overexpression also improves the osteogenic microenvironment and thereby stimulates osteogenesis. To investigate this, we examined the skeletal phenotype of Em-Bmi1 transgenic mice in which Bmi1 is highly expressed in lymphocytes. Western blotting confirmed a high expression level of Bmi1 protein in the thymus, spleen and bone marrow of the transgenic mice. Compared to wild-type mice, skeletal size, BMD, trabecular bone volume, osteoblast number, alkaline phosphatase (ALP)- and type I collagen-positive areas, and mRNA levels of Runx2, ALP, type I collagen and osteocalcin were all significantly increased in the Em-Bmi1 transgenic mice. Total numbers of CFU-f and ALP positive CFU-f generated by bone marrow cell cultures also increased significantly in the transgenic mice and a similar increase was observed in wild-type bone marrow cells cultured with the conditioned medium from lymphocyte cultures of the transgenic mice. In the PTHrP(1-84) knockin (*Pthrp* KI) mice that lack the nuclear localization sequence and the C-terminal region of PTHrP, Bmi1 expression is reduced and premature osteoporosis occurs. We therefore crossed Em-Bmi1 transgenic mice with *Pthrp* KI mice to generate *Pthrp* KI mice with Bmi1 overexpression in lymphocytes for comparison with the *Pthrp* KI and wild-type littermates. Lymphocytic expression of Bmi1 in the *Pthrp* KI background resulted in a longer lifespan, increased body weight, and improvement in skeletal growth and osteoblastic bone formation in the *Pthrp* KI mice, although the defects were not completely rescued. Furthermore, real-time RT-PCR revealed that levels of anti-oxidative enzymes including SOD1, 2 and 3, glutathione reductase and glutathione peroxidase 1 were up-regulated in bony tissues of the Em-Bmi1 transgenic mice, but down-regulated in the *Pthrp* KI mice; importantly, Bmi1 ectopic expression in the *Pthrp* KI mice rescued this down-regulation. Taken together, these results demonstrate that overexpression of Bmi1 in mouse lymphocytes stimulates osteogenesis and partially rescues the defects in skeletal growth and osteogenesis in the *Pthrp* KI mice by inhibiting oxidative stress and improving the osteogenic microenvironment.

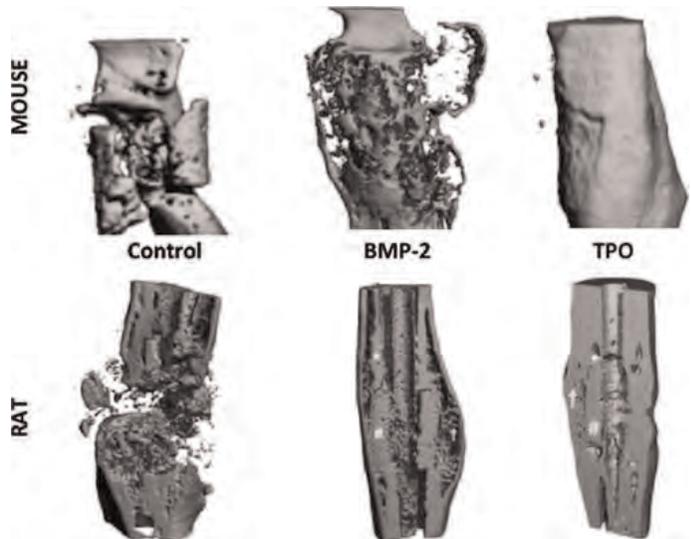

Disclosures: *Xichao Zhou, None.*

Thrombopoietin: A Novel Regulator Of Bone Healing. Monique Bethel^{*1}, Patrick Millikan¹, Alexander Wessel¹, Yinghua Cheng¹, Jonathan Wilhite¹, David Burr¹, Robyn Fuchs², Tien-Min Chu³, Melissa Kacena¹. ¹Indiana University School of Medicine, USA, ²Indiana University, USA, ³Indiana University School of Dentistry, USA

Despite advances in surgical techniques and implants, orthopaedic surgeons are still challenged to obtain fracture union, spine fusion, or bridging of segmental defects. Critical-size defects in bones do not heal spontaneously and usually require the use of grafts. Unfortunately, the use of grafts poses several limitations including harvest site morbidity with autografts and concerns about disease transmission with allografts. To improve bone formation, many clinicians now use bone morphogenetic proteins (BMP), particularly in spinal fusion, fracture healing, and in critical-size defect regeneration. However, multiple side effects of BMP treatment have been uncovered including increased incidence of cancer, greater risks of radiculitis, ectopic bone formation, and osteolysis. With the high cost of BMP and concerns for side effects, there is great interest in investigating other alternatives that allow for safe and effective bone regeneration. Here we present data showing the ability of thrombopoietin (TPO), the main megakaryocyte growth factor, to heal critical-size femoral defects in both rat and mouse models. 5mm or 4mm segmental defects were created in the femur of Long Evans rats or C57BL/6 mice, respectively. The defects were filled with a novel bioabsorbable scaffold which was loaded with recombinant human TPO, BMP-2, or saline, and held stable by a retrograde 1.6mm intramedullary Kirschner wire (rats) or 23G needle (mice). Xrays were taken every 3 weeks in rats and weekly in mice. Animal were sacrificed at 15 weeks, at which time micro-computed tomography (μ CT) and histological analyses were performed. The results observed in mice and rats were similar. The saline control group did not show bridging callus at any time. Both the BMP-2 and TPO groups healed the defect, although bridging callus was evident at earlier times in the BMP-2 groups. However, the TPO groups showed a much more remodeled and physiologic contour on both Xray and μ CT. μ CT and histological analysis confirms that compared to BMP-2, TPO-treated specimens have

a thicker cortex but smaller diameter and smoother contour. TPO appears to restore the original bone contour by stimulating osteoblastogenesis, allowing for periosteal bridging and stabilization to occur, while simultaneously stimulating osteoclast formation. The therapeutic potential of TPO is high as it has already been tested in humans and could be moved into phase 2 studies quickly.

Bone healing in untreated, BMP-2-treated, and TPO-treated mice and rats 15 weeks post-surgery.

PTH Induce Short-Term Hemopoietic Stem Cell Expansion through T Cells. Jau-Yi Li^{*1}, Jonathan Adams¹, Laura Calvi², M. Neale Weitzmann¹, Roberto Pacifici¹. ¹Emory University School of Medicine, USA, ²University of Rochester School of Medicine, USA

Intermittent parathyroid hormone (iPTH) stimulates hemopoietic stem cells (HSCs) expansion in bone marrow (BM), but neither the involved mechanism nor the affected HSPC populations are known. Since T cells contribute the action of iPTH in bone, we investigated the role of T cells in the effects of iPTH on HSCs. iPTH (PTH 1-34, 80 μ g/kg SQ daily for 4 weeks) increased the number of HSCs (Lin-Sca-1+c-Kit+ cells) by ~2 fold and host survival after BM transplantation by ~4 fold in WT mice and T cell reconstituted-T cell deficient mice. By contrast iPTH had no effects on HSCs expansion and survival after BM transplantation in T cells deficient mice, or PPR^{T cells} mice, a strain lacking PTH receptor 1 (PPR) signaling in T cells. Thus, direct PPR signaling in T cells is required for iPTH to expand HSCs and improve post-transplantation survival. Analysis of SLAM receptor expression on HSCs and competitive repopulation assays demonstrated that iPTH specifically expands short-term HSCs (ST-HSCs) without exhausting long-term HSCs (LT-HSCs) in mice with intact PPR signaling in T cells. By contrast iPTH did not expand ST-HSCs in mice lacking T cells or PPR signaling in T cells. Since it is known that activation of Wnt and Notch signaling in HSCs is required for their expansion, we investigated the role of T cells in the iPTH-induced activation of these pathways. We found that PPR signaling in T cells increases the T cell production of Wnt ligand Wnt10b, and that Wnt10b is required for activating Wnt signaling in HSPCs and stromal cells (SCs) in response to iPTH treatment. T cell produced Wnt10b was also essential for upregulating the SC expression of Jagged1, a Notch ligand critical for HSC expansion. Accordingly, iPTH failed to expand ST-HSCs in mice with a specific deletion of T cell produced Wnt10b. Further attesting to the relevance of Wnt10b for HSCs expansion, we found that iPTH failed to promote HSCs engraftment and host survival after BM transplantation in Wnt10b null mice. In summary, these findings demonstrate that activation of PPR signaling in T cells by iPTH stimulates T cells to release Wnt10b, a factor required for activating Wnt signaling in HSCs and SCs as well as for increasing Jagged1 expression in SCs. Activation of Wnt and Notch signaling in HSCs allows iPTH to selectively expand ST-HSCs and improve host survival after BM transplantation. Thus, T cells may provide pharmacological targets for HSPC expansion.

Osterix Expressed in Chondrocytes Is Required for Skeletal Development. Shaohong Cheng^{*1}, Weirong Xing², Catrina Alarcon³, Xin Zhou⁴, Subburaman Mohan⁵. ¹VA Loma Linda Health Care Systems, USA, ²Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, ³Jerry L Pettis VA Med Ctr, USA, ⁴MD Anderson Cancer Center, USA, ⁵Jerry L. Pettis Memorial VA Medical Center, USA

Osterix (Osx) is essential for osteoblast differentiation and bone formation as mice with targeted disruption of the *Osx* gene failed to form either intramembranous or endochondral bone. Previous studies have shown that *Osx*, a downstream target gene of Runx2, is specifically expressed in osteoblasts (Obs) and at low levels in prehypertrophic chondrocytes (CCs). Accordingly, Ob-specific ablation of *Osx* using *Col1a1-Cre* mice resulted in osteopenia, due to impaired Ob differentiation in adult mice. We found that CCs (ATDC5, RCS and primary mouse CCs) in culture expressed *Osx* at levels comparable to that of Obs, thus suggesting *Osx* expressed in CCs may also play a role in skeletal development. To evaluate the role of *Osx* expressed in CCs, we crossed floxed osterix with CC-specific *Col2a1-Cre* mice to conditionally disrupt the *Osx* gene in CCs. Surprisingly, *Cre* positive mice that are homozygous for *Osx* floxed alleles failed to survive after birth. Alcian blue and alizarin red staining of newborn *Cre* positive; *lox/lox* and corresponding wild type (WT) littermates revealed that the lengths of the total body, femur and rib were reduced by 20, 25 and 32% (all $P < 0.001$), respectively, in the knockout (KO) compared to WT mice. Besides demonstrating severely impaired mineralization of bones formed via endochondral but not intramembranous route, several bones including long bones, vertebral column and ribs were bent. In order to determine if haploid insufficiency of *Osx* in CCs influences skeletal development, we compared skeletal phenotypes of *Cre* positive; *lox* heterozygous mice with gender-matched, *Cre* negative heterozygous littermates. Body length was reduced by 6% ($P = 0.002$) in mice with conditional disruption of one allele of the *Osx* gene in CCs. PIXImus measurements revealed that BMC of total body, femur, tibia and vertebra was reduced by 17, 14, 21 and 15% (all $P < 0.01$, $n = 15-20/\text{group}$), respectively, in *Cre* positive mice compared to littermate *Cre* negative mice at 3 wks of age. BMD of total body, femur, tibia and vertebra was reduced by 4.5, 6.6, 6.0 and 9.5% (all $P < 0.05$), respectively, in the *Cre* positive; *lox* heterozygous mice. We found that expression levels of Col X, TRAP and Cathepsin K as measured by real time RT-PCR were significantly reduced (30-70%) in the femurs of *lox* heterozygous *Cre* negative mice. Conclusions: 1) *Osx* expressed in CCs is essential for survival of mice after birth. 2) Haploid insufficiency of *Osx* expressed in CCs results in reduced longitudinal growth, bone size and BMD. 3) *Osx* expressed in CCs regulates skeletal development in part by regulating CC maturation and cartilage resorption.

Jab1 is Required for Chondrogenesis in Embryonic Limb Development. Lindsay Bashur^{*1}, Dongxing Chen¹, Bojian Liang¹, Ruggero Pardi², Brendan Lee³, Shunichi Murakami¹, Guang Zhou¹. ¹Case Western Reserve University, USA, ²Scientific Institute San Raffaele, Italy, ³Baylor College of Medicine & Howard Hughes Medical Institute, USA

The transcriptional cofactor Jab1 controls cell proliferation, apoptosis, and differentiation in many developmental processes by regulating the activity of numerous transcription factors. However, the physiological role of Jab1 in skeletal development is still poorly understood. In this study, we utilized the *loxP/Cre* system to delineate the specific role of Jab1 in limb development. First, to determine the specific role of Jab1 in differentiating chondrocytes, we generated a chondrocyte-specific *Jab1* conditional knockout *Jab1^{fllox/lox}; Col2a1-Cre* mouse model. *Jab1^{fllox/lox}; Col2a1-Cre* mutants exhibited neonatal lethal chondrodysplasia with severe dwarfism. In E18.5 mutants, all skeletal elements developed via endochondral ossification, including the limbs, were extremely small with severely disorganized chondrocyte columns. *Jab1* mutant chondrocytes exhibited increased apoptosis and accelerated chondrocyte hypertrophy. Notably, there was a heightened expression of BMP signaling components and targets in *Jab1* mutant chondrocytes, suggesting that Jab1 is a novel inhibitor of BMP signaling in differentiating chondrocytes *in vivo*. Second, to determine the function of Jab1 in early osteochondro progenitor cells, we bred *Jab1^{fllox/lox}* mice with *Prx1-Cre* transgenes to delete *Jab1* specifically in limb buds. *Jab1^{fllox/lox}; Prx1-Cre* mutant mice displayed drastically shortened limbs starting at E14.5, mirroring the human skeletal disorder phocomelia. The E18.5 mutant limbs exhibited drastically reduced numbers of hypertrophic chondrocytes, disorganized chondrocyte columns, and increased apoptosis. To determine the underlying mechanism for the severe short-limb defect in *Jab1^{fllox/lox}; Prx1-Cre* mutants, we used a micromass culture of E11.5 *Jab1* mutant and wild-type limb mesenchyme cells to study chondrogenesis *ex vivo*. Alcian blue staining showed significantly decreased chondrogenesis in *Jab1* mutant cultures. Real time RT-PCR confirmed that the expression of chondrocyte differentiation markers, including *Sox9* and *Col2a1*, were significantly decreased in *Jab1* mutants. Furthermore, Western blot analysis revealed that the expression of BMP signaling downstream effector phospho-Smad1/5 was increased in *Jab1* mutants, suggesting that Jab1 also negatively regulates BMP signaling during early limb development. In conclusion, our study demonstrates that Jab1 is essential for successive steps of limb development *in vivo*, likely in part by inhibiting BMP signaling.

Inducible Conditional Inactivation of TGF-beta Type II Receptor in Prx-1 Expressing Cells in Utero and Post-natal Life Leads to Prenatal and Postnatal Growth Failure and Joint Defects. Tieshi Li^{*1}, Lara Longobardi¹, Timothy Myers², Joseph Temple³, Michael Kuijter³, Ying Li⁴, Anna Spagnoli¹. ¹University of North Carolina at Chapel Hill, USA, ²University of North Carolina, USA, ³Department of Pediatrics of UNC at Chapel Hill, USA, ⁴UNC School of Medicine, USA

The role of TGF-beta type II receptor (*Tgfr2*) signaling in skeletogenesis has been primarily studied by targeting its genetic manipulation to early embryonic mouse development. Here, to determine the need of *Tgfr2* signaling in late embryonic and postnatal skeletal growth as well as in maintaining joint integrity we have generated the *Prx1CreERT2;Tgfr2^{lox/lox}* mice to obtain temporal and limb-specific control of expression using a tamoxifen (Tam)-inducible-*Cre* system (*Prx1CreERT2*). To determine the *Prx1-Cre* inducible recombination at different prenatal and postnatal ages and to establish the optimal regimen for Tam administrations we generated the *Prx1CreERT2-LacZ-R26R* as a *LacZ-Cre* activity reporter mouse. Tam administrations ranged from E13.5 to P3, single and multiple doses were tested; mice were sacrificed 3 days after Tam. In knee and interphalangeal joints at both prenatal and postnatal stages, we found Tam-induced beta-gal activity in the perichondrium, the superficial layers of articular cartilage, tendons, ligaments and menisci. *Prx1-Cre* Tam-induced activity in these regions overlapped with but was not limited to the regions of *Tgfr2* expression that we characterized by generating *BAC-Tgfr2-LacZ* reporter mice. The lack of beta-gal activity in the *Prx1CreERT2-LacZ-R26R* not exposed to Tam confirmed the absence of *Cre*-activity leakage. We then exposed *Prx1CreERT2;Tgfr2^{fllox/lox}* mice to Tam at P3 to generate *Prx1CreERT2;Tgfr2^{lox/lox}* mice that were sacrificed at different ages. At P31, we found that compared to control (*Tgfr2^{fllox/lox}*), *Prx1CreERT2;Tgfr2^{lox/lox}* had $32.4 \pm 2.6\%$ decrease of body weight and $20.5 \pm 1.1\%$ decrease of body length. Furthermore, histological analyses of P31 *Prx1CreERT2;Tgfr2^{lox/lox}* mice showed a large number of hypertrophic chondrocytes within the knee articular cartilage as an early sign of osteoarthritis. Tam was also administered at E14.5 and *Prx1CreERT2;Tgfr2^{lox/lox}* mice analyzed at E18.5 showed growth failure ($17.1 \pm 2.2\%$ decrease) as a result of a shorter growth plate with disorganized hypertrophic chondrocytes and perichondrium. In *Prx1CreERT2;Tgfr2^{lox/lox}*, BrdU incorporation assay showed reduced proliferative activity within the superficial layer of the articular cartilage and proliferative layer of the growth plate. Our findings indicate that *Tgfr2* signaling regulates postnatal growth and is needed to maintain postnatal joint integrity by regulating chondrocyte proliferation and repressing hypertrophy.

The Skeletal Effects of Notch are Cell-Context Dependent. Stefano Zanotti^{*1}, Kristen Parker², Jian Feng³, Ernesto Canalis¹. ¹St. Francis Hospital & Medical Center, USA, ²Saint Francis Hospital & Medical Center, USA, ³Texas A&M Health Science Center, USA

Transgenic expression of Notch under the control of the *Type 1 collagen* promoter causes osteopenia, and the conditional deletion of *Notch1* and *2* in the skeleton increases bone volume and osteoblastogenesis, indicating that Notch downregulates osteoblastic differentiation/function. However, the biology of Notch is cell-context dependent. To address whether Notch has distinct effects in cells of the osteoblastic lineage at various stages of differentiation, we used the *Rosa^{Notch}* mouse model, where the Notch intracellular domain (NICD) is expressed under the control of the *Rosa* promoter following the excision of a *loxP* flanked STOP cassette between the *Rosa26* promoter and NICD. *Rosa^{Notch}* mice were crossed with transgenics expressing the *Cre* recombinase under the control of the *Osterix (Osx)*, *Osteocalcin (Oc)*, 2.3 kb fragment of *Type 1 collagen (Col2.3)* or *Dentin matrix protein 1 (Dmp1)* promoter to express Notch in osteoblast precursors, mature osteoblasts and osteocytes, respectively. Microcomputed tomography (μCT) and histomorphometry revealed that expression of Notch in undifferentiated (*Osx-Cre;Rosa^{Notch}*) or mature osteoblasts (*Oc-Cre;Rosa^{Notch}*) caused marked femoral and vertebral osteopenia due to decreased bone formation; cortical bone was porous or not present. In contrast to this osteopenic phenotype, expression of Notch in osteocytes (*Dmp1-Cre;Rosa^{Notch}*) caused a marked 3-6 fold increase in femoral and vertebral bone volume, and a pronounced increase in connectivity. The mechanism involved suppressed bone resorption due to enhanced expression of osteoprotegerin. Sclerostin mRNA was suppressed leading to enhanced Wnt signaling in osteocytes. Cortical bone thickness was increased, but the cortex was not compact and had the appearance of cancellous bone. Notch expression in osteoblasts and osteocytes (*Col2.3-Cre;Rosa^{Notch}*) caused a similar but less pronounced phenotype than that observed in *Dmp1-Cre;Rosa^{Notch}* mice. There was no sexual dimorphism in the skeletal phenotypes described. In conclusion, the skeletal effects of Notch are cell-context dependent. When expressed in osteoblasts, Notch causes osteopenia due to impaired osteoblastic differentiation/function, and when expressed in osteocytes Notch causes increased bone mass due to suppressed bone resorption. Compact cortical bone is absent in the presence of Notch suggesting that downregulation of Notch is necessary for the transition of trabecular to cortical bone.

Rbpj-Dependent Notch Signaling in Chondrocytes Modulates Endochondral Ossification during Osteoarthritis Development through Transcriptional Induction by Hes1. Shurei Sugita*¹, Yoko Hosaka², Taku Saito², Haruhiko Akiyama³, Ung-Il Chung⁴, Hiroshi Kawaguchi^{5, 1}, Japan, ²University of Tokyo, Graduate School of Medicine, Japan, ³Kyoto University, Japan, ⁴University of Tokyo Schools of Engineering & Medicine, Japan, ⁵University of Tokyo, Faculty of Medicine, Japan

The Notch signaling constituted of the Notch receptors, the transcriptional effector Rbpj, and the transcription target Hes/Hey family members is a potent modulator of cell differentiation in many organs. Here we examined the involvement of the Notch signaling in the endochondral ossification process which is crucial for osteoarthritis (OA) development. Intracellular domains (ICDs) of Notch1 and 2 were translocated into the nucleus of chondrocytes with their differentiation in mouse limb cartilage and in mouse and human OA articular cartilage. The tissue-specific knockout mice of Rbpj in chondroprogenitor cells (*Sox9-Cre;Rbpj^{fl/fl}*) died shortly after birth, but the embryos exhibited an impaired endochondral ossification with decreases of Mmp13 expression in the limb cartilage. We then generated the inducible conditional knockout mice (*Col2a1-Cre^{ERT};Rbpj^{fl/fl}*), inactivated Rbpj in the adult articular cartilage by tamoxifen injection to the 7-week-old mice after normal skeletal growth and joint formation, and created the surgical OA model. The *Col2a1-Cre^{ERT};Rbpj^{fl/fl}* mice showed resistance to the knee OA development as compared to the control *Rbpj^{fl/fl}* littermates. As for the underlying mechanism, Hes1 was most strongly expressed among Hes/Hey family members during differentiation of cultured mouse chondrogenic ATDC5 cells and primary chondrocytes, with Notch 1, Notch2, Rbpj, and Mmp13 expressions. Overexpression of Notch1 ICD in ATDC5 cells induced Mmp13 expression, and this induction was suppressed by the Hes1 knockdown through the siRNA transfection. Luciferase analyses revealed that the promoter activity of *MMP13* was not affected by Notch1 ICD transfection, but was enhanced by Hes1. In the *MMP13* gene between -1,000 and +1,227 bp relative to the transcriptional start site, there were six E-box motifs but no N-box motif. Deletion and mutagenesis analyses identified the core responsive region of Hes1 as an E-box at +934/+939 bp. However, the *Sox9-Cre;Hes1^{fl/fl}* mouse embryos did not show skeletal abnormality. Contrarily, the inducible conditional knockout of Hes1 (*Col2a1-Cre^{ERT};Hes1^{fl/fl}*) in adult articular cartilage by tamoxifen injection caused resistance to the knee OA development. In conclusion, Hes1, which mediates the Rbpj-dependent Notch signaling in chondrocytes, is a transcriptional inducer of endochondral ossification during OA development, representing a promising therapeutic target of OA without physiological side effects.

An Appropriate Balance of Notch Signaling is Required for Articular Cartilage and Joint Maintenance. Zhaoyang Liu*¹, Anthony Mirando¹, Tyler Moore¹, Alexandra Lang¹, Anat Kohn², Alana Jesse², Regis O'Keefe², Robert Mooney¹, Michael Zuscik³, Matthew Hilton¹. ¹University of Rochester Medical Center, USA, ²UNIVERSITY OF ROCHESTER, USA, ³University of Rochester School of Medicine & Dentistry, USA

Osteoarthritis (OA) is a degenerative disease resulting in severe joint cartilage destruction and disability. While the mechanisms underlying the development and progression of OA are poorly understood, gene mutations have been identified within cartilage-related signaling molecules implicating impaired cell signaling in the pathogenesis of OA. To investigate a novel role for Notch signaling in joint cartilage development, maintenance, and the pathogenesis of OA, we first generated a *Prx1Cre;Rbpjk^{fl/fl}* (cKO RBPjk) mutant mice deleting RBPjk in mesenchymal progenitors giving rise to all synovial joint tissue. Embryonic cKO RBPjk mutants exhibit normal joint cavitation and morphogenesis, while two-week-old cKO RBPjk mutants revealed a delayed formation of the secondary ossification center. Joint integrity analysis in 2, 4, 6, and 8-month old cKO RBPjk mutants via microCT, histology, IHC, ISH, and histomorphometry showed an early onset and progressive postnatal OA-like pathology characterized by fibrosis and degeneration of the articular cartilage and meniscus, subchondral bone sclerosis, osteophyte formation, and progressive loss of extracellular matrix components. Additionally, we generated a cartilage-specific Notch gain-of-function model, *Col2Cre^{ERT2};Rosa-NICD1^{fl/+}* (cGOF NICD1), to determine whether sustained NOTCH1 signaling in postnatal chondrocytes following tamoxifen induction could promote articular cartilage maintenance. Histology, histomorphometry, IHC, and real-time RT-PCR analyses were performed on the knee joints or articular cartilage isolated from several types of cGOF NICD1 mice including mice with 3-months, 4-weeks, and 5-days of sustained NOTCH1 signaling. Interestingly, "long-term" (3-months) induction resulted in severe joint cartilage fibrosis and its own OA-like pathology, while "shorter-term" (4-weeks) induction simultaneously promoted both cartilage anabolism and catabolism, although early signs of fibrosis were also evident in this model. Finally, a brief exposure of articular chondrocytes to sustained NOTCH1 signaling (5-day induction) *in vivo* also demonstrated enhancement in both cartilage anabolic and catabolic factors without the induction of early fibrosis. Therefore, a delicate balance of Notch signaling is required for appropriate cartilage anabolism and catabolism during

postnatal joint homeostasis. Collectively, these data have implicated the Notch pathway as a novel and important therapeutic target for OA.

Cortical Porosity as a Distinct Pathomorphology in Postmenopausal, Diabetic Women with Fragility Fractures. Janina Patsch*¹, Andrew Burghardt¹, Paran Yap¹, Thomas Baum², Ann Schwartz¹, Thomas Link¹. ¹University of California, San Francisco, USA, ²Klinikum rechts der Isar, Technische Universitaet Muenchen, Deu

Cortical porosity (Ct.Po) is increasingly recognized as a skeletal pathomorphology of potential clinical relevance. Type 2 diabetic bone disease is a metabolic bone disease with paradoxically increased fracture rates in spite of relatively high bone mineral density (BMD). The purpose of this study was to assess if Ct.Po was increased in postmenopausal diabetics with fractures when compared with non-fractured diabetics, non-diabetic controls with prevalent fragility fractures, and non-diabetic controls without fractures. All subjects (controls [Co] n=20; controls with fractures [Fx] n=20; diabetics without fracture [DM] n=20; diabetics with fracture [DMFx] n=15) underwent high resolution peripheral quantitative computed tomography (HR-pQCT; distal radius and tibia), DXA (spine, hip, radius), and a blood draw for fasting glucose, HbA1c, and c-peptide. From HR-pQCT scans, volumetric BMD, morphometric standard parameters, and extended measures of cortical bone (including Ct.Po and endocortical bone surface En.BS) [1,2] were obtained. In a 2-way ANCOVA adjusted for age, BMI, and race/ethnicity, Ct.Po was associated with fracture in DM but not controls at the ultradistal tibia (p for interaction=0.038) but not the radius. DmFx displayed the highest cortical porosity of all groups (age-, race & BMI-adjusted means +52.2% vs DM; +36.0% vs Fx; +34.2% vs Co). Coherently, DmFx also had a greater En.BS than DM (+11.12%; p=0.035). However, there were no correlations between En.BS or Ct.Po with fasting glucose, HbA1c or c-peptide. In diabetics, En.BS was significantly correlated with tibial Ct.Po (r=0.533). Compartment-specific volumetric BMD and morphometric indices by HR-pQCT (both sites) remained non-significant among the 4 groups. Patients with prevalent fractures had significantly reduced aBMD measured with DXA, but mean aBMD values remained normal to osteopenic in all patients and were particularly high in diabetics stressing the limitations of DXA. In conclusion, we found tibial Ct.Po and En.BS measured by HR-pQCT to be non-invasive surrogate biomarkers to identify type 2 diabetes mellitus postmenopausal women with prevalent fragility fractures.

TBS (Trabecular Bone Score) is More Sensitive Than BMD to Diabetes-Related Fracture Risk. William Leslie*¹, Berengère Aubry-Rozier², Olivier Lamy², Didier Hans². ¹University of Manitoba, Canada, ²Lausanne University Hospital, Switzerland

Background: Type 2 diabetes (T2D) is associated with increased fracture risk but paradoxically greater BMD. TBS (trabecular bone score), a novel grey-level texture measurement extracted from DXA images, correlates with 3D parameters of bone micro-architecture. We evaluated the ability of lumbar spine (LS) TBS to account for the increased fracture risk in diabetes.

Methods: 29,407 women ≥ 50 years at the time of baseline hip and spine DXA were identified from a database containing all clinical BMD results for the Province of Manitoba, Canada. 2,356 of the women satisfied a well-validated definition for diabetes, the vast majority of whom (>90%) would have T2D. LS L14 TBS was derived for each spine DXA examination blinded to clinical parameters and outcomes. Health service records were assessed for incident non-traumatic major osteoporotic fracture codes (mean follow-up 4.7 years).

Results: In linear regression adjusted for FRAX risk factors (age, BMI, glucocorticoids, prior major fracture, rheumatoid arthritis, COPD as a smoking proxy, alcohol

abuse) and osteoporosis therapy, diabetes was associated with higher BMD for LS, femoral neck and total hip but lower LS TBS (all $p < 0.001$). Similar results were seen after excluding obese subjects with BMI > 30. In logistic regression (Figure), the adjusted odds ratio (OR) for a skeletal measurement in the lowest vs highest tertile was less than 1 for all BMD measurements but increased for LS TBS (adjusted OR 2.61, 95%CI 1.10-5.74). Major osteoporotic fractures were identified in 175 (7.4%) with and 1,493 (5.5%) without diabetes ($p < 0.001$). LS TBS predicted fractures in those with diabetes (adjusted HR 1.27, 95%CI 1.10-1.46) and without diabetes (HR 1.31, 95%CI 1.24-1.38). LS TBS was an independent predictor of fracture ($p < 0.05$) when further adjusted for BMD (LS, femoral neck or total hip). The explanatory effect of diabetes in the fracture prediction model was greatly reduced when LS TBS was added to the model (indicating that TBS captured a large portion of the diabetes-associated risk), but was paradoxically increased from adding any of the BMD measurements.

Conclusions: Lumbar spine TBS is sensitive to skeletal deterioration in postmenopausal women with diabetes, whereas BMD is paradoxically greater. LS TBS predicts osteoporotic fractures in those with diabetes, and captures a large portion of the diabetes-associated fracture risk. Combining LS TBS with BMD incrementally improves fracture prediction.

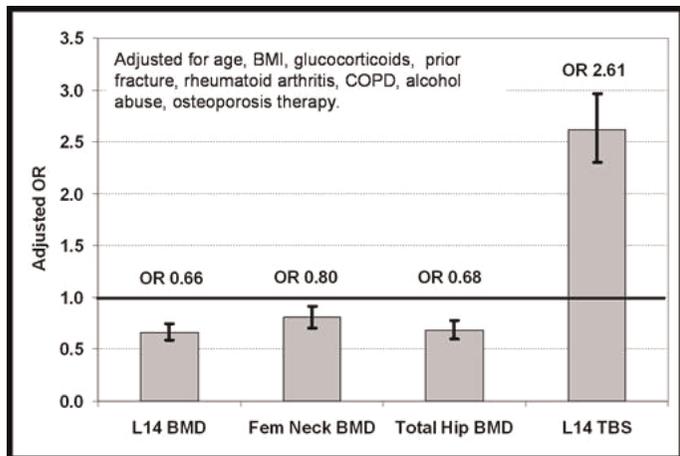

Figure: OR (95%CI) for BMD or TBS in the lowest vs highest tertile according to diabetes status.

Osteoporosis is Not Enough: Cortical Porosity Identifies Women with Distal Forearm Fractures. Yohann Bala¹, Roger Zebaze², Ali Ghasem-Zadeh², James Peterson³, Shreyasee Amin³, L. Joseph Melton³, Sundeep Khosla⁴, Ego Seeman². ¹University of Melbourne, Dept. of Medicine, Australia, ²Austin Health, University of Melbourne, Australia, ³Mayo Clinic, USA, ⁴College of Medicine, Mayo Clinic, USA

Introduction: Trabecular bone loss and vertebral fractures are held to be flagships of 'osteoporosis'. However, 80% of bone is cortical, 80% of fractures are non-vertebral, 70% of all bone loss is cortical and due to intracortical resorption.¹ The resulting porosity is a quantifiable footprint of structural decay and so may predict fracture risk as resistance to bending is proportion to the 7th power cortical apparent density. We hypothesized that porosity discriminates women with distal forearm fractures better than areal BMD.

Methods: One hundred postmenopausal women with a distal forearm fracture and 105 age matched community controls from Olmsted County, Minnesota had 3D cortical imaging and aBMD (g/cm^2) assessed at the ultradistal radius by HR-pQCT and DXA.² Cross-sectional area (CSA), cortical porosity, trabecular and cortical vBMD (Ct. & Tb.vBMD, g/cm^3) were processed from HR-pQCT images using a non-threshold based image analysis, StrAx1.0, which automatically segments cortical bone into compact cortex (CC) and transitional zone (TZ). The proportion of void (porosity) was quantified as the average of void spaces in each voxel. Images were colour coded according to their mineralized matrix content. Results were expressed as a frequency or a void-bone matrix distribution curve. Due to motion artefacts, only 68 cases (63 ± 9 year-old) and 70 controls (66 ± 9 year-old, N.S.) were analysed.

Results: Among cases, 4/5 did not have osteoporosis (t-score ≤ -2.5 SD). aBMD was significantly lower in cases than in controls (0.42 ± 0.07 vs. 0.37 ± 0.08 g/cm^2 , $p < 0.001$). Ct. & Tb. vBMD were -4% and -24% lower in cases ($p < 0.018$). Porosity was higher in cases than controls (CC +11%, $p = 0.03$, TZ +3%, $p = 0.0001$). TZ porosity predicted fracture risk; each SD increase was associated with an odds ratio of 2.09 (95% CI, 1.40-3.11; $p = 0.0001$). The void-bone matrix curve in cases was shifted left in CC and TZ indicative of higher porosity.

Inference: Intracortical remodeling fragments the cortex producing porosity which allow better discriminates and so targets women with distal forearm fractures than aBMD and vBMD alone. 1) Zebaze *et al.* Lancet 2010 2) Melton III *et al.* Osteoporos Int 2010.

Postmenopausal Women with Osteopenia and Fractures Have Thin Cortices and Trabecular Plate Loss. Emily Stein¹, Xiaowei Liu², Thomas Nickolas³, Adi Cohen³, Anna Kepley⁴, X Guo⁴, Elizabeth Shane^{*1}. ¹Columbia University College of Physicians & Surgeons, USA, ²University of Pennsylvania, USA, ³Columbia University Medical Center, USA, ⁴Columbia University, USA

The majority of fragility fractures occur in women with osteopenia rather than osteoporosis by DXA. However, it is difficult to identify which women with osteopenia are at greatest risk. Abnormal microarchitecture is an important determinant of bone strength and fracture susceptibility, independent of areal BMD (aBMD) by DXA. We hypothesized that osteopenic women with fragility fractures would have abnormal microarchitecture compared to controls. We enrolled 117 women with osteopenia by DXA (age 66 ± 6 yrs, 76% Caucasian), 58 with a history of low trauma fracture after menopause (FX) and 59 non-fractured postmenopausal controls (C). All had aBMD of lumbar spine (LS), total hip (TH), femoral neck (FN), 1/3 (1/3R) and ultradistal radius (UDR) by DXA. Trabecular (Tb) and cortical (Ct) volumetric BMD (vBMD) and Tb microarchitecture were measured by high resolution peripheral computed tomography (HRpQCT, voxel size $\sim 82 \mu m$) of the distal radius and tibia. HRpQCT scans were subjected to finite element analysis (FEA) to estimate whole bone stiffness and individual trabecula segmentation (ITS) to assess plate and rod structure of Tb bone. Groups were similar with respect to age, race, BMI and years since menopause. Fracture of the forearm, spine and ankle were most common. Mean T-scores in FX (LS -1.2, TH -1.0, FN -1.6, 1/3R -0.7, UDR -1.1) did not significantly differ from those in C at any site, though they tended to be lower at the LS (0.09) and higher at the 1/3R (0.07). In contrast, there were substantial microarchitectural differences between FX and C (Table). At the radius, FX had lower Ct and Tb vBMD, thinner cortices, thinner more widely separated trabeculae and lower stiffness. By ITS, FX had fewer Tb plates, less axially aligned trabeculae and less Tb connectivity. At the tibia, differences between FX and C were limited to Ct bone. Whole bone stiffness and ITS tended to be lower. In summary, postmenopausal women with osteopenia and fractures had lower Ct and Tb vBMD, thinner, more widely separated and rod-like Tb structure, and less Tb connectivity by HRpQCT compared to controls, despite similar aBMD by DXA. At the radius, both cortical and trabecular abnormalities were associated with fractures and lower stiffness, while at the tibia, cortical abnormalities predominated. Our results suggest that trabecular and cortical bone loss as well as changes in plate and rod structure may be important mechanisms of fracture in postmenopausal women with osteopenia.

Microarchitecture in FX compared to C (% difference)

| | RADIUS | p-value | TIBIA | p-value |
|---------------------------------------|--------|---------|-------|---------|
| Ct Area (mm ²) | -8 | <0.03 | -10 | <0.03 |
| Tb Area (mm ²) | +9 | <0.02 | +8 | 0.06 |
| Total Density (mgHA/cm ³) | -12 | <0.003 | -9 | <0.01 |
| Ct Density (mgHA/cm ³) | -3 | <0.03 | -3 | 0.09 |
| Ct Thickness (mm) | -11 | <0.007 | -13 | <0.02 |
| Tb Density (mgHA/cm ³) | -12 | <0.02 | -6 | 0.14 |
| Tb Number (1/mm) | -5 | 0.10 | -1 | 0.76 |
| Tb Thickness (mm) | -6 | <0.05 | -5 | 0.16 |

Geometry, Density Distribution and Internal Structure of the Proximal Femur in Relation to Age and Hip Fracture Risk in Women. Julio Carballido-Gamio¹, Roy Harnish¹, Isra Saeed¹, Timothy Streeper¹, Sigurdur Sigurdsson², Shreyasee Amin³, Elizabeth Atkinson³, Terry Therneau³, Kristin Siggeirsdottir², Xiaoguang Cheng⁴, L. Joseph Melton³, Joyce Kevak⁵, Vilundur Gudnason², Sundeep Khosla⁶, Tamara Harris⁷, Thomas Lang¹. ¹University of California, San Francisco, USA, ²Icelandic Heart Association Research Institute, Iceland, ³Mayo Clinic, USA, ⁴Beijing Ji Shui Tan Hospital, China, ⁵University of California, USA, ⁶College of Medicine, Mayo Clinic, USA, ⁷Intramural Research Program, National Institute on Aging, USA

Age-related changes in hip structure are non-homogeneous. The least mechanically-stimulated regions are thought to experience the greatest bone loss, and are implicated in hip fracture because they are thought to bear the bulk of impact from lateral falls. Here we examine how the geometry, distribution of BMD, and internal structure of the hip vary with age and fracture status using inter-subject image registration, voxel-based morphometry (VBM; Ashburner 2000), and tensor-based morphometry (TBM; Ashburner 1998). A subset of 349 women representing an age-stratified, random community sample (Riggs 2004) was subdivided into young (<45 yrs; n=94), middle-age (45-59 yrs; n=98), and older (≥60 yrs; n=157) groups. A second subset of 222 age-matched (mean=79.3 yrs) women of the Age, Gene/Environment Susceptibility Reykjavik cohort (Sigurdsson 2006) was subdivided into control (no hip fracture; n=148) and fracture (incident hip fracture; n=74) groups. Using QCT scans and spatial normalization to minimum deformation templates (MDTs), global differences in bone size, and local differences in BMD (VBM) and volume (TBM) between middle-age and young, older and young, and control and fracture women were identified. Local differences were computed with voxel-wise general linear models yielding Student's t-test statistical maps (T-maps; Figure 1). Bones of older and fracture women were significantly larger than those of young and control women, respectively. In middle-age and older women, BMD was preserved in the load-bearing inferomedial and inferolateral cortices, but there were BMD deficits superiorly in the femoral neck. Fracture women had lower BMD in expected areas such as the superior cortex and trochanteric region, but differences were also seen in the inferomedial and inferolateral cortices. TBM showed volume loss in the principal compressive bands and cortices, and enlargement of the trabecular neck area in middle-age and older women compared to young women, and in fracture women compared to age-matched controls. A focal region of cortical volume loss in the superior neck of fracture women was in agreement with a study indicating cortical thinning in this area (Johannesdottir 2011). This study shows that women who sustain incident hip fracture have structural differences from age-matched controls, and a structural phenotype that is fundamentally distinct from that of normal aging, with BMD deficits in hip regions that are usually preserved with age.

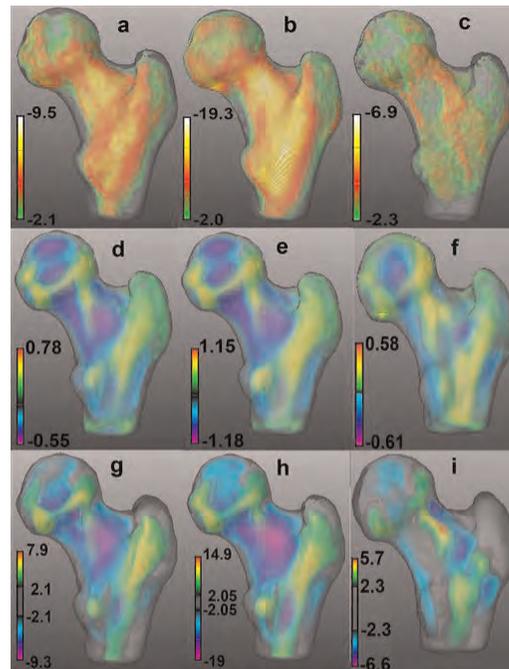

Figure 1. VBM T-maps: a) Middle-age vs Young; b) Older vs Young; c) Fracture vs Controls. Log-determinant of Jacobians showing regions of smaller (negative) and bigger (positive) volumes in the d) Middle-age; e) Older ; and f) Fracture groups than in the MDTs. TBM T-Maps: g) Middle-age vs Young; h) Older vs Young; i) Fracture vs Controls. Nonsignificant voxels after false discovery correction have been rendered semitransparent in the T-maps.

Osteoporotic Vertebral Fracture Prevalences Vary Widely Between Radiological Scoring Methods: The Rotterdam Study. Ling Oei¹, Edwin Oei², Stephan J Breda³, Felisia Ly², Evelien van Meel³, Emma J Dogterom³, Laura GC de Kok³, Joyce BJ van Meurs³, Albert Hofman³, Huibert Pols¹, Andre Uitterlinden⁴, Maria Zillikens², Gabriel P Krestin³, Fernando Rivadeneira¹. ¹Erasmus University Medical Center, The Netherlands, ²Erasmus MC, The Netherlands, ³Erasmus MC, Netherlands, ⁴Rm Ee 575, Genetic Laboratory, The Netherlands

Global trends in ageing of populations implicate increasing numbers of osteoporotic fractures. VFX are associated with considerable morbidity and mortality. VFX are the most common fractures. Several methods for radiological assessment of VFX exist, but a gold standard is lacking. The aim of our study is to analyze differences in prevalences between methods. We applied two methods for scoring osteoporotic VFX in the population-based Rotterdam Study, an ongoing prospective cohort study (age ≥45 years). The algorithm based qualitative (ABQ) method mainly assesses endplate integrity, while quantitative morphometry (QM) based methods evaluate vertebral height loss. Trained research assistants scored lateral spine radiographs (T4-L4), using either ABQ or software-assisted QM (SpineAnalyzer, which applies Genant's classification). With ABQ, radiographs were triaged as normal, uncertain or definite fracture. Definite and uncertain VFX were re-assessed by a musculoskeletal radiologist. We compared fracture prevalences between QM and ABQ methods. Radiographs were scored for 2,475 participants (43% men) aged 46-89 years (mean 57). With QM, a prevalence of 20.8% (95% CI: 19.2%-22.4%) was found, compared to 3.2% (95% CI: 2.6%-4.1%) with ABQ. Of all individuals, 77.9% were identified as having no fractures, while 1.9% were scored fractured according to both methods. 18.9% were scored as having fractures according to QM but not ABQ; 1.3% were judged fractured according to ABQ but not QM. With ABQ, most fractures were found at the thoraco-lumbar junction, lumbar (T11-L3) and mid-thoracic (T7-T9) regions. With QM, most fractures were at the middle (T7,T8) and lower thoracic regions (T11,T12). The distribution of fracture severity was 70.8% mild, 27.1% moderate, 2.1% severe. Shape of deformity was 95.6% wedge, 2.6% biconcave and 1.8% crush. Most ABQ fractures concerned the superior endplate. The superior endplate was more frequently affected at the thoraco-lumbar junction and lumbar regions (T11-L3), while more inferior endplate fractures were seen at the mid-thoracic spine (T7-T8). In conclusion, osteoporotic VFX prevalence rates are significantly different when applying either QM or ABQ. Both QM and ABQ identify a

considerable number of deformities that were scored as normal by the other. VFX are often a first presentation of osteoporosis. Accurate VFX diagnosis is needed to identify patients with high risk for future fractures to optimize patient management.

Genent QM and ABQ fracture prevalences per vertebral level

Denosumab Treatment Is Associated With Progressive Improvements in Cortical Mass and Thickness Throughout the Hip. Ken Poole¹, Graham M. Treece^{*1}, Andrew Gee¹, Jacques P. Brown², Michael R. McClung³, Andrea Wang⁴, Cesar Libanati⁴. ¹University of Cambridge, United Kingdom, ²CHUQ-CHUL Research Centre, Canada, ³Oregon Osteoporosis Center, USA, ⁴Amgen Inc., USA

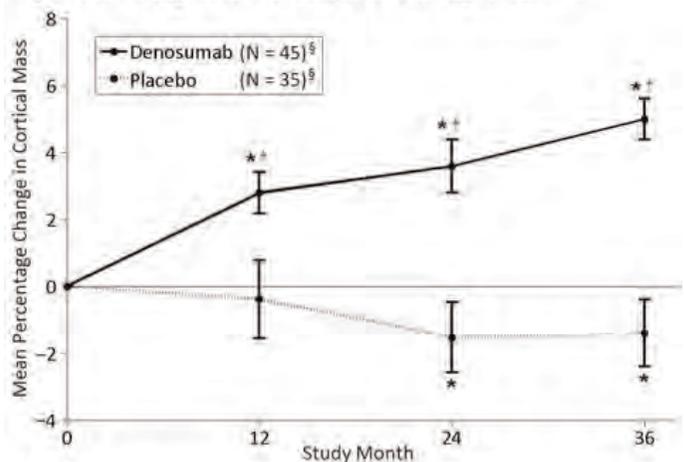

Purpose: Denosumab (a RANK ligand antibody) reduces remodeling, increases bone mineral density, and reduces cortical porosity in postmenopausal women with osteoporosis. In FREEDOM, denosumab treatment reduced the relative risk of hip fracture by 62% in those ≥ 75 years (Boonen JCEM 2011). Bone strength at the hip, estimated by FEA from QCT scans, was significantly improved from baseline and compared with placebo (Keaveny ASBMR 2010). To better characterize the changes, we used a novel cortical bone mapping technique on those same serial QCT scans, to determine the extent and distribution of mass and thickness changes at the proximal femur, a key skeletal site for fracture risk.

Methods: Eighty women age 74 ± 5 years who participated in a FREEDOM substudy underwent hip QCT scanning at baseline, and months 12, 24, and 36 during denosumab (60 mg SC Q6M) or placebo treatment; all subjects received calcium and vitamin D supplementation. For each femur, in addition to overall cortical density, the distributions of cortical mass (in mg per unit cm^2 of periosteal surface) and thickness were measured in a blinded-to-treatment manner. Distributed measures were transferred to an average femur by first registering each individual femur to this surface. Statistical parametric mapping was used to calculate significance of denosumab or placebo effects at each time point in relation to baseline, and between treatments. Distributed results were visualised as a color map over the average femur.

Results: In denosumab-treated women, there was a progressive increase in cortical mass over time, reaching a difference vs placebo of $\sim 6\%$ at 3 years ($p < 0.0001$) (Fig. 1). Approximately one-third of this increase was attributed to an increase in cortical density of $7.6 \pm 1.8 \text{ mg/cm}^3/\text{year}$ ($p < 0.0001$), which in turn remained unchanged in placebo-treated subjects ($p = 0.62$). With denosumab, cortical thickness was also significantly increased, which may represent in-filling of the cortical compartment. In contrast, average cortical mass and thickness decreased in subjects who received calcium and vitamin D alone. Mass color maps (Fig. 2) reveal the distribution of increases in cortical mass with denosumab, which were significant over an increasingly large area of the proximal femur.

Conclusion: In postmenopausal women with osteoporosis, administration of denosumab significantly and progressively increased cortical mass and thickness in regions of the proximal femur associated with hip fracture.

Effects of 5 Years of Denosumab on Bone Histology and Histomorphometry: the FREEDOM Study Extension. Jacques Brown^{*1}, Rachel Wagman², David Dempster³, David Kendler⁴, Paul Miller⁵, Michael Bolognese⁶, Ivo Valter⁷, Jens-erik Beck Jensen⁸, Cristiano Zerbini⁹, Jose Ruben Zanchetta¹⁰, Nadia Daizadeh¹¹, Ian Reid¹². ¹CHUQ Research Centre/Laval University, Canada, ²Amgen, Incorporated, USA, ³Columbia University, USA, ⁴Associate Professor University of British Columbia, Canada, ⁵Colorado Center for Bone Research, USA, ⁶Bethesda Health Research, USA, ⁷Center for Clinical Research, Estonia, ⁸Hvidovre Hospital, Denmark, ⁹Hospital Heliopolis, Brazil, ¹⁰Instituto de Investigaciones Metabolicas (IDIM), Argentina, ¹¹Amgen Inc, USA, ¹²University of Auckland, New Zealand

Purpose: Denosumab (DMAb), a fully human monoclonal antibody to RANKL, reduces bone resorption, increases bone mineral density, and decreases risk for vertebral, nonvertebral, and hip fractures in postmenopausal women with osteoporosis.¹ Consistent with DMAB's mechanism of action, transiliac crest bone biopsies from subjects treated with DMAB for 1 to 3 years demonstrated reduced bone turnover, which was reversible with treatment cessation.^{2,3} Since long-term treatment

with DMAB has shown sustained reduction in bone turnover and low incidence of vertebral and non-vertebral fractures through 6 years,⁴ we evaluated the effects of DMAB on remodeling at the tissue level.

Methods: Transiliac crest bone biopsy assessment was conducted as a substudy of the phase 3 pivotal fracture trial (FREEDOM¹) extension

Results: A total of 41 subjects participated in the bone biopsy substudy at month 24, which corresponded to year 5 of study participation (13 cross-over and 28 long-term subjects). Demographics for this subset were comparable with that of the overall FREEDOM study extension population. Mean (SD) number of months from the last dose of DMAB to the first dose of tetracycline was 5.7 (0.5) months. Qualitative bone histology, assessed in all samples was unremarkable, showing normally mineralized lamellar bone. Five subjects in the long-term group did not have osteoid that could be visualized; samples in 4 of 5 were intact and were reported to show normal mineralization. Structural indices, including cancellous bone volume, trabecular number and surface were similar between the cross-over and long-term groups. Consistent with DMAB's mechanism of action, resorption was decreased as reflected by eroded surface in both cross-over and long-term subjects compared with placebo-treated subjects in FREEDOM (Table). A total of 10/13 (77%) cross-over subjects and 14/28 (50%) long-term subjects had specimens with double-tetracycline label in trabecular and/or cortical compartments; 5 cross-over subjects and 10 long-term subjects were evaluable for dynamic trabecular bone parameters at month 24. Dynamic remodeling indices were low for the cross-over and long-term groups, and consistent with reduced bone turnover with DMAB therapy (Table).

Conclusions: DMAB treatment through 5 years results in normal bone quality with reduced bone turnover, consistent with its mechanism of action.

A Prospective Study of Calcium Supplement Intake and Risk of Cardiovascular Disease in Women. Julie Paik^{*1}, Gary Curhan¹, Kathryn Rexrode¹, JoAnn Manson¹, Rimm Eric¹, Eric Taylor². ¹Brigham & Women's Hospital, Harvard Medical School, USA, ²Brigham & Women's Hospital, Maine Medical Center, USA

Purpose: Previous studies on the association between calcium supplements and cardiovascular disease (CVD) in women have reported conflicting results and the relation remains unclear. A recent post-hoc meta-analysis of secondary CVD endpoints in randomized controlled trials suggested that calcium supplements increase risk of CVD, especially myocardial infarction (MI). The two observational prospective studies to date of calcium supplements and coronary heart disease (CHD) risk in women had limited follow-up (7 and 8 years, respectively); one of the two studies suggested that calcium supplements increase MI risk. No study to date has had long-term follow-up or prospectively studied cumulative average calcium supplement intake and CVD risk in women.

Methods: We conducted a prospective analysis of the relation between calcium supplement intake and the risk of CVD in a cohort of 74,272 women participating in the Nurses' Health Study (1984-2006) who were free of CVD and cancer at baseline. Calcium supplement intake was assessed every four years by semiquantitative food-frequency questionnaires. CVD outcomes were defined as CHD (nonfatal MI or fatal CHD) and stroke (nonfatal or fatal).

Results: During 22 years of follow-up, 4,857 cardiovascular events occurred (2,634 CHD and 2,223 stroke events). The age-adjusted relative risk of CVD was 0.67 (95% CI 0.62, 0.72) for women taking >500mg/day of calcium supplements (8.5% at baseline) compared to no calcium supplements. After multivariable adjustment for age, vitamin D intake, and other CVD risk factors, the relative risk of CVD for women taking >500mg/day of calcium supplements compared to no calcium supplements was 0.88 (95% CI 0.81, 0.95; p for trend <0.001). For cumulative average calcium supplement intake and CVD risk, the relative risk of CVD was 0.92 (95% CI 0.84, 1.02) for women taking >500mg/day compared to no calcium supplements. For calcium supplement use and CHD risk, the multivariable-adjusted relative risk of CHD in women taking >500mg/day compared to no calcium

supplements was 0.83 (95% CI 0.74, 0.93; p for trend <0.001). For cumulative average calcium supplement intake and CHD risk, the relative risk of CHD was 0.88 (95% CI 0.76, 1.01) for women taking >500mg/day compared to no calcium supplements.

Conclusions: In our study, calcium supplements were not associated with increased cardiovascular risk, including MI, in women.

Disclosures: Julie Paik, None.

The Women's Health Initiative (WHI) Calcium plus Vitamin D Supplementation Trial: Health Outcomes 5 years after Trial Completion. Jane Cauley^{*1}, Jean Wactawski-Wende², John Robbins³, Rebecca Rodabough⁴, Zhao Chen⁵, Karen Johnson⁶, Mary Jo O'Sullivan⁷, JoAnn Manson⁸. ¹University of Pittsburgh Graduate School of Public Health, USA, ²University at Buffalo, USA, ³University of California, Davis Medical Center, USA, ⁴Fred Hutchinson Cancer Research Center, USA, ⁵University of Arizona, USA, ⁶University of Tennessee Health Science Center, USA, ⁷University of Miami, USA, ⁸Harvard Medical School, USA

The WHI Calcium plus Vitamin D supplementation trial assessed whether 1000 mg of elemental calcium with 400 IU of vitamin D₃ (CaD) versus placebo reduced the risk of hip fracture and colon cancer in 36,282 women who were age 50 to 79 yrs at study entry. After an average of 7 yrs of follow-up, modest, albeit non-significant, reductions were observed for hip, clinical vertebral and total fracture. Coronary heart disease (CHD) and cancer incidence was similar in the 2 groups. Total mortality was slightly lower in the CaD group. The objective of the current analysis was to determine the effects of CaD on outcomes over 7 yrs (trial) and 5 additional yrs of follow-up through September 2010. Follow-up continued after the planned trial completion among 86% of surviving participants, CaD, n=15025 and placebo, n=14837. Primary outcomes were identified from annual mailed questionnaires and adjudicated centrally. Hip fracture was the only fracture adjudicated in the overall period; all other fractures were self-reported. All analyses were intent-to-treat. All participants were included in the analysis according to their randomized group assignment until last contact. The post-intervention risk (annualized rate) of hip fracture among women randomized to CaD was 0.28% compared with 0.30% in the placebo group, hazard ratio (HR)=0.95; 95% confidence interval (CI) (0.78, 1.15); 0.36% vs 0.43%, respectively for clinical vertebral fractures, HR=0.83; 95% CI (0.71, 0.98); 3.31% vs 3.30%, respectively, for total fractures HR=1.00; 95% CI (0.94, 1.06), (see Table). The risk of invasive colorectal cancer was non-significantly lower among women randomized to CaD in the post-intervention period, HR=0.80; 95% CI (0.61, 1.07), while the risk of breast cancer was slightly elevated, HR=1.17; 95% CI (0.99, 1.38), p=0.06. Total cancers did not differ between the CaD and placebo groups. There was no difference in CHD and total and cardiovascular disease mortality by randomized group in the post-intervention period. In the overall period, no significant differences between treatment groups were observed except that vertebral fractures were 13% lower among women randomized to CaD vs placebo, HR=0.87; 95% CI (0.76, 0.98). In conclusion, among postmenopausal women followed for up to 12 yrs, CaD was associated with a decreased risk of vertebral fractures, but, had little effect on the other skeletal and non-skeletal outcomes.

HRpQCT Reveals That Four Years of Estrogen Therapy in Early Postmenopausal Women Prevents Cortical, but Not Trabecular, Bone Loss.
 Joshua Farr¹, Sundeep Khosla², Virginia Miller³, Ann Kearns¹. ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA, ³Department of Surgery, Mayo Clinic, USA

Cross-sectional and longitudinal studies in women have shown that cortical bone mass remains relatively stable until the menopause and then decreases significantly. By contrast, trabecular bone loss begins early in life (in the third decade) and continues throughout life, albeit with an acceleration following menopause. These observational data suggest the hypothesis that loss of cortical bone is closely tied to estrogen (E) deficiency, whereas trabecular bone loss is largely due to intrinsic age-related processes independent of E. Although a number of clinical trials of E therapy have been conducted, none could directly address this hypothesis as virtually all previous studies used DXA, which cannot separate trabecular from cortical bone or assess bone microstructure. Thus, we used HRpQCT to assess cortical and trabecular microstructure at the distal radius at baseline and at 4 years in a subset of early postmenopausal women (mean age, 53 yrs) enrolled in the Kronos Early Estrogen Prevention Study (KEEPS) in which the women were randomized to placebo, oral (0.45 mg/d conjugated equine estrogens) or transdermal (50 µg/d 17β-estradiol) E (both in combination with progesterone, 200 mg/d for 12 d each month). For this mechanistic analysis, we included women who had completed 4 years of treatment. Since the changes in bone microstructure were similar in the oral and transdermal E groups, they were combined and we report data on 31 placebo (PL) and 45 E-treated (ET) subjects. As shown in the Figure (Panel A), ET prevented the decreases in cortical vBMD and increases in cortical porosity observed in the PL group. By contrast, ET was unable to prevent decreases in trabecular bone volume fraction or trabecular thickness (Panel B). Despite these differences in cortical versus trabecular bone responses to ET observed using HRpQCT, ET consistently prevented decreases in hip, spine, and distal radius areal BMD assessed by DXA, suggesting that changes in cortical bone at these sites may have masked ongoing trabecular bone loss.

These direct interventional data thus support the observational findings showing fundamentally different regulation of cortical versus trabecular bone by E. Further animal and human studies are needed to define the mechanisms for the differential responses of trabecular and cortical bone to E as well as the underlying, E-independent processes leading to trabecular bone loss even early in life.

What's "Normal?" Considerations in Establishing the Appendicular Lean Mass DXA Reference Population. Bjoern Buehring*, Ellen Fidler, Jessie Libber, Jennifer Sanfilippo, Brvan Heiderscheit, Diane Krueger, Neil Binklev. University of Wisconsin, Madison, USA

Sarcopenia definitions include appendicular lean mass (ALM) measurement with "low" defined as 2 SD below the young adult mean. However, population body composition continues to change over time, thereby complicating the reference standard to which DXA measurements are compared. Given this variation in "normal", a potential alternative approach is comparison with people similar to ancestral hunter-gatherers in activity as a physiologic "normal." Young athletes may represent such a population. This work compares athletes' body composition parameters with NHANES young adults and explores sarcopenia prevalence using cutpoints derived from differing reference populations.

Table: Effects of CaD compared with placebo on clinical outcomes during the intervention, post-intervention and combined phases in WHI CaD trial

| | CaD | | Placebo | | HR (95% CI) |

Dose Response to Vitamin D Supplementation: Substantial Underestimate by Endocrine Society Clinical Practice Guidelines (CPG) Compared to the Institute of Medicine (IOM) Report.. Malachi McKenna*, Barbara Murray. St. Michael's Hospital, Ireland

Background: In 2011, IOM updated their *Dietary Reference Intake (DRI)* for vitamin D; they specify that 600 IU/d meets the needs of 97.5% of the population assuming minimal sunlight exposure. Shortly afterwards, the CPG for the *Evaluation, Treatment and Prevention of Vitamin D Deficiency* was published that recommends intakes up to 2000 IU/d without reference to sunlight exposure. There are at least three major differences between IOM and CPG: (1) target 25OHD (IOM noted a plateau effect at 30-to-40 nmol/L with little or no benefit above 50 nmol/L; CPG set a target of 75 nmol/L with a level below this target being labelled as "insufficiency"); (2) definition of vitamin D deficiency (IOM adopts a probabilistic approach based on 25OHD level within a range of 30-to-50 nmol/L; CPG designates vitamin D deficiency as a 25OHD <50 nmol/L); and (3) at-risk individuals (IOM specifies particular at-risk members of the general population that are addressed by their DRIs, but the same groups are considered by CPG as needing higher intakes).¹ Differences in the estimation of vitamin D dose-response may also account for the discrepancies between the two reports. The CPG states that the rate of rise of 25OHD is approximately 2.5 nmol/L/100 IU/d. The IOM dose-response is a logarithmic function that includes all oral vitamin D intake: serum 25OHD=ln(vitamin D intake IU/d). We sought to test the validity of these dose-responses by analyzing responses to vitamin D supplementation from different studies.

Methods: Studies analyzed in three reports (IOM, AHRQ-Ottawa, and AHRQ-Tufts) were selected. The ratio of observed:expected 25OHD for both IOM and CPG was calculated.

Results: Sixty studies were selected with duration ranging from 3-months to 60-months, and with daily doses ranging from 230 IU/d to 2000 IU/d, or intermittent high doses ranging from 15,000 IU/wk to 600,000 IU/6-month. The mean ratio (CI) for CPG at 1.86 (1.53-2.19) was significantly higher than for IOM at 1.13 (1.03-1.24).

Conclusion: The CPG "rule of thumb" underestimates by nearly twofold the dose response to oral vitamin D supplementation. That CPG inflates the problem of vitamin D deficiency coupled with the underestimation of the dose response means that individuals are apt to be put in harm's way if clinicians adhere to the CPG.

Disclosures: Malachi McKenna, None.

Methods: Total body DXA measurements (Lunar iDXA) were obtained in college athletes. NHANES (1999–2004) DXA body composition data (Hologic) were downloaded from the NHANES website; 20–29 year olds were used for comparison. ALM was calculated based on lean mass excluding bone values. Athlete and NHANES BMI, ALM/ht², peripheral % fat and leg fat/lean ratio were compared by t-test using JMP (SAS, Cary, NC).

Results: The mean (range) age and BMI of 313 athletes (163M/150F) and 2116 NHANES (1117M/999F) participants was 20.0 (18–24) vs. 24.3 (20–29) years and 24.5 (18.1–38) vs. 26.9 (14.4–65.0) kg/m² respectively. Athletes had lower BMI, higher ALM/height² ratios (8.58 vs. 7.85 kg/m²), lower % peripheral fat (20.5 vs. 32.4%) and leg fat/lean mass ratios (0.30 vs. 0.58, all p≤0.0001). This was also true when separated by gender (all p≤0.0001). “Low” ALM/ht² cutpoints (2 SD below young mean) differed using the athletes, NHANES and commonly utilized values (Table). Applying these cutpoints to 70–85 year old individuals in NHANES 1999–2004, sarcopenia prevalence ranged from 4% (NHANES as reference) to 32% (athletes as reference).

In conclusion, there is great variation in potential “normal” body composition data depending on the reference population used. Applying ALM/ht² cutpoints using different reference datasets results in large differences in sarcopenia prevalence; similarly, measures of body fat vary dramatically. Simplistic use of a “normal” population, (e.g., NHANES) as a reference dataset, as has been done for BMD, may not be appropriate. An alternative approach using “optimal” or “ancestral” body composition might better predict outcomes such as falls, mobility and/or fracture.

Values to define low ALM/ht² (kg/m²) using different reference data:

| Reference population | Male | Female |
|----------------------|------|--------|
| Athlete | 7.51 | 5.83 |
| NHANES | 5.76 | 4.24 |
| Baumgartner | 7.26 | 5.45 |

Muscle, Fat and Bone Connections: Genetic Risk Factors of Sarcopenic-Obesity and Dynapenic-Obesity and Their Consequent Risks of Osteoporotic Fractures. Yi-Hsiang Hsu*¹, Robert McLean², Elizabeth Newton³, Marian Hannan⁴, L Adrienne Cupples⁵, Douglas Kiel⁶. ¹Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ²Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ³Hebrew SeniorLife Institute for Aging Research, USA, ⁴HSL Institute for Aging Research & Harvard Medical School, USA, ⁵Dept Biostatistics, Sch of Public Health, Boston University, USA, ⁶Hebrew SeniorLife, USA

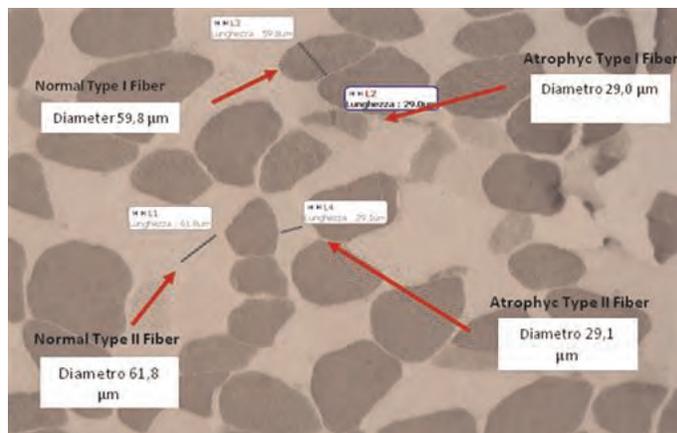

Sarcopenic-obesity (SO) and Dynapenic-obesity (DO) is characterized by excess body fat and decreased muscle mass and strength, respectively. It is common and affecting > 12% of U.S. adults aged ≥ 60 years. As a growing number of US seniors are living longer and an epidemic of obesity, SO has become a major public health burden. Although obesity is a known risk factor for major adverse health outcomes, emerging evidence shows that older adults with SO have an even greater risk on fractures, cardiovascular diseases, mobility impairment and disability compared to those with obesity or sarcopenia alone. Identifying genetic risk factors for SO and DO and their association with fracture may help to understand the underlying biology and identify new molecular targets for treatments. We performed a GWAS in 3,763 Framingham men and women participants > 50 years with 2.6 million SNPs under an additive model adjusted for potential confounders. To identify unique genetic determinants associated with SO only, we applied a mixed-effect multinomial-logit model, which accounts for the relations among obesity alone, sarcopenia alone and SO when estimating the association between SNPs and SO. We defined SO using fat and muscle mass (DXA appendicular lean mass divided by height²); and DO using fat mass and muscle strength (lowest sex-specific tertile of grip strength). Obesity was defined as total body fat % (DXA) >30 in men and >40 in women. We classified 11%, 48% and 10% of participants with SO, obesity alone and sarcopenia alone, respectively. We classified 10%, 47% and 7% of participants with DO, obesity alone and sarcopenia alone, respectively. We found SNPs significantly associated with SO only, but not obesity or sarcopenia alone, i.e. SNPs located in or near *MANBA*, *CENPE*, *PGK2* (associated with SO) and *FNI* (associated with DO) gene. Of note, a few of these SNPs were also reported to be associated with diabetes, restless leg syndrome or subclinical atherosclerosis from other GWAS. We found SNPs significantly associated with obesity alone were not found to be associated with SO (or DO). Several of the top SNPs were also found associated with osteoporotic fractures by mendelian randomization analyses. The top findings (p < 5x10⁻⁵) are further replicating in independent samples. In conclusion, our results reveal novel candidate genes associated with SO and fracture, but not with obesity or sarcopenia alone, which suggests that underlying pathophysiology of SO may be different from fatness alone and/or muscle weakness alone.

Hip Fracture and Sarcopenia: A Model of Osteoporosis-related Muscle Atrophy. Umberto Tarantino*¹, Monica Celi², Jacopo Baldi³, Fabio Luigi Perrone³, Federico Maria Liuni³, Elena Gasbarra³. ¹Azienda Ospedaliera PTV, Italy, ²University of Rome Tor Vergata, Italy, ³orthopaedic Department University of Rome Tor Vergata, Italy

Osteoporosis and sarcopenia are considered two of the hallmarks of the aging process; the reduction of muscle mass and power may affect bone strength and Bone Mineral Density (BMD) by modifying loads to the skeleton. This could lead to an increased risk of fragility fracture, functional limitations and motor dependency. Aim of the study was to evaluate the degree of muscular atrophy in patients with osteoporosis and osteoarthritis and to determine the role of IGF-1/PI(3)/Akt signaling pathway in the genesis of a specific type II osteoporosis-related muscle atrophy. For this study we performed vastus lateralis biopsy in 60 women (mean age 71,53 ± 9,74) underwent orthopaedic surgery; 30 women with osteoporosis undergoing primary Total Hip Arthroplasty (THA) for hip fracture (Group A); 30 women underwent surgery for hip osteoarthritis with no significant functional limitations (Group B). Muscle fibers were measured and classified by ATPase reaction. To evaluate whether Akt and pAkt are involved in osteoporosis-related muscle atrophy, muscle homogenates of twelve patients from Group A presenting higher percentage of type II fiber atrophy and twelve age-matched control biopsies from Group B were immunoblotted. In Group A atrophic type-II fibers were 3-fold more frequent than atrophic type I fibers (36,86%; p<0.01); in Group B the same fibers atrophy were 1.5-fold more frequent than type I atrophy (12,50%; p<0.001). Muscular atrophy significantly correlates with osteoporosis degree (p<0.05) in Group A; in Group B it significantly correlates disease duration, degree of pain and functional impairment of hip joint. Furthermore patients with higher percentage of type II fiber atrophy from Group A shown values of intramuscular Akt two and a half times (60%; p<0,01) lower than the same values from Group B. Immunoblotting didn't verify the activation status of intracellular pAkt probably due to its low expression in atrophic fibers. Osteoporotic patients shown a preferential and diffuse type II fiber atrophy, that seems to be related to disease severity. On the opposite, in osteoarthritic patients, atrophy involves seems to be caused by disuse and pain. The reduction of Akt observed in the muscle of individuals from the osteoporotic group, may be one of the possible moments of compromise in intracellular IGF-1/PI(3)/Akt signaling pathway that is likely to stimulate protein synthesis and cell survival as a result of activation of the complex mTOR/p70S6K22.

Poor Peripheral Nerve Function Is Associated with Higher Bone Marrow Fat and Skeletal Muscle Adiposity: The Osteoporotic Fractures in Men (MrOS) Study. Elsa S. Strotmeyer^{*1}, Jane Cauley¹, Yahtyng Sheu¹, Kimberly A. Faulkner², Tanushree Prasad¹, Rachel E. Ward¹, Sasa Zivkovic³, Peggy Cawthon⁴, Iva Miljkovic¹. ¹University of Pittsburgh Graduate School of Public Health, USA, ²National Institute for Occupational Safety & Health, USA, ³University of Pittsburgh School of Medicine, USA, ⁴California Pacific Medical Center Research Institute, USA

Poor peripheral nerve function has been related to lower muscle strength and lower bone mineral density, independent of diabetes, in older populations. To expand these previous findings, we investigated if peripheral nerve function was related to higher bone marrow fat or skeletal muscle adiposity. Poor sensory nerve function was assessed by lower sural nerve conduction amplitude (SNAP=amplitude in uV) from a neurodiagnostic instrument (NC-stat®, NeuroMetrix, Inc.) and lack of detection from a light touch 1.4-g and standard 10-g monofilament. Poor motor nerve function was assessed by lower peroneal nerve conduction amplitude (CMAP=amplitude in mV), using the same neurodiagnostic instrument. Poor nerve function (worse tertile vs. middle/best tertile or lack of monofilament detection) was related to outcomes from pQCT of calf intermuscular fat (IMAT) and muscle density, which reflects intramuscular fat content, in regression analyses adjusting stepwise (p<0.10 for inclusion) for age, race, diabetes, total calf fat and muscle area, height, smoking, drinking frequency, physical activity, physical function, medications/supplements and diabetes-related conditions. Participants were 613 men (77.5±5.2 years; 99% white; 21% diabetes) from MrOS in Pittsburgh, PA. Lack of monofilament detection (1.4-g for IMAT; 10-g for density) and the worst tertile of CMAP vs. middle/best tertiles were associated with higher IMAT and lower density (Table). Worst SNAP tertile vs. middle/best tertiles related to higher IMAT but not density. In a subset of 144 men, only lack of 1.4g monofilament detection was related with higher % bone marrow fat (BMF; 57.8±1.3 vs. 53.8±1.3%; p<0.05), adjusted for above but total fat and lean mass from DXA rather than pQCT body composition variables. Results indicated poor sensorimotor nerve function is associated with muscle fat infiltration independent of muscle area and poor monofilament detection is related to higher BMF in older men.

Table: Adjusted means of skeletal muscle adiposity by poor peripheral nerve function from regression analyses.

| *p-value < 0.05 | Adjusted mean ± SE | |
|---|-----------------------------|---------------------|
| | Worst tertile | Middle/Best tertile |

Changes in Thigh Muscle Volume Predict Changes in Femoral BMD in Sarcopenic Elderly Obese Adults Undergoing Lifestyle Therapy. Reina Armamento-Villareal¹, Nicola Napoli², Krupa Shah³, Lina Aguirre^{*4}, Tiffany Hilton⁵, David Sinacore⁶, Dennis Villareal¹. ¹University of New Mexico School of Medicine, USA, ²University Campus Biomedico, Italy, ³University of Rochester School of Medicine, USA, ⁴New Mexico VA Health Care System, USA, ⁵Ithaca College, USA, ⁶Washington University School of Medicine, USA

Purpose: Loss of femoral BMD and lean body mass are major complications of weight loss (WL) from lifestyle therapy in frail sarcopenic elderly obese (EO); but these adverse effects can be attenuated by exercise (EX). We reported that WL-induced bone loss is mediated by increase in sclerostin; however, the contribution of mechanical strain loss from muscle loss, particularly at the thigh, is poorly defined. We hypothesize that the negative effects of WL and the protective effect of exercise (EX) on femoral bone is modulated by changes in thigh muscle volume (TMV) leading to differences in mechanical strain and sclerostin production. The objective of this study is to examine changes in TMV and muscle strain and their effects on femoral BMD in EO subjects undergoing WL, EX and WL+EX.

Methods: 107 obese (BMI>30), older (age ≥ 65) subjects were randomized for 1 yr to control (CTRL) (n=27), WL (n=26), EX (n=26) and WL+EX (n=28) groups. WL was by dietary/behavioral intervention designed to induce and maintain WL of 10% of body weight; EX was by 3 supervised resistance/aerobic exercise sessions/wk and CTRL was to continue usual dietary and activity habits. TMV was measured using magnetic resonance imaging of both thighs at 0 and 12 mos; while BMD by DXA, sclerostin by Elisa, strength (knee extension and flexion by BIODEX) and physical function by Physical Performance Testing (PPT), were measured at 0, 6 and 12 mos.

Results: Data on BMD, physical function and sclerostin were reported elsewhere. Significant reduction in TMV relative to CTRL and EX was observed in the WL group while reduction in TMV in the WL+EX (Fig. 1) was not different from the CTRL. These changes followed the same pattern as the changes in total hip BMD. Both knee extension and flexion increased in the EX and WL+EX and were unchanged in the CTRL and WL (Fig. 2). TMV changes correlated with: total hip BMD changes (r=0.55, p=0.000), changes in sclerostin (r=-0.26, p=0.03) and with a borderline correlation with changes in knee flexion (r=0.23, p=0.06). Multivariate analysis showed TMV and PPT changes as predictors for hip BMD changes.

Conclusion: Changes in TMV modulate femoral BMD changes in frail EO patients undergoing lifestyle therapy. WL-induced thigh muscle loss is attenuated by EX resulting in similar improvement in strength in WL and WL+EX groups. This positive effect of EX when added to WL may in part account for the relative reduction in WL-associated bone loss in the WL+EX patients.

Changes in thigh muscle volume during lifestyle intervention in sarcopenic obese older adults

worsening fracture was estimated by logistic regression models adjusted for age, race, clinic, alcohol, smoking, BMI, diabetes, lumbar spine BMD and self-reported physical activity. Complete fracture, physical function and covariate data were available for 3,964 men (mean age: 72.8 years), of whom 444 (11.2%) had a vertebral fracture (SQ \geq 1) at baseline.

During 4.6 years of follow-up, 171 (4.3%) men had a new or worsening vertebral fracture. Weak grip strength; longer time/inability to complete the repeat chair stands; poor balance (inability to complete the narrow walk); and lower leg power were each associated with increased likelihood of new or worsening radiographic vertebral fracture (Table). Slow walking speed was not associated with vertebral fracture. Analysis of the summary physical function score indicated that each additional test with poor performance increased the likelihood of fracture by about 20% [OR: 1.2 (95% CI: 1.1, 1.4) per one unit increase in summary score]. Similar results were seen when analyses were limited to new radiographic vertebral fractures only and when results were adjusted for total hip BMD rather than lumbar spine BMD.

In summary, men with poor physical function, in particular decreased lower leg power, were more likely to develop a radiographic vertebral fracture than men with better function.

Likelihood (Odds ratio, 95% confidence interval) of new or worsening vertebral fracture, by baseline physical function

| Function category | Grip strength* | Leg Power* | Chair stands* | Narrow walk | Walking speed |
|-------------------|----------------|----------------|----------------|----------------|----------------|

Genome-wide Profiling of DNase-Hypersensitivity during Osteoblastogenesis. Phillip Tai*, Hai Wu, Troy W. Whitfield, Jonathan Gordon, Jane Lian, Andre Van Wijnen, Gary Stein, Janet L. Stein. University of Massachusetts Medical School, USA

Gene expression during the process of osteoblastogenesis has been well-described, and multiple studies have focused on characterization of the regulatory mechanisms that define many selected bone-related genes. However, the relationship between chromatin state, bone-related gene regulation, and the cell-type specific partitioning of the genome into promoters, enhancers, silencers, insulators, and locus control regions, has yet to be fully characterized. Traditionally, DNaseI-hypersensitivity assays have been used to discover regions of chromatin that are bound by nuclear-factor complexes *in vivo* without the prior identification of the binding factor(s). The *de novo* identification of regulatory regions is possible because DNaseI preferentially digests chromatin depleted of nucleosomes - presumably due to transcription factor occupancy. We have produced unbiased genome-wide maps of regulatory regions during defined phases of osteoblastogenesis by identifying open regions of chromatin using DNaseI-hypersensitivity coupled with high-throughput sequencing (DNase-seq). Specifically, we have generated DNase-seq libraries of growth-phase MC3T3-E1, a model cell-culture system for studying osteoblastogenesis, as well as libraries of cultures subjected to differentiation conditions. We demonstrate the presence of regions exhibiting dynamic DNase-hypersensitivity at gene promoters that are known to be differentially expressed during osteoblastogenesis, as well as regions that are in close proximity to these genes. Furthermore, the comparison of DNaseI-hypersensitivity regions with the global binding of RUNX2, a master regulator of osteogenesis, as assayed by chromatin immunoprecipitation followed by high-throughput sequencing (ChIP-seq), shows interesting correlations among bone-related genes throughout differentiation. The diversity of RUNX2 enrichment that overlaps DNase-hypersensitivity regions throughout the genome implicates RUNX2 in a variety of roles: 1) its binding at far-distal regions demonstrates its role as a genome organizer, 2) enrichment of RUNX2 at exonic and intronic sequences suggests its role as a modifier of chromatin state and gene transcription, and 3) its occupancy at promoters suggests its function as an activator or repressor of gene expression. This on-going work illustrates the dynamic properties of chromatin architecture and has great potential for revealing novel regulatory regions critical for bone-related gene expression.

Physical Performance and Risk of Vertebral Fractures in Older Men. Peggy Cawthon*¹, Terri Blackwell², John Schousboe³, Lynn Marshall⁴, Howard Fink⁵, Deborah Kado⁶, Kristine Ensrud⁷, Jane Cauley⁸, Dennis Black⁹, Eric Orwoll⁴, Steven Cummings¹⁰. ¹California Pacific Medical Center Research Institute, USA, ²CPMC RESEARCH INSTITUTE, USA, ³Park Nicollet Clinic/University of Minnesota, USA, ⁴Oregon Health & Science University, USA, ⁵GRECC, Minneapolis VA Medical Center, USA, ⁶University of California, Los Angeles, USA, ⁷Minneapolis VA Medical Center / University of Minnesota, USA, ⁸University of Pittsburgh Graduate School of Public Health, USA, ⁹University of California, San Francisco, USA, ¹⁰San Francisco Coordinating Center, USA

Poor physical function has been associated with higher risk of hip and other non-spine fractures in older men, but the relation to vertebral fractures is unclear.

MrOS is a prospective cohort study of ambulatory men aged \geq 65 yrs at baseline. At baseline and again 4.6 years later, lateral spine films were reviewed using semi-quantitative (SQ) grading for new or worsening radiographic vertebral fractures (defined at follow-up as a change in SQ grade \geq 1). Physical function was assessed by walking speed (usual pace, m/s over 6 m); narrow walk (walking speed in m/s over a 6 m by 20 cm course); repeated chair stands ability (time to complete 5 stands); grip strength; and leg power (by Nottingham Power Rig). Physical function measures were analyzed as quartiles with those unable to complete the test included in a separate category (when data were available). A summary physical function score (range: 0-5) was calculated; for each of the 5 tests with poor performance (defined as in the worst performance quartile or unable to complete the measure), one point was added to the summary score; higher scores indicate worse function. Likelihood of new or

miR-17-92 Cluster Critically Regulates Osteoblast Differentiation. Mingliang Zhou*¹, Junrong Ma², Xiang Chen², Meng Gong², Xijie Yu².
¹West China Hospital, Sichuan University, Peoples Republic of China,
²Laboratory of Endocrinology & Metabolism, West China Hospital, Sichuan University, China

The miR-17-92 cluster encodes six miRNAs (miR-17, miR-18a, miR-19a, miR-20a, miR-19b-1, and miR-92-1), which are highly conserved in all vertebrates. Loss-of-function of the miR-17-92 cluster resulted in smaller embryos and immediate postnatal death of all animals due to severely hypoplastic lungs and ventricular septal defects in the hearts. Germline hemizygous deletions of *MIR17HG* were accounted for microcephaly, short stature and digital abnormalities in a few cases of Feingold syndrome. These reports indicate that miR-17-92 may play important function in growth and skeletal development. However the precise roles of the miR-17-92 cluster in skeletal development and growth are largely unknown. To determine the functional roles of miR-17-92 in osteoblast differentiation, embryonic stem cells (ES cells) and bone marrow stromal cells (BMSCs) were induced to different into osteoblasts under osteogenic medium; the expression of miR-17-92 was assayed by quantitative real-time RT-PCR. The expression of miR-17-92 was down-regulated along with osteoblast differentiation, the lowest level was found in mature osteoblast. To determine the systemic function of miR-17-92 in skeleton, the bone mineral density (BMD) and bone volume were assayed in miR-17-92^{+/+} mice by DXA and micro-computed tomography (μ CT) respectively. Compared to wildtype controls, miR-17-92^{+/+} mice showed significantly lower trabecular and cortical BMD, bone volume and trabecular number at 10 weeks old. To determine the possibly direct function of miR-17-92 in bone cells, osteoblasts from miR-17-92^{+/+} mice were investigated by ex vivo cell culture, miR-17-92 was further conditionally deleted in osteoblasts by 2.3-kb *Col1a1-Cre* (miR-17-92^{ΔOB/ΔOB}). Osteoblasts from miR-17-92^{+/+} mice showed lower ALP activity and less calcification. miR-17-92^{ΔOB/ΔOB} mice demonstrated lower BMD, bone volume and trabecular number. Taken together, our results suggest that the miR-17-92 cluster critically regulates skeletal development, and this regulation is mostly through its function in osteoblasts.

miRNA-34c Regulates Notch Signaling during Bone Development. Yangjin Bae*¹, Tao Yang¹, Huan-Chang Zeng¹, Philippe Campeau², Yuqing Chen², Terry Bertin², Brian Dawson², Elda Munivez², Jianning Tao¹, Brendan Lee³.
¹Baylor College of Medicine, USA, ²Baylor College of Medicine, USA, ³Baylor College of Medicine & Howard Hughes Medical Institute, USA

MicroRNAs (miRNAs) are small non-coding RNAs, which mediate post-transcriptional silencing of target genes by either mRNA degradation or translational inhibition. Growing evidence indicates that miRNAs play critical roles during development, cellular differentiation, and homeostasis by regulating hundreds of targets. To date, the important roles of miRNAs in bone development and homeostasis have been suggested by excision of *Dicer* in mice using osteoblast specific *Cre* transgene. However, there are few mouse models that demonstrated either the physiological or pathological role of individual miRNAs in bone. During bone homeostasis, osteoblast and osteoclast differentiation are coupled and regulated by multiple signaling pathways and their downstream transcription factors. Here, we show that miRNA-34c (miR-34c) is significantly up-regulated in BMP2 mediated osteoblast differentiation of C2C12 cells. *In vivo*, osteoblast-specific gain of miR-34c in mice (*Coll1a1-miR34c*) leads to an age-related osteoporosis due to the defective mineralization and reduced proliferation of osteoblasts, and increased bone resorption due to increased osteoclastogenesis. This hyper-resorptive phenotype of *Coll1a1-miR34c* mice phenocopies our earlier study of the loss of Notch in osteoblasts. A transcriptome profile analysis confirmed that miR-34c indeed targets multiple components of the Notch signaling pathway including *Notch1*, *Notch2*, and *Jag1* in a direct fashion, and influences osteoclast differentiation in a non-cell-autonomous fashion. Furthermore, we showed that the defect in the osteoblast differentiation of *Coll1a1-miR34c* mice was due to the cell autonomous effect by the predicted targeting of *Satb2* and *Rumx2* rather than Notch signaling. Taken together, our study demonstrates a critical role of miR-34c in bone homeostasis by affecting both osteoblasts and osteoclasts *in vivo* via the regulation of multiple targets in osteoblasts. Furthermore, miR-34c-mediated post-transcriptional regulation of Notch signaling in osteoblasts may be targeted to antagonize the proliferative effect of Notch in the pathogenesis of osteosarcomas. Therefore, understanding the functional interaction of miR-34 and Notch signaling in normal bone development and in bone cancer could potentially lead to therapies.

Progranulin Accelerates Bone Regeneration through Stimulating Osteoblastogenesis and Repressing Osteoclastogenesis. Chuanju Liu, Yunpeng Zhao*¹, Qingyun Tian, Brendon Richbourgh, Shuai Zhao, New York University, USA

We have previously reported that progranulin (PGRN) growth factor was expressed in the growth plate of long bone and played a critical role in endochondral ossification (Feng JQ, et al, *FASEB J.* 2010;24(6):1879-92, Bai XH, et al, *Mol Cell Biol.* 2009; 29(15):4201-19). Additionally, we recently reported that PGRN directly bound to TNF receptors, antagonized TNF-alpha activity, and protected against bone erosion in inflammatory arthritis (Tang W, *Science.* 2011; 332(6028):478-84). This study is to determine the potential role of PGRN in bone regeneration and the molecular events involved. To do so, we first established several bone defect models, including a drill-hole, a femoral segmental nonunion, and a radial non-union model, and compared the effects of the deletion of the PGRN gene and/or administration of recombinant PGRN growth factor on bone regeneration. Immunohistochemistry revealed that PGRN was clearly expressed in the newly-formed bone *in vivo*. Micro-CT and histological assays demonstrated that the deficiency of PGRN led to a significant defect in bone regeneration, whereas the administration of recombinant PGRN protein stimulated this process. PGRN acted as an important downstream mediator of BMP-2 in the course of osteogenesis since the deletion of PGRN significantly blocked BMP-2-induced osteoblast differentiation *in vitro* and ectopic bone formation *in vivo*. Importantly, the application of recombinant PGRN into PGRN knockout mice could rescue the impairment in BMP-2-triggered bone formation. Molecular studies revealed that the knockdown of PGRN using a siRNA approach in C2C12 mesenchymal precursor cells inhibited, while recombinant PGRN stimulated, the luciferase activity of Cbfa-specific reporter genes and the expressions of marker genes for osteogenesis, including osteocalcin and alkaline phosphatase (ALP). In addition to stimulating the osteoblast differentiation, PGRN was also found to function as an antagonist of TNF α and to inhibit TNF-induced osteoclastogenesis *in vitro* and in TNF transgenic mice. Furthermore, elevated osteoclast activity detected with TRAP staining was observed in the collagen-induced arthritis model of PGRN-null mice when compared with those of wild type mice. Taken together, PGRN is a novel regulator of bone remodeling and mediates this process via a dual mechanism, i.e. the stimulation of osteoblastogenesis and the suppression of osteoclastogenesis. These findings may not only provide novel insights into the role of PGRN in regulating bone regeneration and remodeling, but also present a potential therapeutic target for treating bone defects clinically.

Semaphorin 3A Inhibits Osteoclastogenesis and Promotes Osteoblastogenesis Synchronously. Mikihito Hayashi*¹, Tomoki Nakashima¹, Hiroshi Takayanagi².
¹Tokyo Medical & Dental University, Japan, ²The University of Tokyo Department of Immunology, Japan

Bone homeostasis is maintained by the crosstalk between bone-forming osteoblasts and bone-resorbing osteoclasts. Osteoblasts contribute to the regulation of osteoclasts by producing anti-osteoclastogenic factors. However, an inhibitory factor of osteoclast differentiation derived from osteoblasts was not identified except for Opg, a decoy receptor for RANKL. Here we show that a conditioned medium of Opg-deficient calvarial cells contains factors that inhibit osteoclast formation. By means of functional screening and mass spectrometric analysis, we identified that one of these factors is the axon guidance molecule Semaphorin 3A (Sema3A).

Sema3a^{-/-} mice exhibited a severe low bone mass phenotype accompanied by enhanced osteoclast differentiation. Sema3A-induced inhibition is mediated by the modulation of DAP12-induced ITAM signalling. Neuropilin-1 (Nrp1), a receptor for Sema3A, competes with TREM2 for Plexin-A1, thereby functioning as a suppressor of the Plexin-A1-TREM2-DAP12-induced costimulatory signal. The inhibition of RhoA activation is also involved in the inhibitory effect of Sema3A on the migration of osteoclast precursor cells.

In addition to an osteoclastic phenotype, *Sema3a*^{-/-} mice also showed a severe defect in osteoblast differentiation and an increase in adipocyte differentiation in bone marrow. These findings suggest that Sema3A promotes mesenchymal cell differentiation toward osteoblasts, but not adipocytes. Sema3A stimulates the canonical Wnt/ β -catenin signalling pathway, at least in part, through FARP2-mediated activation of Rac1 during osteoblast differentiation. The osteopenic phenotype in *Sema3a*^{-/-} mice was recapitulated by mice in which the Sema3A-binding site of Nrp1 had been genetically disrupted.

We further investigated the therapeutic potential of Sema3A in a bone regeneration model of cortical bone defects induced by drill hole injury. The local administration of Sema3A into the injured site accelerates bone regeneration. Sema3A treatment reduced bone loss after ovariectomy by both inhibiting osteoclastic bone resorption and promoting osteoblastic bone formation synchronously. Thus, Sema3A is a promising new therapeutic agent in bone and joint diseases. This study demonstrates that Sema3A expressed by osteoblast lineage cells functions as an osteoprotective factor with the capacity to bring both osteoblasts and osteoclasts into a condition which favors bone mineral increase.

Histone Deacetylase 3 Depletion in Mature Osteoblasts Promotes Apoptosis and Progressive Bone Loss With Age. Meghan McGee-Lawrence*, Elizabeth Bradley, Samuel Carlson, Qingshan Chen, Kai-Nan An, Jennifer Westendorf. Mayo Clinic, USA

Histone deacetylase 3 (Hdac3) is a nuclear enzyme that removes acetyl groups from lysine residues in histones and other proteins to epigenetically regulate gene expression. Hdac3 interacts with bone-related transcription factors and co-factors (e.g., Runx2, Zfp521), and thus is poised to play a key role in skeletal development and maintenance. We previously reported that conditional deletion of Hdac3 in osteochondral progenitor cells, using Osterix-Cre recombinase, caused severe osteopenia and increased marrow adiposity with developmental defects in both cartilage and bone. To better understand the effects of Hdac3 in bone, independent of changes in cartilage, we developed a new model where Hdac3 insufficiency was targeted to osteoblast- and osteocyte-enriched populations by driving Cre expression with the Osteocalcin promoter.

Mice deficient in Hdac3 in osteocalcin expressing cells (Ocn-Hdac3 CKO) had low cortical and trabecular bone mass compared to age-matched wildtype (WT) mice. Bone length, body size, and chondrocyte development were unaffected, confirming the bone specificity of this model. Unlike our previous Osterix-Cre Hdac3 insufficient model, changes in marrow adiposity were not observed in Ocn-Hdac3 CKO mice and primary bone marrow stromal cells (BMSC) did not differentiate into adipocytes during osteogenic culture. Bone fractures were common in the Ocn-Hdac3 CKO mice due to reduced cortical bone mineralization and material properties. Hdac3 insufficiency caused a global decrease in both bone formation and resorption. Although osteoblast activity (measured via dynamic histomorphometry) was unaffected, osteoblasts in Ocn-Hdac3 CKO mice had a flattened morphology. BMSC cultures from Ocn-Hdac3 CKO mice expressed lower levels of characteristic osteoblast genes and failed to produce WT levels of mineralized matrix. Cortical bone explants from Hdac3-insufficient mice had decreased expression of osteoblastic genes, pointing to an overall decrease in osteoblast number. Mechanistically, Hdac3 insufficiency in Ocn-expressing cells increased apoptosis both in vivo and in vitro. These data are consistent with the effects of pharmacological Hdac inhibitors on BMSC, which experience DNA damage, cell cycle arrest, and apoptosis in response to pan-Hdac inhibition during osteoblastic differentiation. Thus, Hdac3 expression in mature osteoblasts is essential for osteoblast survival and proper bone formation.

Regulation of Energy Metabolism by Bone Sialoprotein, a Novel Endocrine Mechanism. Jake Jinkun Chen*¹, Yuwei Wu², Liming Yu¹, Shu Meng¹, Qisheng Tu¹. ¹Tufts University School of Dental Medicine, USA, ²Tufts University, USA

Bone sialoprotein (BSP) is a major non-collagenous matrix protein in bone and other mineralized tissues that belongs to the small integrin-binding ligand, N-linked glycoprotein (SIBLING) family, whose members play multiple and distinct roles in the development, turnover, and mineralization of bone and dentin, and endocrine regulation of energy metabolism, but their functional specificities are unknown. To determine the effect of BSP in maintaining bone homeostasis through regulating bone remodeling and in regulating energy metabolism, we have first generated conditional BSP knockout mice (BSP KO) by crossing the floxed BSP mice (homozygosity) with osterix-Cre mice that specifically express Cre in osteoblasts. Although BSP KO mice were viable and bred normally, bone morphological abnormalities were clearly exhibited. When compared with wild type littermates, BSP KO mice displayed that the cartilage cells were pathologically flat and arranged disorderly in the growth plate where the number of cartilage cells decreased and no obvious hypotrophic cartilage cells were present. Histological analyses also showed that at 8 months approximately 3-4 times more megakaryocytes formed in BSP KO mice compared with wild type mice in bone marrow space. Moreover, conditional BSP knockout reduced the expression of Runx2, RANKL, NFATc1 and cathepsin K in bone tissues. Furthermore, BSP deficiency in bones decreased the expression of adiponectin in bone and fat tissues as serum BSP level decreases concomitantly. To further determine the effects of BSP on the secretion of adiponectin by adipocytes we treated 3T3-L1 preadipocyte cells with BSP (50ng/mL), which increased lipid accumulation and the expression of adiponectin, adipocyte fatty acid-binding protein (aP2), and PPAR γ messenger RNA by 3.09, 2.46 and 1.4 fold above basal values, respectively. While overexpression of BSP leads to an uncoupling of bone formation and bone resorption in mice, as shown in our previous gain-of-function study, it is interesting to find that the lack of BSP affects both osteoblast and osteoclast formation and function. For the first time, our results suggest that BSP regulates energy metabolism by modulating adipocytokine and the enzymes of lipid metabolism, aP2 and PPAR γ in an endocrine/paracrine manner and systemic pathway. Continued research and data collection will further develop our understanding of the mechanisms by which BSP contributes to bone development and energy metabolism.

Hdac3 Regulates Chondrocyte Hypertrophy and Matrix Secretion by Repressing Phlpp1 Expression and Facilitating Akt Signaling. Elizabeth Bradley*¹, Lomeli Carpio¹, Meghan McGee-Lawrence¹, Alexandra Newton², Jennifer Westendorf¹. ¹Mayo Clinic, USA, ²University of California, USA

Hdacs epigenetically regulate cellular processes by modifying chromatin and influencing gene expression. Conditional deletion of Hdac3 in osterix-expressing osteo-chondroprogenitor cells causes severe osteopenia and runting because osteoblast numbers are reduced and growth plate chondrocyte maturation is disrupted. Hdac3-deficient chondrocytes enter hypertrophy sooner, but are smaller and secrete less extracellular matrix due to underphosphorylation and decreased activation of the central intracellular kinase, Akt, a crucial factor governing chondrocyte commitment, proliferation and maturation to hypertrophy. Hdac inhibitors also attenuate Akt activation by both Tgf β and Igf1, two modulators of chondrocyte differentiation. In this study we explored the mechanisms by which Hdac3 alters Akt activity in chondrocytes. Using a candidate approach, we surveyed phosphatases that were modulated by both Hdac inhibitors and Hdac3 insufficiency. The Akt phosphatase Phlpp1, but not Phlpp2 or Pp1, was expressed at higher levels both ex vivo and in vivo in Hdac-inhibited cells. Moreover, Phlpp1 expression was elevated in pre-hypertrophic chondrocytes within growth plates of Hdac3 CKO mice. Tgf β induced expression of Phlpp1, but not Phlpp2. In chromatin immunoprecipitation assays, Hdac3 associated with the Phlpp1 promoter near Smad binding elements and was released upon Tgf β exposure. Thus, Hdac3 epigenetically regulates chondrocyte hypertrophy and matrix content by directly repressing Phlpp1 levels and facilitating Akt activation. To determine the function of Phlpp1 in controlling Hdac3-mediated Akt activation, we utilized a truncated Phlpp1 protein unable to bind Akt. Truncated Phlpp1 expression rescued the effects of Hdac inhibition on Akt activation in chondrocytes. Phlpp1^{-/-} mice have shorter snout-to-tail body lengths as well as decreased femur and tibia lengths. Both the articular surface and the growth plate of Phlpp1^{-/-} mice are hypercellular. Furthermore, bone mineral density and trabecular number are decreased in Phlpp1^{-/-} mice. Together these data identify Phlpp1 as a crucial factor in skeletal development and demonstrate that Hdac3 regulates chondrocyte maturation by epigenetically repressing Phlpp1 expression.

Epidermal Growth Factor Receptor Regulates Cartilage Matrix Remodeling during Endochondral Ossification through β -catenin-dependent and -independent Pathways. Xianrong Zhang¹, Ji Zhu¹, Valerie A Siclari², Motomi Enomoto-Iwamoto³, Frank Beier⁴, Ling Qin^{*2}. ¹University of Pennsylvania, School of Medicine, USA, ²University of Pennsylvania, USA, ³Children Hospital of Philadelphia, USA, ⁴University of Western Ontario, Canada

Loss of epidermal growth factor receptor (EGFR) activity in mice alters growth plate development, impairs endochondral ossification, and retards growth. However, the detailed mechanism by which EGFR regulates endochondral bone formation is unknown. We constructed a pharmacological rat model and a transgenic mouse model to study such mechanisms. Administration of an EGFR inhibitor, gefitinib, into 1-month-old rats for 7 days produced profound defects in long bone growth plate characterized by thickening of epiphyseal growth plate (2.0-fold), massive accumulation of hypertrophic chondrocytes (2.3-fold), and decreased in mineralization of hypertrophic cartilage matrix. We observed similar growth plate phenotypes along with a delayed formation of secondary ossification center (SOC) in 1-week old mice with chondrocyte-specific inactivation of EGFR (collagen2a1 promoter driven-Cre Egfr^{W⁵¹/lox}). Immunostaining for Sox9, p57 and Ki67, BrdU labeling and mRNA expression profile of chondrocyte differentiation markers revealed that EGFR inactivation did not alter growth plate chondrocyte proliferation, and differentiation, and matrix synthesis. Vascular invasion into growth plate cartilage was not impaired. However, we observed a 50% decrease in the number of TRAP-positive osteoclasts at the chondro-osseous junction, owing to decreased RANKL expression in the growth plate. Moreover, EGFR inactivation strongly inhibited the expression of matrix metalloproteinases (MMP9 and 13), increased the amount of collagen fibrils, and decreased degraded extracellular matrix products in the growth plate. At the SOC of Col-CreEgfr^{W⁵¹/lox} mice, we observed similar decreases in the chondrogenic expression of MMPs and RANKL, the number of TRAP-positive cells, and matrix mineralization, suggesting that cartilage matrix degradation was also suppressed in this region. In vitro, the EGFR ligand transforming growth factor α (TGF- α) strongly stimulated MMP9 and RANKL expression in primary chondrocytes, which was partially abolished by Wnt/ β -catenin signaling inhibitors, DKK1 and IWR-1-endo. Further study showed that EGFR signaling phosphorylated LRP6 and activated nuclear translocation of β -catenin. Since Wnt/ β -catenin signaling itself elevates these gene expression, we conclude that EGFR signaling cross-talks with Wnt/ β -catenin pathway in regulation of MMP9 and RANKL. In contrast, EGFR-induced MMP13 expression is independent of Wnt/ β -catenin pathway. Together, we demonstrated that EGFR signaling regulates matrix degradation directly by stimulating chondrocytes to express MMPs and indirectly by activating chondrogenic RANKL expression to support osteoclastogenesis. EGFR signaling plays an essential role in the remodeling

of cartilage extracellular matrix into bone through Wnt/ β -catenin-dependent and -independent pathways during endochondral ossification.

Sprouty2 Regulates Skeletogenesis. Adriane Joo*¹, Roger Long², Zhiqiang Cheng¹, Wenhan Chang³, Ophir Klein¹. ¹University of California, San Francisco, USA, ²University of California, Davis, USA, ³Endocrine Unit, VA Medical Center, University of California, San Francisco, USA

Skeletal development is regulated by the cooperative activity of signaling molecules produced locally by cartilage and bone cells as well as by systemic factors. Receptor tyrosine kinase (RTK) superfamily members, including Fibroblast Growth Factor and Insulin-like Growth Factor, play critical roles in the proliferation, survival, and differentiation of chondrocytes, osteoblasts, osteoclasts, and other cells in the bone during embryonic development and postnatal bone remodeling. Recently, several molecules that inhibit RTK signaling pathways have been identified, including members of the Sprouty (Spry) family (*Spry1*, *Spry2*, *Spry3*, and *Spry4*). Spry proteins function intracellularly to antagonize RTK signaling through diverse mechanisms. By *in situ* hybridization and quantitative PCR, we found that *Spry1*, *Spry2*, and *Spry4*, but not *Spry3*, are expressed by proliferating chondrocytes, pre- and hypertrophic chondrocytes, osteoblasts, and osteocytes in adult long bones. To determine the role of Sprouty genes in skeletal development *in vivo*, we analyzed the skeletal phenotypes of Sprouty knockout (KO) mice by micro-computed tomography (μ CT). μ CT analysis showed that both the trabecular and cortical bones of *Spry2* KO mice are smaller and thinner than those of their wild-type (WT) littermates at 4 weeks, 6 weeks, and 12 weeks of age, while *Spry1* and *Spry4* KO mice showed minor to no change. In addition, static and dynamic histomorphometric analysis of global *Spry2* KO showed that both osteoblast and osteoclast activities are reduced in *Spry2* KO mice. To further investigate the function of *Spry2* in skeletogenesis, we generated (1) cartilage- or (2) bone-specific KOs of *Spry2* by crossing floxed *Spry2* mice with transgenic mice expressing Cre under (1) type II collagen- α 1 or (2) 2.3 kb fragment of the collagen I- α 1 promoters, respectively. μ CT data showed that both cartilage- and bone-specific *Spry2* KO mice had smaller and thinner trabecular bone, although their skeletal abnormalities were milder than those of the global *Spry2* KO mice. Furthermore, histological and immunohistochemical analysis of E16.5 and E18.5 limbs showed that *Spry2* mutant have smaller pre- and hypertrophic zones and increased chondrocyte proliferation compared to that of WT littermates. In both embryonic and adult bones, we detected altered expression of several molecular markers. Thus, *Spry2* regulates bone development by modulating both chondrogenesis and osteoblastogenesis.

Mice Lacking Pten in Osteoblasts Have Improved Intramembranous and Late Endochondral Fracture Healing. Travis Burgers*¹, Martin Hoffmann², Michael Morris³, Martin Alvarado⁴, Debra Sietsema⁵, Jim Mason¹, Clifford Jones⁶, Bart Williams⁷. ¹Van Andel Institute, USA, ²Grand Rapids Medical Education Partners, USA, ³Michigan State University, USA, ⁴Creston High School, USA, ⁵Orthopaedic Associates of Michigan; Michigan State University, USA, ⁶Orthopaedic Associates of Michigan, USA, ⁷Van Andel Research Institute, USA

The failure of an osseous fracture to heal (development of a non-union) is a common and debilitating clinical problem. It is estimated that 10–20% of fractures do not heal in a timely manner and progress towards non-union (Court-Brown and McQueen, 2008, and Parker et al. 2007). Mice lacking Pten in osteoblasts (*OC-cre^{tg}+*; *Pten^{fl/fl}*) have dramatic and progressive increases in bone volume and density throughout life (Figure 1; Liu et al. 2007). Since fracture healing is a recapitulation of bone development, we hypothesized that Pten mutants (*OC-cre^{tg}+*; *Pten^{fl/fl}*) would have improved fracture healing.

Mid-diaphyseal femoral fractures induced in wild-type mice and in mice lacking Pten in osteoblasts (Pten mutants) using an established technique (Bonnarens and Einhorn, 1984). They were studied via radiographs, micro-computed tomography (μ CT) scans, biomechanical testing, Western blotting and histological analysis.

Pten mutant mice had significantly stiffer and stronger intact bones relative to controls in all cohorts (Figure 2A). They also had significantly stiffer healing bones at day 28 post-fracture (PF) and significantly stronger healing bones at days 14, 21, and 28 PF (Figure 2B). Radiographs and μ CT scans showed more mineralization in the Pten mutants at the proximal and distal ends of the callus (Figure 3). Pten mutants also had larger and more mineralized calluses. The cellular composition of the callus did not differ between groups during healing, but there was less Pten and more p-Akt, indicating activated Akt signaling, in the fracture callus from the mutants late in healing (Figure 2C). Pten mutants had improved intramembranous bone formation during healing originating from the periosteum. They also had improved endochondral bone formation later in the healing process, after mature osteoblasts are present in the callus.

Our results indicate that the inhibition of Pten can improve fracture healing and that the local or short-term use of commercially available Pten-inhibiting agents may have clinical application for enhancing fracture healing.

Potential Role of Periosteal Macrophages in Mediating Cathepsin K inhibition-Induced Cortical Bone Formation. Weizhong Chang¹, Shuo Liu¹, Hui Xie*¹, Maureen Pickarski², Le Thi Duong³, Xu Cao¹. ¹Johns Hopkins University, USA, ²Merck & Co., Inc., USA, ³Merck Research Laboratories, USA

Bone is composed of cortical and trabecular bone and cortical bones predominantly support the mechanical functions of bones. During growth, periosteal

cortical bone formation coordinated with endocortical bone resorption results in expansion in diameters of the long bones. Because cortical geometry is a major determining factor of bone strength, stimulation of periosteal cortical bone formation in the mature skeleton would be an effective strategy to prevent bone fracture due to bone loss disorders. Current antiresorptives, including bisphosphonates and anti-RANKL antibody have been focused on trabecular bone remodeling. Cathepsin K (CatK) inhibitor was found to stimulate cortical bone formation in various animal models and the current study is focused on the molecular mechanism of the inhibition of CatK in stimulating cortical bone formation. CatK is a major enzyme expressed by osteoclasts responsible for degradation of bone matrix during bone resorption process. In CatK KO mice or WT mice treated with a CatK inhibitor, L-006235, the number of TRAP-positive macrophages on the surface of the periosteum was increased. Nestin-positive mesenchymal stem cells (MSCs) and osteoblastic lineage cells were also increased in the periosteum of these mice. We also demonstrated that these TRAP-positive macrophages are in proximity to the Nestin-positive MSCs in the periosteal bone modeling area. Next, we prepared conditioned media with macrophages treated with a CatK inhibitor vs. vehicle. The conditioned media were then used to examine the effect on the migration of MSCs. Our results demonstrated that conditioned media from macrophages treated with L-006235 induced migration of MSCs more effectively relative to control conditioned media. The migration of MSCs was only partially inhibited by a TGF-beta1 neutralization antibody, indicating that other factor(s) are involved in the recruitment of MSCs in the periosteum in addition to TGF-beta1. Taken together, our results suggest that periosteal macrophages act as signaling cells to recruit MSCs and enhance bone formation in the periosteum.

Contribution of Bone Resorption to the Control of Glucose Metabolism. Mathieu Ferron*, Gerard Karsenty. Columbia University, USA

Osteocalcin is a hormone produced by osteoblasts that regulates energy metabolism by enhancing insulin secretion, insulin sensitivity and energy expenditure. While osteocalcin can exist in two forms, γ -carboxylated (GLA) and undercarboxylated (GLU), only the undercarboxylated form of this molecule appears to function as a hormone. Recent studies proposed that the osteoclast, the bone-resorbing cell, is responsible of decarboxylating and activating the osteocalcin trapped in the extracellular matrix (ECM) through the low pH generated during bone resorption. Yet direct evidence implicating osteoclasts in the maintenance of energy metabolism is still lacking. To address this question we analyzed mutant mouse strains harboring either an increase or a decrease in osteoclasts number. Osteoprotegerin (*Opg*) deficient mice are characterized by an increase in the number of functional osteoclasts. *Opg*^{-/-} mice were hypoglycemic at 1 and 3 month of age and significantly more glucose tolerant than wild type animals. Moreover, *Opg*-deficient mice were more sensitive to insulin as determined by insulin tolerance test (ITT) and had reduced fat mass. Analysis of osteocalcin carboxylation status in serum using specific ELISA assays revealed that the levels of undercarboxylated GLU13 osteocalcin was increased more than ten times in *Opg*^{-/-} mice compared to wild type. Next, to analyze the consequences on energy metabolism of a lack of osteoclasts we generated a model of conditional osteoclast-ablation through the use of the diphtheria toxin (DTA). Specifically we crossed mice that harbor a flox-stop-flox-DTA gene cassette under the control of the *Rosa26* promoter (*floxDTA*) with *Ctsk-Cre* mice, in which the Cre recombinase is expressed in mature osteoclasts only to generate osteoclast-poor (*AOsc*). As expected *AOsc* mice were severely osteopetrotic due to a decrease in osteoclasts number. These mutant mice were also characterized by a decrease in glucose tolerance, a decline in serum insulin levels and a ~50% reduction in β -cell mass. Finally, the serum levels of undercarboxylated GLU13 osteocalcin were decreased more than two fold in *AOsc* compared to control mice. Taken together, these results support the notion that osteoclasts play an important role in the control of glucose metabolism. This function occurs, at least in part, through the regulation of osteocalcin carboxylation status.

Targeted Expression of Catalase to Mitochondria in Cells of the Macrophage/Osteoclast Lineage Inhibits Osteoclastogenesis and Increases Bone Mass. Shoshana Bartell*, Li Han¹, Aaron Warren¹, Julie Crawford¹, Peter Rabinovitch², Stavros Manolagas¹, Maria Jose Almeida¹. ¹Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, ²University of Washington, USA

Mitochondrial biogenesis and reactive oxygen species generation are critical for RANKL-induced osteoclast formation, activation, and survival. Moreover, an increase in the generation of ROS has been causally linked with increased resorption in estrogen deficiency and inflammatory arthritis. Catalase is a critical enzyme for the detoxification of H₂O₂ - the most abundant of the reactive oxygen species. Based on this evidence, we have examined the role of catalase in osteoclasts. To do this, we first measured catalase levels and activity in bone marrow-derived macrophage cultures. In preparations from three different mouse strains, catalase gene expression and enzymatic activity were dramatically and consistently down-regulated during the

transition of macrophages to mature osteoclasts in the presence of M-CSF and RANKL. Encouraged by this finding, we next generated transgenic mice expressing catalase targeted to the mitochondria in cells of the monocyte/macrophage lineage, by crossing MitoCat-flox stop mice (provided by P. Rabinovitch, University of Washington) with LysM-Cre mice (MitoCat;LysM-Cre). Osteoclast cultures generated from the bone marrow of MitoCat;LysM-Cre mice exhibited 4-fold higher catalase activity than osteoclasts from control LysM-Cre mice. Bone marrow cultures from MitoCat;LysM-Cre mice exhibited a significant decrease in the number of osteoclast progenitors and in mature osteoclast formation. Moreover, the stimulation of RANKL-induced osteoclastogenesis by H₂O₂, seen in cells from control mice, was completely abrogated in cells from MitoCat;LysM-Cre mice. More important, MitoCat;LysM-Cre mice exhibited an increase in cancellous bone volume at 3 months of age as determined by micro-CT, in both the vertebrae and the femurs. These changes were associated with increased trabecular number and decreased trabecular separation. In addition, MitoCat;LysM-Cre mice had increased femoral cortical thickness. These results demonstrate that up-regulation of H₂O₂ production contributes to osteoclast generation and bone resorption. Thus, H₂O₂ production represents a rationale and appealing drug target for diseases associated with increased bone resorption, especially because targeted expression of catalase to mitochondria in mice also prevents the age-associated energy imbalance, muscle insulin resistance, and hypertensive cardiomyopathy (Cell Metab. 12, 668, 2010; Circ Res 108, 837, 2011).

Deletion of the Cell-adhesion Mediator PODXL in Early Osteoclast Precursors Impairs Bone Resorption and Causes a High Bone Mass Phenotype through Reduced Activation of Rac1. Megan Weivoda*, Muzaffer Cicek¹, Ashok Kumar², Larry Pederson³, Ming Ruan³, Michael Hughes⁴, Christine Hachfeld³, Rachel Davey⁵, Kelly McNagny⁶, Merry Jo Oursler¹. ¹Mayo Clinic, USA, ²Mayo Clinic College of Medicine, USA, ³Endocrine Research Unit, Mayo Clinic, USA, ⁴University of British Columbia, Canada, ⁵University of Melbourne, Australia, ⁶Biomedical Research Centre, University of British Columbia, Canada

Podocalyxin (PODXL) is a mediator of cell adhesion that is expressed by hematopoietic stem cells. We have observed that PODXL expression decreases during osteoclast differentiation *in vitro*. Because PODXL functions as an anti-adhesive in tumor progression, we hypothesized that targeted deletion of PODXL in mice would lead to increased osteoclast fusion and osteopenia. Floxed PODXL mice were crossed with Vav-Cre or Cathepsin K (Ctsk)-Cre mice to obtain mice with PODXL deleted in early hematopoietic cells (Vav/PODXL^{del}) or late osteoclast precursors (Ctsk/PODXL^{del}). Femurs were assessed by pQCT, μ CT, and histomorphometry. Bone marrow cells were examined for signaling responses, differentiation, and resorptive activity. Vav/PODXL^{del} bones displayed increased osteoclast numbers. Surprisingly, bone mineral density, bone volume, and bone formation indices were all increased. Vav/PODXL^{del} bone marrow cultured with RANKL and M-CSF produced increased osteoclast numbers *in vitro*. Although these osteoclasts adhered to bone surfaces, they did not form resorption pits. Unlike Vav/PODXL^{del} mice, Ctsk/PODXL^{del} bones did not exhibit significant changes in bone density. Ctsk/PODXL^{del} bone marrow cultures formed more and larger osteoclasts than Cre control cells, consistent with an anti-adhesive PODXL function. In contrast to Vav/PODXL^{del} osteoclasts, mature osteoclasts formed from Ctsk/PODXL^{del} marrow resorbed bone normally. These data show that late osteoclast lineage deletion of PODXL does not interfere with osteoclast function. M-CSF signaling was assessed in Vav/PODXL^{del}, Ctsk/PODXL^{del}, and control precursors. M-CSF induced ERK1/2 phosphorylation was markedly reduced in the Vav/PODXL^{del} precursors. There was also decreased Rac1 activity in Vav/PODXL^{del} osteoclasts. Constitutively active Rac1 overexpression restored bone resorption of Vav/PODXL^{del} osteoclasts *in vitro*. We conclude that PODXL is necessary for early osteoclast precursor M-CSF/ERK and Rac1 signaling and lack of PODXL in early osteoclast precursors prevents the development of functional osteoclasts due to reduced Rac1 activation. We therefore have found that mature osteoclasts that lack PODXL throughout differentiation, although able to bind to bone, cannot resorb bone whereas mature osteoclasts that lose PODXL just prior to maturity are fully functional. Resolution of these differences may provide avenues to pursue to suppress bone resorption while preserving the anabolic influences of osteoclasts.

Ablation of Connexin 43 in Osteoclasts Leads to Decreased *in vivo* osteoclastogenesis. Mitchell Sternlieb, Emmanuel Paul, Henry Donahue, Yue Zhang*. The Pennsylvania State University College of Medicine, USA

Previous *in vitro* studies suggest that gap junction (GJ) deficiency affects osteoclastic cell formation and activity. Here, we examined the hypothesis that decreasing levels of osteoclastic connexin 43 (Cx43) the predominate Cx in bone *in vivo*, results in decreased osteoclastic bone resorption.

Mice expressing Cre recombinase under the control of the human cathepsin K promoter (ctsk-Cre; Cx43^{fl/+}) were bred with mice in which the Cx43 gene is flanked by two loxP sites (Cx43^{flx/flx}) to generate OC-Cre; Cx43^{flx/flx} (conditional Cx43

deficient) and $Cx43^{flx/flx}$ (wild type) littermate mice. Our data showed that deletion of $Cx43$ occurs during the pre-osteoclastic period. Furthermore, osteoclasts derived from osteoclast-specific $Cx43$ deficient mouse nonadhesive marrow cells (NAMCs) displayed dramatically reduced gap junctional intercellular communication (GJIC) relative to cells derived from wild type mouse NAMCs, suggesting that we had indeed reduced $Cx43$ expression in osteoclastic cells. Distal femurs from 8-week-old osteoclast specific $Cx43$ deficient mice showed a nearly significant increase in trabecular number (14.8%, $p=0.05$) and bone volume/total volume (9.2%, $p=0.05$) and a significantly reduced trabecular bone spacing (22.1%, $p<0.05$) relative to wild type mice. Femoral mid-diaphyses from osteoclast-specific $Cx43$ deficient mice displayed increased cortical bone thickness (9.1%, $p<0.05$) and reduced endosteal volume (7.9%, $p<0.05$) (Figure 1). TRAP staining revealed that the number of osteoclastic cells induced from $Cx43$ deficient NAMCs was decreased relative to those induced from wild type NAMCs. Histological examination also revealed that distal femurs from osteoclast specific $Cx43$ deficient mice had fewer osteoclasts than did femurs from wild type mice. Additionally, NFATc1 protein levels in osteoclasts from $Cx43$ deficient mice were significantly decreased, suggesting that $Cx43$ and GJIC regulate osteoclastogenesis via NFATc1.

Our data, derived using a genetic approach, reveal for the first time that $Cx43$ contributes to osteoclastogenesis both *in vitro* and *in vivo*. These results, combined with our previous studies with osteoblast/osteocyte specific $Cx43$ deficient mice, suggest that $Cx43$ mediated GJIC is critical for regulation of both bone formation and resorption *in vivo*. Furthermore, $Cx43$ -mediated GJIC in osteoclastic cells may be a novel therapeutic target for bone disease.

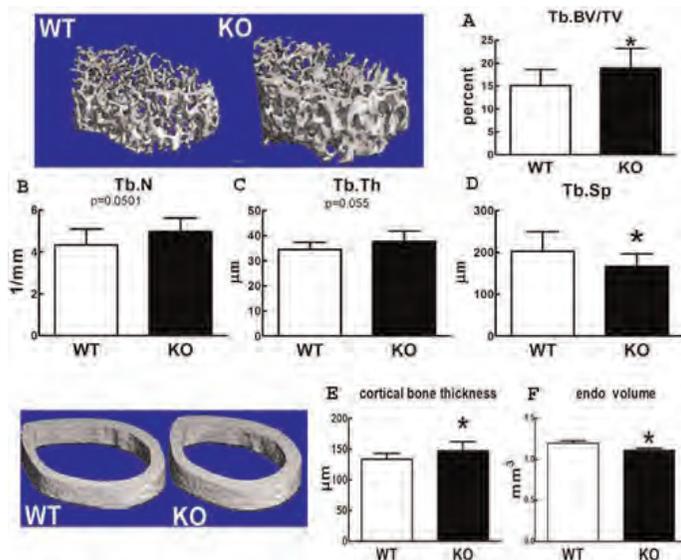

Figure 1. MicroCT reveals that osteoclast specific distal femurs from $Cx43$ deficient mice (KO) have i

The Role of Osteoclasts in Neurofibromatosis Type 1 Pseudarthrosis. Steven Rhodes*, Keshav Menon, Yongzheng He, Karl Staser, Shi Chen, Khalid Mohammad, Theresa Guise, Feng-Chun Yang. Indiana University, USA

Skeletal manifestations cumulatively affect ~70% of neurofibromatosis type 1 (NF1) patients. Tibial pseudarthrosis, the chronic non-union of a spontaneous tibial fracture, is a debilitating skeletal malady affecting children with NF1 early in life. These non-healing fractures typically respond poorly to surgical intervention and often require amputation.

Previous studies have implicated $Nf1$ deficient osteoblasts (OBLs) in the recalcitrant bone repair process. Although osteoclast (OCL) bioactivity increases during fracture repair, the role of OCLs in the pathogenesis of NF1 pseudarthrosis remains unknown. Studies have confirmed that OCLs from NF1 patients and mice exhibit multiple gain-in-functions. We recently established that transplantation of $Nf1^{flx}$ bone marrow (BM) cells to $Nf1^{flx};Col2.3Cre$ mice [carrying $Nf1^{flx}$ OBLs and wild-type (WT) background] can induce osteoporosis and severe non-union fracture healing as compared to transplantation of WT BM cells, suggesting that in concert with $Nf1^{flx}$ OBLs, $Nf1^{flx}$ BM cells play a critical role in pathogenesis of these osseous defects.

Based on these data, we hypothesized that $Nf1^{flx}$ OCLs are the key hematopoietic cell lineage contributing to the osteoporosis and impaired fracture healing in mice harboring $Nf1^{flx}$ OBLs and $Nf1^{flx}$ BM cells. To test this hypothesis, we generated $Nf1^{flx};LysMCre$ mice permitting conditional inactivation of a single $Nf1$ allele in OCLs and their progenitors. Here we report that $Nf1^{flx};LysMCre$ mice exhibit increased frequency of OCL progenitors (CFU-M), enhanced osteoclastogenesis, and accelerated bone resorption following ovariectomy induced resorptive stress. To examine the role of $Nf1^{flx}$ OCLs on fracture healing *in vivo*, lethally irradiated $Nf1^{flx};Col2.3Cre$ mice were transplanted with BM cells from WT or $Nf1^{flx};LysMCre$ mice. A fixed

tibial fracture was subsequently induced after stable reconstitution. Compared to WT BM cells, $Nf1^{flx};LysMCre$ BM cell reconstituted $Nf1^{flx};Col2.3Cre$ mice exhibited significantly reduced callus bone volume fraction (BV/TV) as determined by microcomputed tomography, revealing a substantial deficit in fracture repair. Collectively, these results suggest that in the context of $Nf1$ deficient OBLs, $Nf1^{flx}$ OCLs are the culprit hematopoietic cell lineage responsible for the pathogenesis of NF1 non-union fracture. As such, therapy targeting both the osteoclast and osteoblast lineages may be necessary to maximally augment bone healing in NF1 pseudarthrosis.

Talin1 and Rap1 are Critical for Osteoclast Function. Wei Zou*¹, Tingting Zhu², Takashi Izawa³, Jean Chappel⁴, Susan Monkley⁵, David Critchley⁵, Brian G Petrich⁶, Alexei Morozov⁷, Mark H Ginsberg⁶, Steven Teitelbaum¹. ¹Washington University in St. Louis School of Medicine, USA, ²Washington University in St. Louis-School of Medicine, USA, ³Washington University in St. Louis, USA, ⁴Department of pathology, Washington University School of Medicine, USA, ⁵Department of Biochemistry, University of Leicester, United Kingdom, ⁶Department of Medicine, University of California, USA, ⁷Behavioral Genetics Unit, NIMH, USA

The interaction of talin1 with β -subunit cytoplasmic domains is an essential step in integrin activation. To determine talin1's role in osteoclasts, we mated $TLN1^{flx/flx}$ mice with those expressing cathepsin K-Cre (CtsK- $TLN1$) to delete the gene specifically in mature osteoclasts, or with lysozyme M-Cre (LysM- $TLN1$) mice to delete $TLN1$ in all osteoclast lineage cells. Absence of $TLN1$ impairs macrophage colony-stimulating factor (M-CSF) inside-out integrin activation and consequent cytoskeleton organization in mature osteoclasts. Talin1-deficient precursors normally express osteoclast differentiation markers when exposed to M-CSF and receptor activator of nuclear factor κ B ligand (RANKL) but attach to substrate and migrate poorly, arresting their development into mature resorptive cells. In keeping with inhibited resorptive function, CtsK- $TLN1$ mice exhibit an ~5 fold increase in bone mass. Osteoclast-specific deletion of Rap1, which in conjunction with RIAM promotes talin/ β integrin recognition, similarly yields osteopetrotic mice, which mirror CtsK- $TLN1$ animals. In keeping with osteoclast dysfunction, mice in whom talin is deleted late in the course of osteoclastogenesis are substantially protected from ovariectomy-induced bone loss and the periarticular osteolysis attending inflammatory arthritis. Thus, talin1 and Rap1 are critical for osteoclast function and their inhibition, in mature osteoclasts, may retard pathological bone loss.

Lean Body Mass Mediates Associations between Physical Activity, Sedentary Behavior, and Bone Microstructure in Post-menarcheal Girls. Leigh Gabel*¹, Heather McKay¹, Lindsay Nettlefold², Douglas Race², Heather Macdonald¹. ¹University of British Columbia, Canada, ²University of British Columbia, Canada

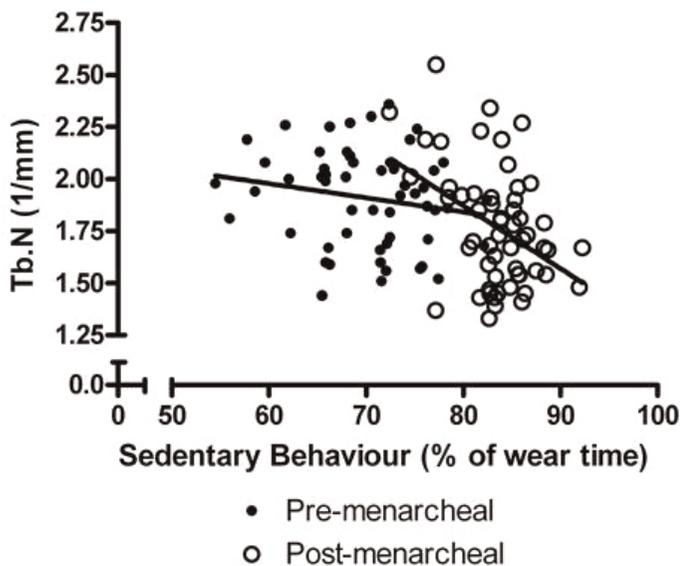

Purpose: Physical activity (PA) enhances bone accrual during growth; however, we know little about how PA and sedentary behavior (SED) influence bone microstructure during adolescence. We aimed to: 1) determine the independent contributions of moderate-to-vigorous PA (MVPA) and SED to bone microstructure and strength in pre- and post-menarcheal girls and, 2) to evaluate the role of lean mass in mediating these associations.

Methods: We used high-resolution pQCT (HR-pQCT, Scanco Medical) to measure bone microstructure and estimate bone strength at the distal tibia (8% site) in 55 pre-menarcheal (10.5 y \pm 0.6) and 56 post-menarcheal (17.7 y \pm 2.5) girls who were participants in the UBC Healthy Bones III study. Bone outcomes included total bone mineral density (Tt.BMD), total area (Tt.Ar), trabecular bone volume ratio (BV/TV), trabecular thickness (Tb.Th) and number (Tb.N), and cortical density (Ct.BMD), porosity (Ct.Po) and thickness (Ct.Th). We applied finite element (FE) analysis to HR-pQCT scans to estimate bone strength (ultimate stress). We used Actigraph GT1M accelerometers to measure MVPA and SED using 15-sec epochs and age-specific cutpoints. We included data for participants who wore the accelerometer for 3 days and at least 10 hr/day. We fit separate multivariable regression models for pre-menarcheal and post-menarcheal girls, and adjusted for age (post-menarcheal only), maturity (pre-menarcheal only), tibia length, and lean body mass.

Results: Pre-menarcheal girls accumulated significantly more MVPA and less SED than post-menarcheal girls ($p<0.001$). In pre-menarcheal girls, MVPA tended to be a positive predictor of Ct.Po and Ct.Th, accounting for 4-5% of the variance ($p=0.10$ and 0.07, respectively). In post-menarcheal girls, SED was a negative predictor of Tb.N and explained 8% of the variance ($p=0.013$). When lean mass was replaced by weight in the model, MVPA was a positive predictor of Tb.N, accounting for 5% of the variance ($p=0.048$), and SED was a negative predictor of Tb.N, accounting for 10% of the variance ($p=0.005$).

Discussion: Our findings illustrate how the skeleton responds negatively to sedentary behaviours, especially during the key period of childhood and adolescent growth. Lean body mass mediates the relation between bone microstructure and SED

and MVPA in post-menarcheal girls. The apparent maturity-specific influence of sedentary behaviour on bone microstructure is important and warrants further investigation.

Relationship between trabecular number and sedentary behaviour in pre- and post-menarcheal girls.

Femoral Neck Cortical Thickness Declines in the Elderly Three-fold Faster Superiorly than Inferiorly: The AGES-REYKJAVIK Longitudinal Study.

Fjola Johannesdottir¹, Thor Aspelund², Jonathan Reeve³, Kenneth Poole³, Sigurdur Sigurdsson², Tamara Harris⁴, Vilundur Gudnason⁵, Gunnar Sigurdsson⁶. ¹Faculty of Engineering, University of Iceland, Iceland, ²Icelandic Heart Association, Iceland, ³University of Cambridge, United Kingdom, ⁴Intramural Research Program, National Institute on Aging, USA, ⁵Icelandic Heart Association Research Institute, Iceland, ⁶Landspítali, Iceland

Background: Marked thinning of the mid-femoral neck cortex with advancing age has been described in cross-sectional studies, both ex-vivo and in-vivo. We previously found that superior cortical thinning of the mid-femoral neck was important in determining resistance to femoral neck fracture. Therefore, we aimed to study changes in regional cortical thickness with increasing age, by using serial QCT measurements in older men and women.

Design, Setting and Participants: This is a longitudinal study of 100 men and 300 women from the Age Gene/Environment Susceptibility-Reykjavik Study (AGES-REYKJAVIK), a large prospective population-based cohort of Icelandic individuals aged 66 years and older. Segmental QCT (slice thickness 1mm) analysis of the mid-femoral neck was applied to estimate cortical thickness (CtTh) in the superior and inferior surfaces of the mid neck, using QCTPro-BIT2 (Mindways software). Participants had two measurements of cortical thickness over a median follow-up of 5.1 yr. Femoral neck (FN) areal bone density (aBMD) (DXA-like) was also measured. Relative change in cortical thickness and FN aBMD during follow-up was estimated from mixed effects regression models.

Results: The relative loss in CtTh was substantial and significantly greater in the superior surface compared to the inferior surface in both genders (see Table). Women lost relatively more cortex than men in both surfaces. The difference in FN aBMD loss was not significantly different between genders.

Conclusion: The relative age-related changes were about threefold greater in the superior surface than in the inferior surface of the mid femoral neck. Older women lost cortical thickness more rapidly than men, especially in the superior femoral neck and this is only weakly reflected in the DXA-like results. Since fractures may initiate superiorly, this increased rate of loss may contribute materially to the greater risk of femoral neck fracture in women than men.

This study was funded by NIH contract N01-AG-1-2100.

| | Age at follow-up Mean (SD) | Superior CtTh Mean % (95%CI) | Inferior CtTh Mean % (95%CI) | FN aBMD Mean % (95%CI) |
|-------|-------------------------------|---------------------------------|---------------------------------|---------------------------|
| Women | 79.5 (5.2) | -15.6 (-13.5 to -17.6) | -4.5 (-3.8 to -5.2) | -6.2 (-4.9 to -7.5) |
| Men | 78.9 (4.4) | -7.9 (-5.7 to -10.1) | -2.5 (-1.4 to -3.5) | -4.1 (-2.3 to -6.0) |

Similar Effects on Cancellous Bone Matrix Mineralization by Alendronate and Two Different Doses of Odanacatib in Rhesus Monkeys. Paul Roschger¹, Phaedra Messmer¹, Nadja Fratzl-Zelman¹, Barbara M. Misof¹, Klaus Klaushofer¹, Maureen Pickarski², Le T. Duong². ¹Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUA Trauma Centre Meidling, 1st Medical Department, Hanusch Hospital, Vienna, Austria, ²Bone Biology, Merck Research Laboratories, West Point, USA

Odanacatib (ODN) is a potent and selective inhibitor of cathepsin K and is currently in clinical development for the treatment of postmenopausal osteoporosis. In the present study we aimed to explore the effect of ODN treatment on the bone mineralization density distribution (BMDD) in rhesus monkeys. Ovariectomized animals treated with either vehicle (VEH, n=8), Odanacatib @ 2 mg/kg/day (ODN-L, n=8), Odanacatib @ 8 to 4 mg/kg/day (ODN-H, n=8), or alendronate @ 30mg/kg/week (ALN, n=8) for 20-months were compared. Vertebrae and diaphyseal cortex of tibiae were harvested for BMDD analyses using quantitative backscattered electron imaging (qBEI). Group comparison of BMDD variables was based on ANOVA or Kruskal-Wallis tests (Tukey's or Dunn's post-hoc analysis, respectively). In vertebral cancellous bone, average calcium concentration (CaMean +6.5%, p<0.001) was increased in ODN-L while the heterogeneity of mineralization (CaWidth -22%, p<0.001) and the percentage of low mineralized areas (CaLow -36%, p<0.01) were decreased vs. VEH. Similar BMDD differences versus vehicle were also found for ODN-H and ALN. Among the treatment groups (ODN-L, ODN-H, ALN), no significant differences could be detected. In tibial osteonal bone, CaMean was higher in the ALN group (+3.4%, p<0.01), and CaLow was decreased in the ALN (-29%, p<0.01) group all compared to VEH. No other treatment effect on osteonal bone was observed. Our BMDD findings after ODN or ALN treatment in rhesus monkeys are consistent with the previously observed antiresorptive action of ALN and other agents in postmenopausal osteoporosis. The higher CaMean is in line with an increased average tissue age due to a longer period of secondary mineralization for the bone packets. Simultaneously, CaLow, is decreased as a lesser amount of new bone is formed. Further, CaWidth is reduced, which is a typical, transient response to the bone remodeling rate reduction. Our BMDD results also indicate that vertebral bone was more responsive to treatment effects than tibial cortical bone, likely due to its higher bone turnover rates at the cancellous sites before treatment. The similarity of the vertebral cancellous BMDD for both dosages of ODN indicates that the effect on matrix mineralization had leveled off. Moreover, the overall effects of ODN and ALN was similar, though their underlying mechanisms of bone turnover rate reduction are different.

Alterations in Intrinsic Bone Material Properties of Sclerosteosis Patients.

Eleftherios Paschalis¹, Paul Roschger², Antoon Van Lierop³, Rutger Van Bezooijen³, Sonja Gamsjaeger⁴, Birgit Hofstetter¹, Klaus Klaushofer⁵, Socrates Papapoulos^{3*}. ¹Ludwig Boltzmann Institute for Osteology, Austria, ²L. Boltzmann Institute of Osteology, Austria, ³Leiden University Medical Center, The Netherlands, ⁴Ludwig Boltzmann Institute of Osteology, Austria, ⁵Hanusch Hospital, Austria

Sclerosteosis (SC) is a rare, autosomal recessive, bone sclerosing dysplasia characterized by generalized osteosclerosis, caused by loss-of-function mutations in the SOST gene encoding for sclerostin, a protein produced in bone by osteocytes that decreases bone formation by inhibiting the Wnt signaling pathway in osteoblasts, resulting in unrestrained bone formation. SC patients do not sustain fractures suggesting that their bone is of good quality. To test this hypothesis we examined intrinsic material properties in bone from such patients.

Chips of compact bone obtained during surgery from 4 children (SCc; age 4-16 yrs) and 2 adults (SCa; age 24 & 43) diagnosed with SC, and 4 control subjects (CTRL; age 37-71 years), were analyzed by quantitative Backscattered Electron Imaging (qBEI) and Raman spectroscopy (RS). The former technique provides information on the bone mineral density distribution (BMDD), while the latter on the mineral/matrix ratio, proteoglycan (modulators of mineralization) content, and mineral crystallinity. Data were also compared against a historical control cohort of normal children (NC; N = 54, age 2-20 years).

qBEI analysis indicated no significant differences between the CTRL and SCa subjects in any of the outcomes. On the other hand, SCc subjects had a significantly lower CaMean (weighted mean of BMDD), CaPeak (peak position of BMDD), and CaHigh (fraction of highly mineralized bone) values compared to CTRL. CaWidth (indicative of heterogeneity of mineral distribution) in SCc was significantly higher compared to CTRL subjects. SCc had lower mineral content, and higher CaWidth and CaLow compared to NC.

RS analysis indicated that SCc subjects had lower mineral/matrix ratio compared to either CTRL or SCa while there was no difference between the CTRL and SCa values. The proteoglycan content was higher in SCc compared to either SCa or CTRL. Mineral crystallinity was lower in the SCc compared to either SCa or CTRL, while the SCa itself had lower values compared to CTRL. All outcomes were similar between SCc and NC except mineral crystallinity (significantly lower in SCc).

The results of the present study suggest that human bone formed in the absence of sclerostin has decreased mineral crystallinity, and BMDD slightly shifted to lower mineralization with higher heterogeneity. These favorable bone properties in the presence of highly increased bone mass may be responsible for the increased bone strength of patients with sclerostinosis.

Lower Cortical Porosity and Higher Cortical Tissue Mineral Density Help to Explain Stronger Bones in Chinese versus Caucasian Women. *Stephanie Boutroy*¹, *Marcella Walker*², *Julia Udesky*¹, *Donald McMahon*³, *George Liu*⁴, *John Bilezikian*³. ¹Columbia University Medical Center, USA, ²Columbia University, USA, ³Columbia University College of Physicians & Surgeons, USA, ⁴New York Downtown Hospital, USA

Asian women have lower rates of hip and forearm fractures compared to other racial groups despite lower areal BMD (aBMD). We have demonstrated micro-architectural differences, including greater cortical thickness (Ct.Th) and Ct volumetric BMD (Ct.vBMD), in Chinese-American (CH) versus Caucasian (CA) women. It is not known whether greater Ct.vBMD in CH women is due to greater tissue mineral density (TMD) or reduced cortical porosity (Ct.Po), both of which are being increasingly recognized as important determinants of bone strength. Using high-resolution peripheral QCT (HRpQCT, Scanco Medical AG, Switzerland), we tested the hypothesis that CH women have better cortical skeletal integrity due to lower cortical porosity and higher cortical mineral density compared with CA women.

80 CH women (46 premenopausal 36±7 yrs and 34 postmenopausal 62±2 yrs) and 82 CA women (53 premenopausal 35±4 yrs and 29 postmenopausal 63±3 yrs) were studied. Data were adjusted for height, weight and serum 25OH vitamin D.

Premenopausal CH vs. CA women had greater Ct.Th, Ct.vBMD, Ct.TMD and decreased Ct.Po at both the radius and tibia (Table). Results remained significant after adjustment except for tibial Ct.Po. A similar pattern was observed among postmenopausal women, but only Ct.Th at the radius remained significant after adjustment. As expected, postmenopausal vs. premenopausal women had lower Ct.vBMD and Ct.Th at the radius and tibia in both races. At the radius, Ct.Po more than doubled between pre- and post-menopausal women in both races (CH: 3.5±1.1% vs. 7.2±2.7%, p<0.001; CA: 4.5±1.3% vs. 9.2±4.5%, p<0.001), while Ct.TMD decreased by 3% (p<0.001) in both races. At the tibia, Ct.Po also more than doubled (CH: 6.3±1.6% vs. 13.7±3.8%, p<0.001; CA: 7.1±1.7% vs. 16.1±5.8%, p<0.001) between pre- and post-menopausal women in both races, while Ct.TMD decreased by 6-7% respectively in CA and CH women (p<0.001 for both). Age-related differences in Ct.Po and Ct.TMD did not differ by race.

In summary, both reduced Ct.Po and greater Ct.TMD explain higher Ct.vBMD in CH vs. CA premenopausal women. Thicker and preserved cortical bone structure in CH women is likely to confer greater resistance to fracture compared to CA women.

Bone Microstructure, Serum PINP, and Plasma Osteopontin Levels are Correlated With Sympathetic Activity Measured by Microneurography in Human. *Joshua Farr*¹, *Nisha Charkoudian*², *Jill Barnes*³, *David Monroe*⁴, *Louise McCready*¹, *Elizabeth Atkinson*⁵, *Shreevasee Amin*¹, *L. Joseph Melton*¹, *Michael Joyner*³, *Sundeep Khosla*⁵. ¹Mayo Clinic, USA, ²U.S. Army Research Institute of Environmental Medicine, USA, ³Department of Anesthesiology, Mayo Clinic, USA, ⁴Mayo Foundation, USA, ⁵College of Medicine, Mayo Clinic, USA

There is increasing evidence from animal studies that the sympathetic nervous system regulates bone turnover and mass. Specifically, increased β -adrenergic activity leads to increased bone resorption, decreased formation, and decreased bone mass. In addition, osteopontin is required for β -adrenergic signaling in bone, since β -adrenergic stimulation has no effect on bone mass in osteopontin knock-out mice. There are, however, currently no data on the relationship of sympathetic activity to bone turnover or mass in humans. Thus, we used microneurography of the peroneal

nerve to directly measure sympathetic activity in 23 women aged 20 to 72 yrs (10 premenopausal [preM] and 13 postmenopausal [postM]) and correlated sympathetic activity to bone microstructure at the distal radius using HRpQCT as well as to circulating levels of bone turnover markers and osteopontin. Sympathetic activity (bursts/100 heart beats) was 2.5-fold higher in postM compared to preM women [mean (SD), 61.8 (13.4) in postM vs 24.7 (14.0) in preM, P < 0.001]. After adjusting for age, sympathetic activity was inversely correlated with trabecular bone volume fraction (Spearman $r = -0.55$, P < 0.01) and trabecular thickness ($r = -0.59$, P < 0.01), whereas positive correlations were observed for trabecular separation ($r = 0.45$, P < 0.05) and structure model index ($r = 0.46$, P < 0.05). Sympathetic activity was also negatively correlated with plasma osteopontin levels ($r = -0.43$, P = 0.045), driven mainly by the correlation in postM women ($r = -0.76$, P = 0.002). Sympathetic activity was negatively correlated with serum PINP in postM women ($R = -0.65$, P = 0.02), with a similar trend in preM women ($r = -0.58$, P = 0.08).

These findings represent the first demonstration in humans, using direct measurements of sympathetic activity, of a relationship between sympathetic activity, bone microstructure, and circulating levels of PINP and osteopontin. Given the critical role of osteopontin in mediating effects of β -adrenergic signaling in bone cells, the inverse association between sympathetic outflow and plasma osteopontin levels may reflect a negative feedback loop to limit the deleterious effects of sympathetic activity on bone metabolism. Our findings point to the need for additional human and animal studies to test this hypothesis and to further define the utility of β -adrenergic blockers (selectivity and dosage) in preventing age-related bone loss.

Structural and Mechanical Implications of Antiresorptive and Anabolic Treatment of Osteoporosis by In Vivo Micro-MRI Based Techniques. *Yusuf Bhagat*¹, *Maite Aznarez-Sanado*¹, *Jeremy Magland*¹, *Theresa Scattergood*¹, *Peter Snyder*¹, *Felix Werner Wehrli*². ¹University of Pennsylvania, USA, ²University of Pennsylvania Medical Center, USA

Antiresorptive and anabolic drugs hold the potential to arrest or reverse bone loss. High-resolution micro-MRI-based virtual bone biopsy (VBB) methods allow quantification of trabecular bone (TB) microarchitectural changes at peripheral skeletal locations. Here we present data from an ongoing serial translational patient study at 3 Tesla designed to evaluate the efficacy of anabolic and antiresorptive treatments in postmenopausal women (ages, 58-84) with osteoporosis. High-resolution 3D micro-MR images from the left distal tibia were acquired at baseline, 12 months (n=26) and 24 months (n=15) following randomization to either teriparatide (Forteo, Eli Lilly, 20mg daily, s.c.) or zoledronic acid (Reclast acid, Novartis, 5mg annually, i.v.), and resulted after processing in a 3D grayscale image of 137x137x410 μm^3 voxel size. Follow-up images were co-registered to the baseline grid by rigid body registration. Data were subjected to VBB processing yielding parameters of scale (bone volume fraction (BVF)) and topology (surface-to-curve (S/C) ratio and erosion index (EI)). Finite element analysis was performed on the full tibial cross section with image voxels converted to hexahedral finite elements. Axial stiffness (E_{zz}) was computed as the stress/strain ratio. Serially registered images and VBB cores (23x23x68 μm^3) from a 61-year subject are shown in Fig. 1. Most structural features are replicated in repeat VBBs and some remodeling changes upon Forteo treatment are clearly detectable as plate perforations (green arrows) observed at baseline diminishing and filing in over the duration of treatment. In both treatment arms, significant increases in spinal bone mineral density (BMD) were observed (Fig. 2). Furthermore, increases of 2.6% to 14% (p<0.001) were seen in BVF, S/C and E_{zz} over 24 months of treatment, with topology and mechanics being stronger determinants of the therapeutic efficacy in TB microarchitecture relative to BVF. The relative change in topological parameters of subjects randomized to Reclast (n=14) was similar to those in the Forteo treatment arm (n=12) over 24 months (13-14% increase in S/C and 11-12% decrease in EI, p<0.001). Axial stiffness increased by 5% (p<0.001) and 4% (p=0.07), in the Reclast and Forteo groups, respectively, with the Reclast group only eliciting a statistically significant response. Data in this ongoing treatment study demonstrated an improvement in TB microstructural parameters over a 24-month period.

Differential Effects of Teriparatide and Zoledronic Acid on the Outer and Inner Surfaces of Cortical Bone in Postmenopausal Women with Osteoporosis: Results from the SHOTZ Trial. David Dempster^{1*}, Hua Zhou², Robert Recker³, Jacques Brown⁴, Michael Bolognese⁵, Christopher Recknor⁶, David Kendler⁷, E. Michael Lewiecki⁸, David Hanley⁹, D. Sudhaker Rao¹⁰, Paul Miller¹¹, Grattan Woodson¹², Robert Lindsay², Neil Binkley¹³, Xiaohai Wan¹⁴, Valerie Ruff¹⁴, Boris Janos¹⁵, Kathleen Taylor¹⁴. ¹Columbia University, USA, ²Helen Hayes Hospital, USA, ³Creighton University Osteoporosis Research Center, USA, ⁴CHUQ Research Centre Laval University, Canada, ⁵Bethesda Health Research, USA, ⁶United Osteoporosis Center, USA, ⁷Associate Professor University of British Columbia, Canada, ⁸University of New Mexico School of Medicine, USA, ⁹University of Calgary, Canada, ¹⁰Henry Ford Hospital, USA, ¹¹Colorado Center for Bone Research, USA, ¹²USA, ¹³University of Wisconsin, Madison, USA, ¹⁴Eli Lilly & Company, USA, ¹⁵Eli Lilly Canada, Inc., Canada

Purpose: Previously, we contrasted the mechanisms of action (MOA) of teriparatide (TPTD) and zoledronic acid (ZOL) using a complete set of histomorphometric indices in the cancellous envelope of bone biopsies from postmenopausal women with osteoporosis. Recognizing the contribution of cortical bone to fracture resistance, we now extend our observations to the endocortical and periosteal envelopes.

Methods: In this randomized, double-blind, active comparator-controlled study, transiliac bone biopsies were obtained after double tetracycline labeling from 58 subjects receiving TPTD (20 µg/day, sc injection) or ZOL (5 mg/y, IV infusion). We measured a panel of dynamic and static histomorphometric indices in the cancellous, endocortical, and periosteal bone envelopes after 6 months of treatment.

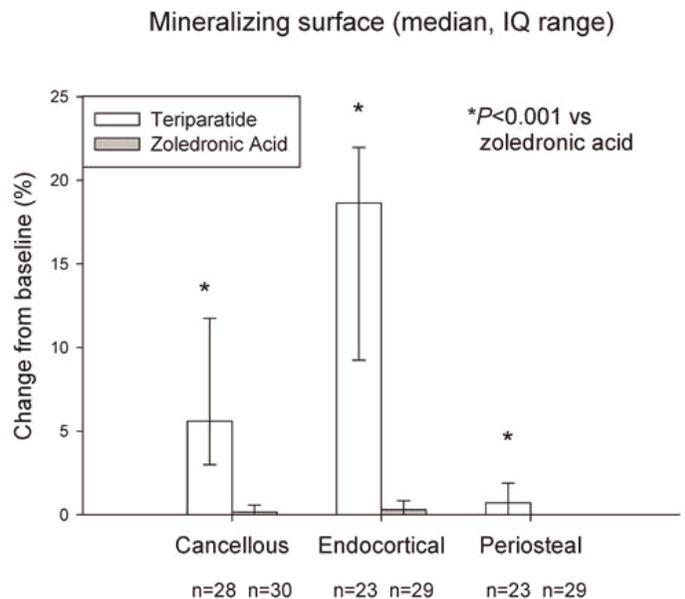

Results: The proportion of samples with tetracycline labels was significantly higher in all 3 envelopes in the TPTD group compared to the ZOL group (p < 0.001) (Table). On the endocortical surface, 100% of samples from the TPTD group displayed labels, all of which included double labels. In contrast, 52% of samples from the ZOL group had labels, 21% of which included double labels. On the periosteal surface, 70% of samples in the TPTD group displayed labels (26% with double labels) compared to 17% of samples in the ZOL group (7% with double labels). Mineralizing surface/bone surface (MS/BS), bone formation rate (BFR/BS), osteoid surface (OS/BS), osteoid thickness (O.Th), wall thickness (W.Th), and mineral apposition rate (MAR) were all significantly higher in the TPTD than the ZOL group in both cancellous and endocortical envelopes. Conversely, in both envelopes, eroded surface (ES/BS) was lower in the ZOL than the TPTD group. Periosteal MS/BS and BFR/BS were higher with TPTD than with ZOL.

Conclusions: The contrasting effects of ZOL and TPTD on bone remodeling are evident on all 3 bone envelopes with MS/BS and BFR/BS providing the most striking differentiation of the MOA of the 2 drugs. While the effect of TPTD was smaller on the periosteal than the endocortical surface, the higher values of MS/BS and BFR/BS relative to the ZOL group suggests the possibility of periosteal expansion and, therefore, an increase in bone size with TPTD. Further, in TPTD samples, MS/BS and BFR/BS were higher in the endocortical than the cancellous envelope which, coupled with an increase in wall thickness, provides a mechanism for cortical thickening with TPTD treatment.

| Number samples (%) with the following: | Cancellous | | Endocortical | | Periosteal | |

Overlapping and Follow-up of Alendronate to Teriparatide Treatment Results in Maintenance of Excess BMD Gain. Christian Muschitz^{1*}, Roland Kocijan², Astrid Fahrleitner-Pammer³, Heinrich Resch⁴. ¹St. Vincent's Hospital, Austria, ²St. Vincent Hospital Vienna, Austria, ³Medical University Graz, Austria, ⁴Medical University Vienna, Austria

Purpose: After 9 months of teriparatide (TPTD) treatment the combination of alendronate (ALN) and TPTD for consecutive 9 months results in enhanced BMD gain, mostly at cortical sites, compared with 18 months of TPTD monotherapy. Administration of raloxifene (RAL) instead of ALN was less advantageous. Both antiresorptive combination therapies maintain TPTD induced bone formation to some extent, while bone resorption declines more on ALN than RAL. Our aim was to

investigate the BMD changes for the 12 months after cessation of TPTD treatment but with continuation of the respective antiresorptive treatment.

Methods: 125 postmenopausal women (mean age 71.7 ± 8.5 ys, 91.5% prevalent fractures, 95.7% prior antiresorptive treatment) were prospectively randomized after 9 months of TPTD treatment into three open-label groups for another 9 months: ALN (70 mg/week, 41 pts) or RAL (60 mg/day, 37 pts) added to TPTD treatment or no additional medication (TPTD monotherapy, 47 pts). After TPTD termination, patients were treated with the respective antiresorptive agent for another 12 months (extension phase). All subjects received 1000mg calcium and 800 IU vitamin D daily. Serum levels of intact amino terminal propeptide of type I procollagen (PINP) and type I collagen cross-linked C-telopeptide (CTX) as well as BMD measured by DXA at lumbar spine, total hip and femoral neck were evaluated at randomization, end of TPTD treatment, and at 6 and 12 months in the extension phase.

Summary: Lumbar spine BMD increased in all groups during the extension phase. Compared with values at the time of randomization, at the end of the extension phase, the increase in lumbar spine BMD was significantly higher in the ALN ($10.1 \pm 7.3\%$, $p=0.002$) and RAL ($8.4 \pm 5.4\%$, $p=0.019$) groups than in the TPTD monotherapy group ($4.5 \pm 10.3\%$). At total hip addition of RAL ($0.5 \pm 3.8\%$) did not alter the effects of TPTD monotherapy on BMD ($0.5 \pm 5.5\%$). Addition of ALN resulted in a superior increase in both total hip BMD ($8.2 \pm 5.8\%$) and femoral neck BMD ($9.1 \pm 10.1\%$, $p<0.001$ for both) compared with RAL or TPTD alone. PINP and CTX significantly declined in all groups in the extension phase reaching the lowest concentrations in the ALN combination group.

Conclusions: Our data suggest that continuation of ALN after its addition to the second 9 months of an 18-month TPTD treatment cycle resulted in a robust and enhanced BMD increase especially in the hip region.

Genetic Variants in the Promoter of LRP5 May Be Associated with Teriparatide Response, in the Treatment of Osteoporosis. Lee O'Brien^{*1}, Haojun Ouyang², Jared Kohler³. ¹Lilly, USA, ²Eli Lilly & Company, USA, ³Biostat Solutions, Inc, USA

The goal of this study was to identify genetic markers associated with teriparatide response in patients with osteoporosis. Variants in eleven candidate genes in the Wnt (bone formation) or RANK (bone resorption) pathways were investigated in a Caucasian genetic cohort collected from a teriparatide clinical trial (NCT00035256, n = 118). Changes in bone mineral density (BMD) from baseline to 12 months was assessed in teriparatide-treated patients using ANCOVA: the model included covariate adjustments for baseline BMD, BMI, age and genotype. Results from the genetic analysis indicate that 6 genetic variants in LRP5 (total of 62 variants genotyped) were associated with a change in femoral neck BMD at 12 months (unadjusted $p = 0.01-0.03$). Average percent change in femoral neck BMD for the LRP5 genetic variant, rs312009, was 0.24, 2.54 and 3.02 for the CC, CT and TT genotypes (unadjusted $p = 0.0261$). The C allele at rs312009 disrupts a RUNX2 transcription factor binding site. In reporter-gene experiments, the C allele had poorer transcription efficacy, which may translate into less LRP5 protein and decreased Wnt pathway activation (1), resulting in decreased bone formation. Although not significant, similar directional trends were observed for teriparatide-induced changes in lumbar spine BMD (7.64, 8.29 and 10.93 for CC, CT and TT, respectively, $p = 0.4431$). Additional variants in LRP5 that were associated with teriparatide efficacy were also located in the 5' UTR, and several of these are predicted to disrupt TF binding sites including a site for a Ccaat/Enhancer Binding Protein (rs312024). These data suggest a genetic association may exist between SNPs in LRP5 and response to teriparatide treatment. Further clinical trials are needed to establish replication of these results, and to determine if these markers are associated with efficacy for other bone anabolic agents.

Femur QCT Analysis using MIAF in Postmenopausal Women Treated with Odanacatib - Results of a 2-year Placebo-controlled Trial. Klaus Engelke^{*1}, Thomas Fuerst², Bernard Dardzinski³, John Kornak⁴, Shabana Ather⁵, Harry Genant⁶, Anne De Papp⁷. ¹University of Erlangen, Germany, ²Synarc Inc, USA, ³Merck Sharp & Dohme Corp., USA, ⁴UCSF, Dep. of Epidemiology & Biostatistics, USA, ⁵Merck & Co, Inc., USA, ⁶UCSF/Synarc, USA, ⁷Merck & Co., Inc., USA

Background: Odanacatib, a selective cathepsin K inhibitor, increases areal BMD at the spine and hip of postmenopausal women. To gain additional insight into the clinical effects in trabecular and cortical bone of odanacatib, we assessed femoral BMD by QCT in postmenopausal women treated with odanacatib.

Methods: This international, randomized, double-blind, placebo-controlled, 2-year, phase 3 trial enrolled 214 postmenopausal women with a mean age of 64 years and mean BMD T-scores of -1.8 at the lumbar spine and femoral neck. Subjects were randomized to odanacatib 50 mg weekly (ODN) or placebo (PBO); all participants received calcium and vitamin D. Hip QCT scans at 2 years were available for a subset

of these women (n=158, ODN (78), PBO (80)). BMD, BMC and volume of the integral, cortical and trabecular compartments were measured in the QCT images using MIAF (Erlangen, Germany). Subregions included the neck, trochanter and intertrochanter. Results are presented as percent change from baseline after 2 years of treatment.

Results: There were consistent and significant differential treatment effects (ODN-PBO) for integral, trabecular and cortical BMD at 24 months (see table). With no significant differential treatment effect on total femur volume, the results for BMC closely matched those of BMD for integral and trabecular compartments, respectively. However, with small but mostly significant differential increases in cortical volume (1.0-1.3%) and thickness (1.4-1.9%), the percent cortical BMC increases were numerically larger than those of BMD.

With a total femur BMC differential treatment effect (ODN-PBO) of nearly 1000mg, the proportion of BMC attributed to cortical gain was 45%, 44% 52%, 40% for the total, neck, trochanter and intertrochanter subregions, respectively.

Conclusions: In postmenopausal women treated for 2 years, odanacatib improved integral, trabecular and cortical BMD as well as BMC at all regions of the femur relative to placebo. Cortical volume and thickness significantly increased in all regions except the neck, where it was marginally non-significant. The increase in cortical volume and BMC paralleled the increase in cortical BMD, demonstrating a consistent effect of ODN on cortical bone. Approximately one-half of the absolute BMC gain occurred in cortical bone.

Denosumab Significantly Improved Trabecular Bone Score (TBS), an Index of Trabecular Microarchitecture, in Postmenopausal Women With Osteoporosis. Michael R. McClung^{*1}, Kurt Lippuner², Maria Luisa Brandi³, Jean-Marc Kaufman⁴, Jose R. Zanchetta⁵, Marc-Antoine Krieg⁶, Henry G. Bone⁷, Roland Chapurlat⁸, Didier Hans⁶, Andrea Wang⁹, Jang Yun⁹, Carol Zapalowski⁹, Cesar Libanati⁹. ¹Oregon Osteoporosis Center, USA, ²Osteoporosis Policlinic, University of Bern, Switzerland, ³University of Florence, Italy, ⁴University Hospital of Ghent, Belgium, ⁵Instituto de Investigaciones Metabólicas, Argentina, ⁶Lausanne University Hospital, Center of Bone Diseases, Switzerland, ⁷Michigan Bone & Mineral Clinic, USA, ⁸Hôpital Edouard Herriot, France, ⁹Amgen Inc., USA

Purpose: The trabecular bone score (TBS), a novel gray-level texture index determined from lumbar spine DXA scans, correlates with 3D parameters of trabecular bone microarchitecture known to predict fracture. TBS may enhance the identification of patients at increased risk for vertebral fracture independently of bone mineral density (BMD) (Hans *JBMR* 2011; Boutroy *JBMR* 2010). Denosumab (DMAb) decreased bone turnover, increased BMD, and reduced new vertebral fractures in postmenopausal women with osteoporosis. We explored the effect of DMAb on TBS over 36 months and evaluated the association between TBS and lumbar spine BMD in women who had DXA scans obtained from eligible scanners for TBS evaluation in FREEDOM.

Methods: FREEDOM was a 3-year, randomized, double-blind trial that enrolled postmenopausal women with a lumbar spine or total hip DXA T-score ≤ -2.5 , but not < -4.0 at both sites. Women received placebo or 60 mg DMAb every 6 months. A subset of women in FREEDOM participated in a DXA substudy where lumbar spine DXA scans were obtained at baseline and months 1, 6, 12, 24, and 36. We retrospectively applied, in a blinded-to-treatment manner, a novel software program (TBS iNsite[®] v1.9, Med-Imaps, Pessac, France) to the standard lumbar spine DXA scans obtained in these women to determine their TBS indices at baseline and months 12, 24, and 36. From previous studies, a TBS >1.35 is considered as normal microarchitecture, a TBS between 1.35 and >1.20 as partially deteriorated, and ≤ 1.20 reflects degraded microarchitecture.

Results: There were 285 women (128 placebo, 157 DMAb) with a TBS value at baseline and ≥ 1 post-baseline visit. Their mean age was 73, their mean lumbar spine

BMD T-score was -2.79, and their mean lumbar spine TBS was 1.20. In addition to the robust gains in DXA lumbar spine BMD observed with DMAB (9.8% at month 36), there were consistent, progressive, and significant increases in TBS compared with placebo and baseline (Table & Figure). BMD explained a very small fraction of the variance in TBS at baseline ($r^2 < 0.07$). In addition, the variance in the TBS change was largely unrelated to BMD change, whether expressed in absolute or percentage changes, regardless of treatment, throughout the study (all $r^2 < 0.06$); indicating that TBS provides distinct information, independently of BMD.

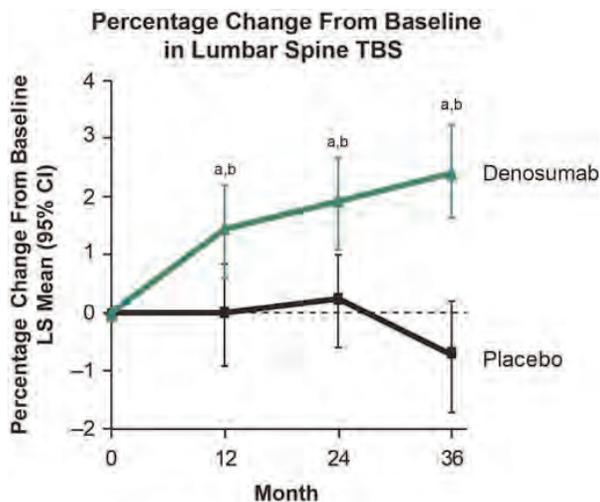

Conclusion: In postmenopausal women with osteoporosis, DMAB significantly improved TBS, an index of lumbar spine trabecular microarchitecture, independently of BMD.

Longitudinal Tracking of DXA Bone Measures in Children and Adolescents Over a 6-Year Period. Tishya Wren^{*1}, Heidi Kalkwarf², Babette Zemel³, Joan Lappe⁴, John Shepherd⁵, Sharon Oberfield⁶, Karen Winer⁷, Vicente Gilsanz¹. ¹Children's Hospital Los Angeles, USA, ²Cincinnati Children's Hospital Medical Center, USA, ³Children's Hospital of Philadelphia, USA, ⁴Creighton University Osteoporosis Research Center, USA, ⁵University of California, San Francisco, USA, ⁶Columbia University Medical Center, USA, ⁷National Institutes of Health, NICHD, USA

Measuring bone mass during childhood and adolescence may allow for early identification of individuals at risk for future development of osteoporosis. However, early assessment is only useful if bone measurements "track" during growth, with children who have low bone mass continuing to have low bone mass as they mature. The purpose of this prospective longitudinal multi-center study was to examine tracking of dual-energy x-ray absorptiometry (DXA) bone measures in children and adolescents over a 6-year period. The study subjects were 974 healthy boys and girls, ages 6 to 16 years, who completed 6 years of longitudinal follow-up in the multi-center Bone Mineral Density in Childhood Study (BMDCS). DXA measures of the whole body, lumbar spine, hip, and forearm were obtained annually. The correlation between baseline DXA measures and measures 6 years later was examined.

The tracking of DXA Z-scores ($r = .66$ to $.81$) was similar in magnitude to the tracking of height (Table 1). In general, tracking was better for BMD vs. BMC and for height-adjusted DXA Z-scores vs. unadjusted scores. Tracking was also slightly better for girls compared with boys. When examined as a function of sexual maturity at baseline, tracking remained strong for girls of all Tanner stages ($r = .61$ to $.89$). The weakest tracking was for Tanner stage 3, where height adjustment improved the tracking ($r = .57$ to $.76$ for unadjusted vs. $r = .69$ to $.85$ for height adjusted). Boys had poor tracking of unadjusted DXA Z-scores in Tanner stage 3 ($r = -.05$ to $.74$). Height adjustment greatly improved tracking in this group ($r > .6$ except for hip neck BMC which improved from $r = -.05$ to $r = .34$; Table 2).

In conclusion, DXA bone measures demonstrate good tracking in children and adolescents. During puberty, however, it is important to adjust DXA measures for height, particularly for boys. These results suggest that bone mass measurements during childhood may be useful for early identification of children at risk for osteoporosis later in life. This information may assist in counseling patients and initiating early interventions.

Table 1: Correlation of Z-scores between baseline and 6 years later

HRpQCT Reveals Cortical Thinning and Deficits in Bone Microstructure in Children and Adolescents With a Distal Forearm Fracture Due to Mild but Not Moderate Trauma. Joshua Farr^{*1}, Shreyasee Amin¹, Salman Kirmani¹, Louise McCready¹, Sara Achenbach¹, L. Joseph Melton¹, Sundeeep Khosla². ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA

Distal forearm fracture (DFF) incidence peaks during growth and has increased significantly in recent years. There is mounting evidence that fractures during growth are related to skeletal fragility and some studies have shown that this relationship is independent of trauma severity. However, previous studies have been confounded by reliance on techniques (e.g., DXA) that have limitations in assessing bone mass/structure during growth, have relied on self-reported fractures, and have included subjects with miscellaneous fractures. Thus, in order to better characterize the underlying skeletal phenotype associated with DFF during growth, we used HRpQCT to determine whether a recent fracture (due to mild vs moderate trauma) is related to deficits in bone geometry and microstructure as compared to non-fracture controls. Cortical and trabecular bone parameters were assessed at the distal radius and tibia in boys ($n = 112$) and girls ($n = 96$) aged 8-15 yrs. The Landin classification (Acta Orthop Scand 202:1, 1983) was used to assign trauma levels based on medical record review and an interview. As shown in the Figure, boys (Panel A) and girls (Panel B) with a mild trauma (e.g., simple fall) DFF had significantly lower cortical area (CtA) at the radius (by 26% for both), but both boys and girls with a moderate trauma (e.g., fall from a bicycle) DFF had virtually identical CtA values as compared to controls. Cortical thickness (CtTh) at the radius was also reduced in boys and girls with a mild trauma DFF (by 14% and 13%, respectively; $P < 0.05$), with no differences in the moderate trauma DFF cases versus controls. Similar findings were noted for CtA and CtTh at the tibia. Furthermore, at the radius and tibia, boys and girls with a mild (but not moderate) trauma fracture had deficits in trabecular bone volume fraction (6-9%), although this was statistically significant only in the boys at the tibia.

Thus, a mild, but not moderate, trauma DFF during growth is associated with cortical thinning and deficits in bone microstructure not only at the distal radius, but also at the tibia. Our data suggest that DFFs during growth have two distinct

etiologies: those due to underlying skeletal deficits leading to fractures with mild trauma versus those due to more significant trauma in the setting of normal bone mass/structure. Identification of children with mild trauma fractures may be particularly important so as to target them for lifestyle and nutritional interventions.

Fractures During Growth in Healthy Females: Relation with Bone Structural Alterations and Importance of Pubertal Timing. [Thierry Chevalley](#)*¹, [Jean-Philippe Bonjour](#)², [Bert van Rietbergen](#)³, [Rene Rizzoli](#)⁴, [Serge Ferrari](#)⁵.
¹University Hospitals of Geneva Division of Bone Diseases, Switzerland, ²University Hospital of Geneva, Switzerland, ³Department of Biomedical Engineering, Eindhoven University of Technology, Netherlands, ⁴University Hospital, Switzerland, ⁵Geneva University Hospital & Faculty of Medicine, Switzerland

In this study in healthy young adult women, we have assessed which bone variables are significantly associated with an increased risk of fractures during growth. Taking into account the major importance of pubertal timing in bone development, we also quantified the fracture risk related to later vs. earlier menarcheal age. We prospectively recorded fracture occurrence in healthy girls during childhood and adolescence. Healthy girls (n=124) were followed-up from the age of 7.9 ± 0.5 to 20.4 ± 0.6 (\pm SD). During the 12.5 y follow-up period, fractures, pubertal stages, menarcheal age, anthropometric variables and radius aBMD were recorded at regular intervals. At the age of 20.4 y, microstructural and strength variables of the distal radius were determined by HR-pQCT and Finite Element Analysis (μ FEA). Sixty one fractures occurred in 42 subjects. Most fractures (41%) were localized in forearm and wrist. At the age of 20.4 y mean aBMD was lower in the fracture (FX) as compared to the non-fracture (No-FX) group at both radial diaphysis ($P=0.005$) and metaphysis ($P=0.008$). Distal radius trabecular volumetric density ($P=0.010$) and thickness ($P=0.014$) were lower in the FX group. μ FEA indicated reduction in stiffness ($P=0.013$), failure load ($P=0.013$) and apparent modulus ($P=0.046$). As illustrated on the figure, calculation of Odds ratios (OR, 95% CI) revealed an increased risk of fracture for 1 SD reduction in radial aBMD diaphysis: 1.97 (1.22-3.19, $P=0.006$) and metaphysis: 1.97 (1.19-3.24, $P=0.008$), trabecular volumetric density: 1.89 (1.16-3.10, $P=0.011$) and thickness: 1.97 (1.13-3.43, $P=0.017$), stiffness: 2.02 (1.15-3.53, $P=0.014$), failure load: 2.00 (1.15-3.50, $P=0.014$) and apparent modulus: 1.79 (1.02-3.14, $P=0.043$). Menarcheal age occurred at a later age in the FX than in the No-FX group (13.5 ± 1.1 vs. 12.8 ± 1.2 y, $P=0.003$). For 1 SD (1.2 y) later menarcheal age, the risk of fracture increased twofold (OR: 2.1, 95% CI, 1.31-3.33, $P=0.002$). In conclusion, this longitudinal study with 12.5 y follow-up shows that low trabecular volumetric density and thickness in the distal radius are associated with reduced bone strength and increased risk of fractures during growth. It also documents the importance of menarcheal age on bone fragility in healthy women by demonstrating that the negative effects of later pubertal timing on bone strength is associated with increased incidence of fracture during childhood and adolescence.

Pre-Pubertal Bone Mass Predicts Peak Bone Mass – A 28 Year Prospective Observational Study of 214 Children. [Christian Buttazzoni](#)*, [Bjorn Rosengren](#), [Magnus Tveit](#), [Lennart Landin](#), [Jan-Åke Nilsson](#), [Magnus Karlsson](#). Skåne University Hospital Malmö, Lund University, Sweden

Purpose: There is an ongoing debate if bone mass “tracks” from growth to adulthood. We therefore undertook this prospective long-term observational study as to answer if low bone mineral content (BMC) in the pre-pubertal children is a risk factor for low BMC in young adulthood.

Methods: Distal forearm cortical BMC (g) was measured with single photon absorptiometry (SPA) in 214 children (74 recruited after a fracture, 56 with premature birth and 84 as part of a control cohort). There were 120 boys with a mean age of 9.9 years (range 3-17) and 94 girls with a mean age of 10.7 years (range 4-17). BMC was then re-measured with the same SPA apparatus in the same region mean 28 years (range 26-29) later when the boys had become mean 36.6 years (range 28-44) and the girls mean 37.4 years (range 28-44). For each individuals we calculated BMC Z-scores at childhood and adulthood, respectively, based on BMC data in the 84 controls. We used Pearssons correlation coefficient to compared baseline and follow-up Z-scores values. The proportions of children within the lower quartile of BMC, with osteopenia (BMC < -1.0 SD) and with osteoporosis (BMC < -2.5 SD) were also registered at each occasion.

Results: BMC Z-score at childhood correlated with BMC Z-score BMC in adulthood in both boys ($r=0.48$) and girls ($r=0.64$) (both $p<0.0001$). The same was found if including only children who were 10 years or older at baseline (boys $r=0.52$ and girls $r=0.73$, both $p<0.0001$) and if including only children who were below age 10 years (boys $r=0.44$ and girls $r=0.52$, both $p<0.0001$). 55% of the children in the lowest quartile of BMC were still in the lowest quartile in adulthood (57% boys and 52% girls) and 66% of the children with osteopenia still had osteopenia in adulthood (56% boys and 79% girls). The single child with osteoporosis had osteopenia in adulthood.

Conclusions: Bone mass seems to partially “track” from childhood to adulthood, so that 23% of the variance in young adult men and 41% of the variance in young adult women could be explained by the level of bone mass in childhood. Furthermore, 19% of the variance in young adult men and 27% of the variance in young adult women could be attributed to the level of bone mass before age 10 years. We infer that low bone mass in children ought to be regarded as a risk factor for low peak bone mass.

Genome-wide Association Analysis of Skull BMD in Children: A Powerful Strategy to Identify Genetic Determinants of Osteoporosis-related Traits. John Kemp^{*1}, Carolina Medina-Gomez², Karol Estrada², Denise Happe², Maria Zillikens², Nicholas Timpson³, Beate St Pourcain⁴, Albert Hofman², Vincent Jaddoe², George Davey Smith⁵, André Uitterlinden², David Evans⁶, Fernando Rivadeneira², Jonathan Tobias⁷. ¹MRC Centre for Causal Analyses in Translational Epidemiology, United Kingdom, ²Erasmus Medical Center, Netherlands, ³MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, United Kingdom, ⁴School of Social & Community Medicine, University of Bristol, United Kingdom, ⁵School of Social & Community Medicine, University of Bristol, United Kingdom, ⁶MRC Centre for Causal Analyses in Translational Epidemiology, University of Bristol, United Kingdom, ⁷School of Clinical Science at North Bristol, University of Bristol, United Kingdom

Aim: The skull is a skeletal site minimally influenced by loading, muscular activity and is less masked by environmental influences. This is reflected in the high heritability of skull BMD ($h^2=80\%$) making it a suitable trait for genetic investigations which can provide further insight into the molecular regulation of skeletal function. Yet, the relevance for osteoporosis has not been determined. We performed a genome-wide association study on skull BMD in children seeking the identification of genetic loci relevant to osteoporosis.

Methods: GWAS was performed using 9395 subjects, combining the Avon Longitudinal Study of Parents and their Children (ALSPAC, $n=5299$, mean age=9.9, SD=0.32 years) and the Generation R study (GENR, $n=4096$, mean age=6.2, SD=0.5 years), using skull aBMD from total body DXA scans, and imputed genotype data. For each cohort, association analysis was performed with MACH2QTL, using linear regression models based on an expected allelic dosage model for SNPs, adjusting for sex, age, height and population stratification. SNPs with MAF <1% and poor imputation quality ($r^2<0.3$) were excluded. After controlling for genomic inflation, we combined association data for ~2.5 million imputed autosomal SNPs into an inverse variance fixed-effects additive model meta-analysis, using METAL.

Results: SNPs in seven known BMD loci reached genome wide significance including: *WNT4* ($P=1.6 \times 10^{-12}$), *RSPO3* ($P=3.3 \times 10^{-11}$), *WNT16* ($P=2.6 \times 10^{-28}$), *TNFRSF11B* ($P=2.1 \times 10^{-11}$), *LIN7C* ($P=1.6 \times 10^{-17}$), *LRP5* ($P=1.3 \times 10^{-11}$) and *TNFRSF11A* ($P=1.8 \times 10^{-8}$). In addition, a common SNP mapping to 6q23.2 (ALSPAC: MAF=0.35; B=-0.125; P=7.7x10⁻¹⁰) and (GENR: MAF=0.31; B=-0.129; 3x10⁻⁸) upstream of the Eyes Absent 4 (*EYA4*) gene achieved genome-wide significance after meta-analysis (MAF=0.35; B=-0.1267; P=8.3x10⁻¹⁷), explaining 0.72% of the variation in Skull-BMD.

Conclusion: This study demonstrates that skull BMD assessed in children is a suitable trait for genetic investigations of osteoporosis, allowing for the dissection between bone attainment and bone loss in a setting less prone to environmental influences. Furthermore, we identified a novel locus containing a signal mapping upstream of *EYA4*. Loss of function mutations in *EYA4* are associated with sensorineural hearing loss. A link between sensorineural hearing loss and BMD has previously been identified in sclerosteosis, where skull base overgrowth occurs in the context of high bone mass, leading to cranial nerve compression.

Effects of Glucocorticoid Therapy on Changes in Volumetric Bone Mineral Density (vBMD) and Cortical Structure in Childhood Nephrotic Syndrome (NS). Anne Tsampalieros^{*1}, Pooja Gupta², Babette Zemel¹, Rachel Wetzsteon¹, Mary Leonard¹. ¹Children's Hospital of Philadelphia, USA, ²Emory University School of Medicine, USA

Our prior cross-sectional study in childhood nephrotic syndrome (NS) demonstrated significantly lower trabecular vBMD and greater cortical vBMD, compared with controls. However, the impact of glucocorticoids (GC) on changes in vBMD and cortical structure during growth has not been addressed.

Objectives: To examine changes in vBMD and cortical structure over one year in children and adolescents with NS and normal renal function, and to determine the longitudinal relations between GC exposure, bone outcomes, and growth.

Methods: Tibia peripheral computed tomography (pQCT) scans were obtained at enrollment, 6 and 12 months in 56 NS participants, ages 5-21 yr. Sex-, race and age-specific Z-scores were generated for trabecular BMD (TrabBMD), cortical BMD (CortBMD), and cortical dimensions based on reference data in > 650 controls. Cortical dimension Z-scores were further adjusted for tibia length. Multivariable regression models examined determinants of interval changes in Z-scores, adjusted for baseline values.

Results: 56 NS participants with a median (range) of 4 (0-16) years since diagnosis were enrolled. Mean (SD) GC doses over the first and second 6 month intervals were 0.56 (0.71) and 0.48 (0.63) mg/kg/day, respectively. Changes in TrabBMD Z-scores were not associated with GC dose. Increases in CortBMD Z-scores were independently associated with greater GC dose ($p<0.001$) and smaller increases in tibia growth ($p<0.01$). Cortical area, section modulus, and periosteal and endosteal circumference Z-scores decreased significantly over 12 months (Table). Greater increases in tibia length were associated with greater decreases in cortical dimension

Z-scores (all $p<0.01$); this association was absent in reference participants (interaction $p<0.02$). Greater GC dose was associated with decreases in height Z-score ($p<0.001$) but was not associated with changes in cortical dimension Z-scores.

Conclusions: GC therapy was associated with increases in CortBMD, potentially related to suppression of bone formation and greater secondary mineralization. Conversely, greater growth (i.e. new bone formation) was associated with declines in CortBMD. The failure to identify correlates of changes in TrabBMD may relate to the limitations of pQCT measures of trabecular compartment vBMD. The growing skeleton may be especially vulnerable to GC effects on increases in cortical dimensions. Future studies are needed to determine the fracture implications of these findings.

| Z-Scores | Enrollment | 12 Months | Change 0-12 month | 0-12 p value |
|----------------------------|---------------|--------------|-------------------|--------------|
| TrabBMD | 0.54 ± 1.32* | 0.60 ± 1.40 | -0.01 ± 0.46 | 0.76 |

Familial Hypocalcemic Hypercalcemia Type 3 (FHH3) is Caused by Mutation in Adaptor Protein 2 Sigma 1 (*AP2S1*). M. Andrew Nesbit^{*1}, Fadi Hannan¹, Sarah A. Howles¹, Anita A.C. Reed¹, Treena Cranston², Clare E. Thakker¹, Lorna Gregory³, Andrew J. Rimmer³, Nigel Rust⁴, Una Graham⁵, Patrick J. Morrison⁶, Steven J. Hunter⁵, Michael Whyte⁷, Gil McVean³, David Buck³, Rajesh Thakker¹. ¹Nuffield Department of Clinical Medicine, University of Oxford, United Kingdom, ²Oxford Medical Genetics Laboratories, Oxford University Hospitals NHS Trust, United Kingdom, ³Wellcome Trust Centre for Human Genetics, University of Oxford, United Kingdom, ⁴Sir William Dunn School of Pathology, University of Oxford, United Kingdom, ⁵Regional Centre for Endocrinology & Diabetes, Royal Victoria Hospital, United Kingdom, ⁶Department of Medical Genetics, Queen's University Belfast, Belfast City Hospital, United Kingdom, ⁷Shriners Hospital for Children-Saint Louis, USA

Familial hypocalcemic hypercalcemia (FHH) is an autosomal dominant disorder characterized by lifelong elevation of serum calcium concentrations with inappropriately low urinary calcium excretion. It is genetically heterogeneous with defined types referred to as FHH1, FHH2 and FHH3 whose chromosomal locations are 3q21.1, 19p and 19q13.3, respectively. FHH1, caused by mutations of the calcium-sensing receptor (*CaSR*), occurs in >65% of FHH patients, whilst the etiologies of FHH2 and FHH3 are not known. To identify the genetic defect in FHH3, we performed exome capture and high-throughput sequencing in FHH3 patients from two unrelated kindreds. Over 2,500 previously unreported non-synonymous single nucleotide polymorphisms (SNPs) were found in the whole exome of each patient, and 5 of these were non-synonymous SNPs in 5 genes from 19q13.3. Amongst these SNPs, one that involved a C to T transition that predicted occurrence of a missense mutation, Arg15Cys, in adaptor protein 2 sigma 1 (*AP2S1*), was present in the patients from both kindreds. This mutation, which altered an evolutionary conserved arginine residue, was confirmed by independent dideoxynucleotide sequencing and *HhaI* restriction endonuclease analysis which demonstrated co-segregation of the mutation with FHH3 in 32 affected members from 5 generations of the two kindreds. Wild-type (Arg15) and mutant (Cys15) AP2S1 proteins were transiently expressed in HEK293 cells stably transfected with CaSR, and an assessment of their effect on intracellular calcium in response to changes in extracellular calcium demonstrated that the mutant Cys15 AP2S1 protein shifted the dose-response curve rightward with a significantly higher EC₅₀ = 2.77mM (95% confidence interval (CI) 2.64-2.90mM) when compared to the wild-type AP2S1 EC₅₀ = 2.29mM (95% CI 2.22-2.37mM) (P<0.0001), consistent with a loss-of-function mutation. AP2S1 forms part of the AP2 complex that has a role in G protein-coupled receptor recycling, and the Arg15 residue of AP2S1 has been implicated in cargo protein acidic dileucine motif recognition. Indeed, an examination of the crystal structure of AP2 revealed that replacement of the basic, polar Arg15 residue of AP2S1 with the neutral, slightly polar Cys15 residue compromises a key contact with a polar residue found within acidic dileucine motifs.

Thus, our studies have identified the genetic defect underlying FHH3 and give important insights into calcium homeostasis.

Inactivation of SKI-1 in Osteocytes Leads to Obesity in Adult Mice and Suggests a New Bone to Brain Endocrine Pathway Regulating Body Mass.

Jeffrey Gorski¹, Nichole T. Huffman², Anne C. Breggia³, Clifford Rosen³, Sridar Chittur⁴, Amber Stern¹, Mark Dallas², Nabil G. Seidah⁵, Lynda Bonewald¹. ¹University of Missouri - Kansas City, USA, ²University of Missouri-Kansas City, USA, ³Maine Medical Center, USA, ⁴Center for Functional Genomics, Univ. at Albany, USA, ⁵Institut de Recherches Cliniques de Montreal, Canada

Obesity is a major health problem and mechanisms controlling weight gain are incompletely understood. Osteocytes are endocrine cells embedded in bone secreting sclerostin, MEPE, and FGF-23 in response to load induced strain in bone. The hypothalamus regulates body mass and bone formation via similar leptin-serotonin pathways. Inactivation of the serine protease SKI-1 in osteocytes (oscKO) by breeding [SKI-1 (fl/-) DMP1 Cre (+/-)] males with [SKI-1 (fl/fl)] females leads to a rapid increase in body mass only upon reaching skeletal maturity (Fig. 1, representative of one of three litters). Similar findings were obtained in two separate breeding programs. SKI-1 is required for activation of transmembrane bound transcription factors including ATF-6, SREBP-1, SREBP-2 and CREB-like factors. Interestingly, maturity-dependent onset of obesity is not seen in leptin-deficient ob/ob mice. At 9-11 months of age, male oscKO are significantly heavier, 44.4 +/- 6.12 gm (n=8), than control littermates, 37.9 +/- 5.17 gm (n=12) (p<0.02, t-test). Female oscKO mice (n=2) trended in the same way but did not reach significance compared with same sex littermate controls. Although heavier, male oscKO mice exhibited the same or slightly smaller femoral cortical and trabecular bone volume by microCT, and ash weight mineral content as littermate controls. Similar to ob/ob, the oscKO mouse was hyperinsulinemic yet displayed elevated blood glucose. Nesfatin1, an appetite suppressant synthesized by osteocytes and released from nucleobindin-2, was almost 20-fold higher in serum from the leanest littermate (Fig. 1). Whole genome array studies on osteocyte mRNA showed 29 genes were reduced >2-fold in oscKO compared with three control littermates, while 53 genes were increased by >2-fold in the oscKO compared to the controls. In summary, inactivation of floxed SKI-1 in osteocytes using DMP1 Cre leads to a dramatic increase in body mass only after reaching skeletal maturity, a phenotype distinct from leptin deficient ob/ob mice. We hypothesize that osteocytes, cellular endocrine sensors of load induced strain in bone, suppress appetite by release of a systemic anorexigenic factor like nucleobindin-2/nesfatin1 which is able to cross the blood brain barrier and act on the hypothalamic appetite control center. The known increase in bone stiffness occurring with skeletal maturity suggests that bone biomaterial properties also play a role in this proposed bone to brain signaling pathway.

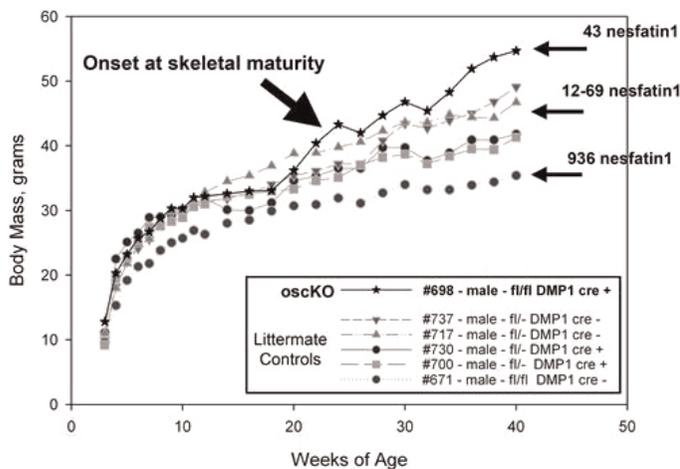

Fig 1. DMP1 Cre SKI-1 cKO mice gain weight rapidly after skeletal maturity

Reverse Regulation of Ca²⁺ Signaling and NFATc1 Activity by TRPM4 Stimulates Osteoblast but Suppresses Osteoclast Differentiation and Increases Bone Mass.

Liesbet Lieben¹, Barbara Colsoul², Sophie Torrekens³, Grzegorz Owsianik², Rudi Vennekens², Geert Carmeliet⁴. ¹KU Leuven, Belgium, ²Laboratory of Ion Channel Research, KU Leuven, Belgium, ³Clinical & Experimental Endocrinology, KU Leuven, Belgium, ⁴Katholieke Universiteit Leuven, Belgium

Differentiation of osteoblasts and osteoclasts requires Ca²⁺-dependent NFATc1 activation. Regulation of [Ca²⁺]_i levels is thus crucial, but the mechanism is poorly characterized. The Ca²⁺-activated cation channel, TRPM4, controls Ca²⁺ influx in several cell types by inducing cell depolarization. TRPM4 is highly expressed in osteoblasts and osteoclasts and is therefore a likely candidate to fine-tune [Ca²⁺]_i signaling. By analyzing *Trpm4*^{-/-} mice, we show that TRPM4 regulates [Ca²⁺]_i signaling and differentiation of osteoblasts and osteoclasts in reverse direction.

First, we demonstrate that in osteoblasts, TRPM4-mediated depolarization stimulates Ca²⁺ influx via voltage-gated Ca²⁺ channels (VGCCs) which enhances NFATc1-mediated differentiation. Indeed, pharmacological activation of TRPM4 elicited a profound Ca²⁺ influx, which was suppressed by VGCC antagonists and by genetic *Trpm4* inactivation. Accordingly, *Trpm4*^{-/-} osteoblasts exhibited reduced basal [Ca²⁺]_i and *Nfatc1* mRNA levels resulting in impaired *in vitro* differentiation (mRNA differentiation markers) and mineralization.

Second, we show that osteoclasts lack VGCC activity, and as a result, the TRPM4-mediated depolarization reduces the driving force for Ca²⁺ influx and hereby smoothens the Ca²⁺ oscillations and limits NFATc1-mediated differentiation. In fact, RANKL-induced osteoclastogenesis was increased in *Trpm4*^{-/-} hematopoietic cells and was associated with an increase in the frequency and amplitude of Ca²⁺ oscillations and with enhanced NFATc1 activity. Consistent herewith, osteoclast formation was more profoundly stimulated when *Trpm4*^{+/+} osteoblasts were cultured with *Trpm4*^{-/-} vs. *Trpm4*^{+/+} hematopoietic cells. However, fewer osteoclasts were formed when *Trpm4*^{-/-} osteoblasts were used, indicating that *Trpm4*^{-/-} osteoblasts have less capacity to induce osteoclastogenesis.

These cellular effects explained the significantly reduced bone mass in *Trpm4*^{-/-} mice characterized by a manifest decrease in bone formation (serum osteocalcin, dynamic bone formation) and osteoblast differentiation (mRNA markers), with unaltered osteoclast number (TRAP, mRNA markers).

In conclusion, TRPM4-regulated [Ca²⁺]_i signaling differentially affects NFATc1 activity in bone cells, leading to stimulation of osteoblast yet suppression of osteoclast differentiation and the combined effects promote bone mass accrual.

Hypophosphatemic Rickets in Dentin Matrix Protein 4 (Dmp4) Knockout Mice.

Robert Brommage¹, Jeff Liu¹, Sabrina Jeter-Jones¹, David Powell¹, Andrea Thompson¹, Thomas Wronski², Peter Vogel¹. ¹Lexicon Pharmaceuticals, USA, ²University of Florida, USA

Raine syndrome (Simpson, Am J Hum Genet 81:906; 2007) in humans results from mutations in the FAM20C gene. Affected individuals usually die at birth from respiratory failure, with autopsy findings of generalized osteosclerosis.

Dmp4 is the mouse ortholog of FAM20C, with 86.5% sequence identity (Hao, J Biol Chem 282:15357; 2007) and expression in chondrocytes, osteoblasts, osteocytes, ameloblasts, odontoblasts and cementoblasts. (Wang, J Histochem Cytochem 58:957; 2010). Dmp4 knockout (KO) mice were generated by disruption of exons 1 and 2 employing homologous recombination. For all data provided below, P < 0.001 for the differences between KO and wild-type littermate mice.

Serum parameters measured in Dmp4 KO mice through weaning at 18, 22, 26 and 30 days of age (males and females combined, with Ns = 6 to 17) show modest (11%) hypocalcemia, severe (55%) hypophosphatemia and a 2.1-fold elevation of alkaline phosphatase independent of age. Newborn KO mice are normophosphatemic.

Extramedullary hematopoiesis occurs in liver and spleen. Incisors and molars are small and deformed, with degeneration and disorganization of ameloblasts and lack of mineralized enamel. The odontoblast layer is mildly disrupted with regions of dentin that contain round basophilic bodies. At 30 days of age KO mice have reduced body weight (30%), femur/tibia lengths (24%), and midshaft tibia bone diameter (22%), marrow diameter (15%) and cortical thickness (34%).

Examination of decalcified bone sections at 4 and 14 week of age shows that growth plate cartilage is thickened and disorganized in long bones, with almost total absence of cartilage cores in newly formed trabeculae. With age there is a progressive osteosclerosis affecting metaphyses of the long bones. Ribs, nasal turbinates and other bones of the skull are thicker than normal, but cortical bone in the shafts of long bones is reduced. Both nasal turbinate bones and trabeculae in the sternum are irregularly shaped.

Examination of undecalcified sections of vertebrae and femur shows extensive unmineralized osteoid, consistent with hypophosphatemic rickets and osteomalacia. Material BMD of tibial cortical bone by microCT is reduced 18%, consistent with osteomalacia.

With severe hypophosphatemia in KO mice and expression in osteocytes, FAM20C/Dmp4 is likely involved in the FGF23/DMP1/PHEX/MEPE system of phosphate homeostasis (Sapir-Koren, IBMS BoneKey 8:286; 2011).

Pharmacological Inhibition of FGFR Signaling Ameliorates FGF23-mediated Hypophosphatemic Rickets. Simon Woehrle^{1*}, Christine Henninger¹, Olivier Bonny², Anne Thuery¹, Noemie Beluch¹, Nancy Hynes³, Vito Guagnano¹, William Sellers⁴, Francesco Hofmann¹, Michaela Kneissel¹, Diana Graus Porta¹. ¹Novartis Institutes for BioMedical Research, Switzerland, ²University of Lausanne, Department of Pharmacology & Toxicology, Switzerland, ³Friedrich Miescher Institute for Biomedical Research, Switzerland, ⁴Novartis Institutes for BioMedical Research, USA

Fibroblast growth factor 23 (FGF23) is a circulating factor secreted by osteocytes, which is essential for phosphate homeostasis. In kidney proximal tubular cells FGF23 inhibits phosphate reabsorption and vitamin D biosynthesis. Excess levels of FGF23 cause renal phosphate wasting and suppression of circulating vitamin D levels and are associated with several hereditary hypophosphatemia disorders with skeletal abnormalities, including X-linked hypophosphatemic rickets (XLH) and autosomal recessive hypophosphatemic rickets (ARHR). Currently, therapeutic approaches to these diseases are mainly limited to dietary vitamin D and phosphate supplementation, often merely resulting in partial correction of the skeletal aberrations. Here, we evaluate the use of FGFR inhibitors for the treatment of FGF23-mediated hypophosphatemia disorders using NVP-BGJ398, a novel selective, pan-specific FGFR inhibitor currently in Phase I clinical trials for cancer therapy. In two different hypophosphatemic mouse models, Hyp and *Dmp1*-null mice, resembling the human diseases XLH and ARHR, we find that pharmacological inhibition of FGFRs efficiently abrogates aberrant FGF23 signaling and normalizes the hypophosphatemic and hypocalcemic conditions of these mice. Correspondingly, long-term FGFR inhibition in Hyp mice leads to enhanced bone growth, increased mineralization and reorganization of the disturbed growth plate structure. We therefore propose NVP-BGJ398 treatment as a novel approach for the therapy of FGF23-mediated hypophosphatemia diseases.

Systems Genetics Identifies *Lhfp* as a Bone Mineral Density Candidate Gene and Regulator of Osteoblastogenesis. Cheryl Ackert-Bicknell¹, Daniel Gatti¹, Rachel Madenjian², John Sundberg¹, Gary Churchill¹, Charles Farber^{2*}. ¹The Jackson Laboratory, USA, ²University of Virginia, USA

It is well understood that peak bone mass is a heritable phenotype. Thus, there has been considerable effort focused on identifying and functionally characterizing the genes underlying this phenotype. Genome-wide association (GWA) and network analysis are two powerful approaches used to accomplish these goals. When used in concert, they not only identify the genes underlying a phenotype, but also aid in determining their functional role. In this study, we performed GWA for bone mineral density (BMD) using data obtained from 27 classical inbred strains of mice (i.e. not wild derived). Specifically, BMD data was collected on female and male mice at 6, 12, and 20 months of age and GWA was performed using the Efficient Mixed-Model Association algorithm. This analysis identified high-confidence BMD associations on Chromosomes (Chrs) 2, 3, and 17. To minimize false positives a second BMD GWA was performed in a partially overlapping set of 31 classical inbred strains. This replicated the association on Chr. 3. In both sets of mice the Chr. 3 association spanned a 500 Kbp genomic interval containing two annotated genes, lipoma HMGIC fusion partner (*Lhfp*) and component of oligomeric golgi complex 6 (*Cog6*). Causality modeling in a separate F2 cross was used to generate additional evidence supporting a causal role for one or both genes. These results suggested that *Lhfp*, and not *Cog6*, was a regulator of BMD. A co-expression network analysis revealed that *Lhfp* was a member of a co-expression module enriched for genes involved in osteoblast function and gene expression studies confirmed that this gene is indeed highly expressed in mouse primary calvarial osteoblasts (mOBs). Within this module, *Lhfp* was most strongly connected to genes encoding bone extracellular matrix proteins. Together, these data suggested that *Lhfp* was a regulator of osteoblast function. To test this hypothesis, we determined the effect of *Lhfp* knockdown on the differentiation of mOBs. At 10 days post-differentiation, we observed significant ($P < 0.05$) dose-dependent reductions in mineralized nodule production by cells treated with two independent *Lhfp* targeting siRNAs, substantiating our hypothesis that this gene is indeed involved in osteoblast function. In conclusion, we have used a multifaceted systems genetics approach in mice to identify *Lhfp* as a regulator of osteoblastogenesis and a promising candidate gene for BMD.

Targeted Disruption of Heparan Sulfate in Osteoblasts Leads to Severe Osteoporotic Phenotype in Mice. Satoshi Nozawa^{1*}, Fumitoshi Irie², Shinji Iizuka², Thomas Clemens³, Kazu Matsumoto⁴, Yu Yamaguchi^{2, 1}, USA, ²Sanford-Burnham Medical Research Institute, USA, ³Johns Hopkins University, USA, ⁴Gifu University, School of Medicine, Japan

Background: Although accumulating *in vitro* data suggest important roles for heparan sulfate (HS) in osteoblast differentiation, there is little information about whether and how HS is involved in bone formation *in vivo*. This study aims to determine the role of HS in the osteoblast lineage and to dissect the mechanism by which HS influences the function of these cells.

Methods: We eliminated heparan sulfate from mature osteoblasts by conditionally inactivating *Ext1*, the gene encoding an enzyme essential for heparan sulfate synthesis. Analysis of bone mass was performed by osteocalcin-Cre (Oc-Cre)-driven conditional *Ext1* mutant mice, *Oc-Cre; Ext1^{fllox/fllox}*. Standard histomorphometric variables were calculated. This was followed by initial *in vitro* investigations into the mechanism of osteogenesis and osteoclastogenesis.

Result: *Oc-Cre; Ext1^{fllox/fllox}* mice show severe osteoporotic phenotype. The reduction in bone volume observed in mutant mice was progressively more evident with increasing animal age compared with wild type. BV/TV in mutant lumbar vertebrae decreased by 52% ($p < 0.01$) at 5 weeks of age and by 22% ($p < 0.001$) at 3 months (Figure). The bone formation rates of mutants were equivalent to normal littermates. On contrast, osteoclast number (N.Oc/T.Ar, N.Oc.N/B.Pm) in mutant bones were significantly increased in the mutant mice ($p < 0.01$). Moreover, urinary deoxypyridinoline was increased in mutant mice ($p < 0.05$). As for the cause, we focused Osteoprotegerin (Opg) which contains a highly basic heparin-binding domain, suggesting that direct interaction with HS could be involved in osteoclastogenesis through the intermediary of RANK-RANKL-OPG triad. We measured cell surface-associated and soluble Opg in the NaCl extracts. We detected smaller volume of Opg on mutant osteoblast ($p < 0.05$). To elucidate the interaction with Opg and heparan sulfate, we produced recombinant Opg lacking heparin binding domain by site directed mutagenesis. The results show Opg lacking heparin binding domain could not inhibit osteoclastogenesis *in vitro* assays than the wild type Opg, which suggests heparan sulfate is required to Opg mediated osteoclastogenesis inhibition.

In summary, *Oc-Cre; Ext1^{fllox/fllox}* mice show severe osteoporotic phenotype. We suggest that HS is required for cell surface association of Opg and HS suppresses osteoclastogenesis by increasing cell surface-associated Opg, which could interfere RANK-RANKL interaction.

Oc-Cre; Ext1^{fllox/fllox} mice show severe osteoporotic phenotype.

EphrinB2 Signaling in Osteoblasts and Chondrocytes is Required for their Differentiation and Support of Osteoclast Formation. Stephen Tonna^{1*}, Farzin Takvar², Ingrid Poulton³, Patricia Ho³, Narelle McGregor³, Carl Walkley³, Brian Liddicoat³, Liliana Tatarczuch⁴, Eleanor Mackie⁵, T. John Martin⁶, Natalie Sims⁷. ¹St Vincent's Institute, Australia, ²St. Vincent's Institute of Medical Research, Australia, ³St Vincent's Institute of Medical Research, Australia, ⁴Veterinary Science University of Melbourne, Australia, ⁵University of Melbourne, Australia, ⁶St Vincent's Institute of Medicine, Australia, ⁷St. Vincent's Institute for Medical Research, Australia

Osteoblasts express both EphB4 and its cognate ligand, ephrinB2, and treatment with PTH rapidly induces their expression of ephrinB2. Simultaneous blockade of both ephrinB2 and EphB4 signaling impedes both osteoblast differentiation and mineralization *in vitro*, while stimulation of ephrinB2 in the hematopoietic lineage inhibits osteoclast differentiation. To investigate ephrinB2 signaling within osteoblasts and chondrocytes we generated mice with conditional deletion of the ephrinB2 cytoplasmic domain in osteoblasts and sporadic hypertrophic chondrocytes (*Osx1:GFP; Cre; Efnb2^{fl/fl}*).

EphrinB2 cytoplasmic domain expression was reduced ~95% in FACS-isolated *Osx1.Efnb2^{fl/fl}* primary calvarial osteoblasts compared with *Osx1.Efnb2^{+/+}* and ~80% in *Osx1.Efnb2^{fl/fl}* primary chondrocytes. In FACS-sorted *Osx1.Efnb2^{fl/fl}* osteoblasts both early (Runx2, Osx, ALP) and late differentiation markers (OCN, PTHR1,

MEPE, SOST) were reduced by 80-90%. Similar findings were obtained when exogenous viral Cre was introduced to *Efnb2^{fl/fl}* osteoblasts. Consistent with these changes, bone formation rate was reduced by ~50% in adult *Osx1.Efnb2^{fl/fl}* mice, and late osteoblast differentiation markers were impaired by ephrinB2:ephrinB4 receptor antagonists (sEphB4 and TNYL). *Osx1.Efnb2^{fl/fl}* osteoblasts also demonstrated reduced RANKL expression (50%) and impaired support of osteoclast formation in co-culture with wild-type bone marrow precursors. This indicates that ephrinB2 signaling within the osteoblast lineage is required for appropriate differentiation and mineralization by osteoblasts and to support osteoclast formation.

Reduced support of osteoclast formation was also observed in *Osx1.Efnb2^{fl/fl}* neonates, which demonstrated high trabecular bone volume, prominent cartilage remnants, and a 75% reduction in osteoclast numbers at the growth plate; a mild osteopetrosis that resolved by 12 weeks of age. Electron microscopy revealed that the osteoclasts near the growth plate showed reduced contact with cartilage and bone, did not form ruffled borders or sealing zones and exhibited convoluted nuclei. In addition contact between osteoblasts and between osteoblasts and the bone surface was reduced and chondrocytes at all stages of maturation contained more condensed chromatin. In conclusion, these results indicate that osteoblastic ephrinB2 signaling regulates osteoblast and chondrocyte differentiation and the support of osteoclast formation by both chondrocytes and osteoblasts.

Hypoxia-inducible Factor-1 α Restricts PTH-induced Anabolic Signals by Sequestration of β -catenin. Julie Leslie^{*1}, Thomas Clemens¹, Ryan Riddle². ¹Johns Hopkins University, USA, ²Johns Hopkins University School of Medicine, USA

The hypoxia inducible factors (Hifs) are evolutionarily conserved transcriptional factors that control homeostatic responses to low oxygen. In developing bone, Hif-1 generated signals are required for angiogenesis, which appears to be necessary for initial specification of bone-forming osteoblasts. In mature mouse bone, loss of Hif-1 α in osteoblasts resulted in a more rapid accumulation of trabecular and cortical bone. Moreover, removal of Hif-1 α from osteoblasts sensitized mature bone to load-induced bone formation by enhancing the response of osteoblasts to mechanical stimuli (Riddle, 2011 J Biol Chem 286:44449-44456). These findings suggested that Hif-1 exerts distinct developmental functions and acts in the mature skeleton as a negative regulator of bone formation. In this study, we investigated the function of Hif-1 α in osteoanabolic signaling by assessing the effect of Hif-1 α loss-of-function on bone formation in response to parathyroid hormone (PTH). Exposure of primary mouse osteoblasts to PTH resulted in the rapid induction of Hif-1 α protein levels via a post-transcriptional mechanism, but had no effect on Hif-2 α . In vivo, PTH treatment (40 μ g/kg BW/day for 6 weeks) increased trabecular bone volume to a significantly greater extent in Δ Hif1 α mice than in control littermates. To clarify the mechanism underlying increased sensitivity to PTH, we examined the activation of signaling events downstream of the PTH receptor in osteoblasts lacking Hif-1 α . The activation of cAMP and MAP kinase signaling by PTH was not significantly affected by the loss of Hif-1 α function. However, PTH induced β -catenin activity was enhanced, as evidenced by prolonged elevations in Axin2 mRNA levels in Hif-1 α -deficient cells. Further, PTH-induced occupancy of the Axin2 promoter by β -catenin (ChIP) was greater in osteoblasts lacking Hif-1 α compared to controls. Taken together, these data indicate that Hif-1 α functions in the mature skeleton to restrict osteoanabolic signaling. The availability of pharmacological agents that reduce Hif-1 α function suggests the value in further exploration of this pathway to optimize the therapeutic benefits of PTH.

Serotonin Receptor 5-HT_{2B} Controls Osteoblast Cell-cell Adhesion and Mineralization by Multiple Pathways. Yasmine Chabbi Achengli^{*1}, Jean Marie Launay², Luc Maroteaux³, Marie-Christine De Vernejoul⁴, Corinne Collet¹. ¹INSERM U606, France, ²Laboratoire de biochimie Hopital Lariboisière, France, ³INSERM UMR S-839 Institut du Fer a Moulin, France, ⁴Fédération De Rhumatologie Et INSERM U606, France

The serotonergic 5-HT_{2B} receptor is implicated in various physiological and pathological functions. Our previous in vivo results showed that in the absence of 5-HT_{2B} receptor (5-HT_{2B}^{-/-} mice) there was a decreased bone formation due to reduced mineralizing surfaces (Collet et al., 2008). In order to decipher the mechanism(s) responsible(s) for the osteoblast defect, we studied primary calvaria osteoblast cultures. Firstly, we observed that both osteoblast proliferation and mineralization were markedly impaired in 5-HT_{2B}^{-/-} cells, associated with a reduced alkaline phosphatase gene expression (-34%). Moreover, cell-cell adhesion of 5-HT_{2B}^{-/-} osteoblasts was also lower (-62%) with N-cadherin intra-cytoplasmic localization. Wnt 3a treatment induced an increase proliferation of the WT but not of the 5-HT_{2B}^{-/-} osteoblast. As multiple signaling pathways could be responsible for this phenotype we first investigated the phospholipase A2 (PLA2) pathway that has been shown to be linked to 5-HT_{2B} in an osteoprogenitor cell line. Treatment with mepacrine, a specific inhibitor of PLA2, induced a decreased cell aggregation and induced N-cadherin mislocalization. Furthermore the protein expression of COX2

was strongly decreased in 5-HT_{2B}^{-/-} culture as compared to WT. We therefore measured the level of prostaglandin E2 (PGE2) and the expression of PGE2 synthase (PGES), and we observed no differences. By contrast, the level of prostacyclin (PGI2 prostaglandin I2) was 10 fold higher and PGI synthase activity was markedly increased (WT: 11 \pm 5.2 vs 5-HT_{2B}^{-/-}: 42 \pm 6.3 p<0.0001) in absence of 5-HT_{2B} receptors. As prostacyclin is the endogenous ligand of peroxisome proliferator activated receptor β/δ (PPAR- β/δ) we hypothesized that PPAR β/δ activation could be responsible in part of the 5-HT_{2B}^{-/-} osteoblast phenotype. One of the target of PPAR β/δ is the protein convertase (PC) that is involved in N-cadherin maturation and migration to cell membrane. We showed a decrease in PC activity in 5-HT_{2B}^{-/-} osteoblasts, that was restored by treatment with GSK0660 a specific PPAR β/δ inhibitor. Treatment with GSK0660 improved 5-HT_{2B}^{-/-} osteoblast aggregation and N-cadherin localization to the membrane, and completely restored the mineralization defect of the 5-HT_{2B}^{-/-} osteoblast. In conclusion we show that osteoblast 5-HT_{2B} receptor signal mainly by the PGI2 pathway and could involve PPAR β/δ .

Gli1 Participates in the Indian Hedgehog-mediated Osteogenesis during Endochondral Ossification. Hironori Hojo^{*1}, Shinsuke Ohba², Fumiko Yano³, Taku Saito⁴, Toshiyuki Ikeda⁵, Keiji Nakajima⁶, Yusuke Komiyama⁶, Naomi Nakagata⁷, Kentaro Suzuki⁷, Tsuyoshi Takato⁸, Hiroshi Kawaguchi⁹, Ung-Ii Chung¹⁰. ¹The Center for Disease Biology & Integrative Medicine, Japan, ²Division of Biotechnology, Center for Disease Biology & Integrative Medicine, Japan, ³University of Tokyo, Japan, ⁴University of Tokyo, Graduate School of Medicine, Japan, ⁵Information Technology Services, Inc., Japan, ⁶The University of Tokyo, Japan, ⁷Kumamoto University, Japan, ⁸Graduate School of Medicine The University of Tokyo, Japan, ⁹University of Tokyo, Faculty of Medicine, Japan, ¹⁰University of Tokyo Schools of Engineering & Medicine, Japan

With regard to hedgehog (Hh) signaling in mammalian skeletal development, most research has focused on Gli2 and Gli3 rather than Gli1. This is because *Gli1^{-/-}* mice do not show any gross abnormalities in adulthood, and no detailed analyses of fetal *Gli1^{-/-}* mice are available. Therefore, we aimed to determine physiological roles of Gli1 in osteogenesis. We initially examined the contribution of Gli1 to Hh signaling-mediated osteogenesis compared with Gli2 and Gli3 *in vitro* and *in vivo*. In primary perichondrial cell (PPC) cultures, wild-type (WT) cells acquired phenotypes of early osteoblasts upon Hh signaling activation by SAG, a Smoothed agonist. The SAG-mediated osteoblast differentiation was impaired in *Gli1^{-/-}* as well as *Gli2^{-/-}* cells relative to that in WT cells, whereas it was enhanced in *Gli3^{-/-}* cells. Histological analyses on *Gli1^{-/-}* mice revealed that the bone collar was absent in metatarsals of the mice at embryonic day 17.5. The *Gli1^{-/-}* perichondrium showed a decreased region of alkaline phosphatase (*Alp*)-expressing cells compared with that in the WT perichondrium, and it lacked expression of bone sialoprotein (*Bsp*). Expression of runt-related transcription factor (Runx2) or osterix was not detected in the *Gli1^{-/-}* perichondrium at this stage. In addition, *Gli1^{-/-};Gli2^{-/-}* mice showed more severely-impaired osteogenesis than either *Gli1^{-/-}* or *Gli2^{-/-}* mice, and osteoblast differentiation was impaired in *Gli1^{-/-};Gli3^{-/-}* perichondrial cells compared with *Gli3^{-/-}* cells *in vitro*. We next attempted to elucidate how Gli1 regulated osteogenesis. *Gli1* overexpression upregulated the early osteoblast markers *Alp* and *Bsp*, but not the late osteoblast marker *osteocalcin*, in PPCs and C3H10T1/2 cells. *Gli1* knockdown with shRNA inhibited the SAG-induced expressions of *Alp* and *Bsp* in C3H10T1/2 cells. *Gli1* overexpression not only rescued impaired expressions of *Alp* and *Bsp* in Indian hedgehog (*Ihh*)^{-/-} PPCs, but also upregulated their expressions in *Runx2^{-/-}* PPCs. Luciferase assay, EMSA and CHIP revealed that Gli1 transactivated *Alp* and *Bsp* via its binding to 5' regulatory regions of these genes, possibly underlying the activity of Gli1 in osteogenesis. Thus, Gli1, acting downstream of *Ihh*, contributes to early osteoblast differentiation, at least to some extent, in a Runx2-independent manner; it plays redundant roles with Gli2 and is involved in the repressor function of Gli3. We propose that Gli1 functions collectively with Gli2 and Gli3 in osteogenesis.

Conditional Disruption of the Prolyl Hydroxylase 2 (PHD2) Gene Defines its Key Role in Skeletal Development. Shaohong Cheng^{*1}, Weirong Xing², Sheila Pourteymoor³, Subburaman Mohan⁴. ¹VA Loma Linda Health Care Systems, USA, ²Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, ³Jerry L Pettis VA Memorial Med Ctr, USA, ⁴Jerry L. Pettis Memorial VA Medical Center, USA

Disruption of gulonolactone oxidase, a key enzyme involved in ascorbic acid (AA) biosynthesis, results in spontaneous fractures (Sfx) in mice caused by deficient osteoblast (OB) functions. Studies on the molecular mechanism for AA regulation of OBs revealed that the increase in osterix (*Osx*) expression during OB maturation is dependent on AA and that AA effects on *Osx* mRNA expression is mediated via a

novel mechanism that involves PHD2-dependent proteasomal degradation of a yet to be identified transcriptional repressor of *Osx* gene expression. Because PHD2 is strongly expressed in OBs and that inhibition of PHD2 expression using shRNA reduces AA-induced *Osx* expression and OB differentiation, we predict that PHD2 is important in the OB differentiation pathway. In order to determine if lack of PHD2 in bone cells influences the skeletal phenotype, we first generated conditional knockout (KO) of PHD2 by crossing PHD2 floxed mice with transgenic *Osx-Cre* mice. Surprisingly, none of the surviving 65 mice were *Cre* positive and homozygous for floxed PHD2 alleles. However, *Cre* positive embryos that were homozygous for floxed PHD2 alleles were detected at embryonic day 14. Since *Osx* is known to be expressed in chondrocytes besides OBs, we next crossed PHD2 floxed mice with *Coll1 α 2-Cre* mice in which expression of *Cre* recombinase is placed under the control of the procollagen type 1 α 2 promoter. Of the homozygous PHD2 floxed mice, the *Cre* positive genotype was identified in 60% fewer mice as compared to the *Cre* negative genotype. The surviving mice exhibited a 27% and a 12% reduction in body weight and femur length at 3 wks of age ($P < 0.01$). At 5 and 8 wks of age, femur and tibia BMD, measured by DXA, were reduced by $>15\%$ ($P < 0.01$) in the conditional mutants. To determine the mechanism for BMD reduction in PHD2 conditional KO mice, we measured expression levels of transcription factors, bone formation and differentiation markers using RNA extracted from femurs of conditional KO and littermate control mice. We found that mRNA levels of *Osx*, osteocalcin and ALP were reduced by 50%, 58% and 30%, respectively, in the femurs of conditional KO mice (all $P < 0.05$). In contrast, expression levels of TRAP, Runx2 and *Dlx5* were unaffected. Based on our published data and current findings, we conclude that PHD2 is critically involved in regulating OB functions and thereby bone formation in part via regulating *Osx* expression.

Loss of the Wnt Inhibitor Tiki2 Results in a High Bone Mass Phenotype. Bryan MacDonald¹, Alexander Robling², Xi He¹. ¹Children's Hospital Harvard Medical School, USA, ²Indiana University, USA

Activation of the Wnt/ β -catenin pathway in osteoblasts and osteocytes results in increased bone mass. Therefore therapies that target antagonists of the Wnt pathway represent promising anabolic treatments. Here we report the characterization of new antagonist of the Wnt signaling pathway and the high bone mass phenotype of the Tiki2 knockout mouse.

The TIKI gene family was identified in screen for Wnt pathway regulators in *Xenopus* embryos¹. Named after the large headed humanoid carving in Polynesian mythology; expression of TIKI resulted in embryos with enlarged heads consistent the inhibition of the Wnt/ β -catenin pathway. TIKI proteins contain an amino terminal signal sequence, a conserved TIKI domain of 330 amino acids and a carboxyl terminal transmembrane region with almost no intracellular domain. Heterologous expression shows that TIKI proteins are localized within the secretory pathway and present at the plasma membrane. Our current data indicate that TIKI acts as a protease to cleave the amino terminal residues of Wnt ligands, thereby inactivating Wnt to prevent receptor binding¹.

To analyze the role of Tiki2 in mammals we generated a Tiki2 knockout mouse. Homozygous Tiki2^{-/-} null mice are viable and fertile, and are found at the expected Mendelian frequencies on a mixed genetic background. Mouse Tiki2 is expressed in osteoblasts suggesting a role for Tiki2 in regulating bone mass. Offspring from a Tiki2^{+/-} intercross were analyzed by μ CT, and a greater amount of trabecular bone was found in Tiki2^{-/-} mice. Quantification of the trabecular bone properties revealed a significant increase in bone volume fraction (KO 0.183 \pm 0.063 BV/TV vs WT 0.099 \pm 0.038 BV/TV), trabecular number (KO 4.34 \pm 0.81 #/mm³ vs WT 3.12 \pm 0.47 #/mm³) and trabecular thickness (KO 0.0659 \pm 0.0052 mm vs WT 0.0590 \pm 0.0057 mm) in male 16 week old Tiki2^{-/-} mice (n=6) compared with +/- littermates (n=7). Our results demonstrate that genetic inhibition of the Wnt antagonist Tiki2 increases trabecular bone and suggest that inhibition of TIKI proteins may be a therapeutic option for treating low bone mass disorders.

Selective Deletion of the Soluble Colony Stimulating Factor 1 Isoform *in vivo* Eliminates Estrogen-deficiency Bone Loss in Mice. Gang-Qing Yao¹, Benhua Sun¹, Jian Jun Wu², Karl Insogna¹. ¹Yale University School of Medicine, USA, ²Yale University, USA

It has been reported that a neutralizing antibody to CSF1 completely prevents ovariectomy(OVX)-induced bone loss in mice. There are two isoforms of CSF1, soluble (sCSF1) and membrane-bound (mCSF1), but their individual biological functions are unclear. Estrogen-withdrawal increases levels of IL-1 and TNF in bone marrow, which induce the formation of a stromal cell population producing high levels of sCSF1. However, others have found that estrogen-withdrawal selectively up-regulates expression of mCSF1 and down-regulates sCSF1 expression in rat bone marrow cultures. We recently reported that one month after surgery, five month-old mCSF1 knockout (*k/o*) and wild type (*wt*) female mice experienced the same degree of

bone loss following ovariectomy (OVX). OVX induced a significant 4-fold increase in the expression of sCSF1 in the bones of *wt* mice while expression of mCSF1 was unchanged. These findings indicate that mCSF1 does not appear to be required for estrogen-deficiency bone loss but sCSF1 could play a key role in this pathologic process. To test this hypothesis we engineered sCSF1 *k/o* mice. Isoform-specific RT-PCR confirmed the absence of transcripts for sCSF1 in bone tissue isolated from these animals and no circulating CSF1 was detected in these animals when assayed with a sensitive ELISA. Surprisingly, there were no significant differences in BMD as assessed by DXA, between sCSF1 *k/o* mice and *wt* controls. To examine the effect of estrogen withdrawal in these animals 5 month-old sCSF1 *k/o* and *wt* female mice underwent ovariectomy (OVX) or sham-OVX. One month after surgery, femoral, spinal and total BMD (determined byDXA) were reduced by 7.6% and 4.9% and 6.6% respectively in OVX-*wt* animals as compared to sham-OVX *wt* mice. OVX sCSF1-*k/o* mice showed 3.8% and 6.1% and 0.89% reductions in femoral, spinal and total BMD respectively compared to sham-OVX sCSF1-*k/o* animals. MicroCT analyses demonstrated an 18% reduction of femoral trabecular bone density in OVX-*wt* animals compared to sham-OVX *wt* mice. In striking contrast, OVX sCSF1-*k/o* mice showed no reduction in femoral BV/TV. Our findings indicate important non-redundant functions for the two isoforms of CSF1. In particular, our data indicate that sCSF1 but mCSF1 plays a key role in estrogen-deficiency bone loss. However, mCSF1 is essential for normal bone remodeling.

Conditional Deletion of gp130 in Osteoblasts and Osteocytes has Divergent Effects on Trabecular and Cortical Bone. Rachele Johnson¹, Holly Brennan¹, Ingrid Poulton¹, Narelle McGregor¹, Tzen Koh¹, Muhammad Zainuddin¹, Emma Walker¹, T John Martin¹, Natalie Sims². ¹St. Vincent's Institute of Medical Research, Australia, ²St. Vincent's Institute for Medical Research, Australia

Glycoprotein 130 (gp130) is a cytokine co-receptor that transduces intracellular signals in response to IL-6, IL-11, leukemia inhibitory factor (LIF) and oncostatin M (OSM). These cytokines stimulate osteoblastic RANKL expression, osteoclast formation and bone formation, but surprisingly, global deletion of gp130 resulted in enhanced osteoclast formation, while the effect of gp130 deletion on bone formation was complicated by neonatal lethality and systemic defects. To determine the role of gp130 in the osteoblast lineage, gp130 was deleted conditionally from early stages of osteoblast differentiation (*Osx1-Cre*) to late stage osteoblasts/osteocytes (*DMP1-Cre*) in C57BL/6 mice. Efficient gp130 recombination was verified by real-time PCR.

MicroCT and histomorphometry on 12-week old male mice revealed a significant reduction in trabecular bone volume (~50%) in tibiae, femora and vertebrae of *Osx1 gp130^{off}* and *DMP1 gp130^{off}* mice compared with appropriate *Cre+ wt/wt* controls. Both low bone mass phenotypes were accompanied by significant reductions (between 22-51%) in trabecular number, mineralizing surface and bone formation rate, indicating that late-stage osteoblast/osteocytic gp130 signaling is essential for normal bone formation. Although gp130-binding cytokines stimulate osteoclast formation, osteoclast number, surface and size were not changed in either KO, suggesting that while osteoblastic gp130 is critical for bone formation, it is not required for normal osteoclast formation. Even in 3-day old *Osx1* and *DMP1 gp130* KOs, no differences in osteoclast numbers were detected, indicating compensation for the lack of gp130 to support osteoclast formation in the context of normal development and remodeling.

In contrast to trabecular bone, cortical analysis by microCT revealed a significant increase in cortical thickness (4 & 12%), marrow volume (18 & 29%) and periosteal surface area (10 & 17%) in *Osx1* and *DMP1 gp130* KOs, respectively, with no change in bone length, indicating that osteoblastic gp130 may function in dramatically different ways in trabecular and cortical bone.

In conclusion, while osteoblastic gp130 is not required for osteoclast formation, its deletion may allow for osteoblast and osteocyte compensatory signaling to support osteoclast development. Furthermore, the similarity between *Osx1* and *DMP1 gp130* KO phenotypes indicates that gp130 signaling in late osteoblasts and osteocytes, but not early osteoblasts, is critical for normal bone formation.

Macrophage Migration Inhibitory Factor (MIF) Promotes Osteoclastogenesis, RANKL Signaling and Arthritic Bone Erosion. Ran Gu¹, Julian Quim², Leilani Santos³, Eric Morand⁴, Devi Ngo⁴, Huapeng Fan⁴, Jiak Xu⁵, Richard Bucala⁶. ¹Monash Medical Centre, Australia, ²Prince Henry's Institute of Medical Research, Australia, ³Monash University, Australia, ⁴Monash Medical Centre, Australia, ⁵University of Western Australia, Australia, ⁶Yale School of Medicine, USA

In rheumatoid arthritis (RA), MIF promotes the recruitment and activation of leukocytes, but its role in bone erosion is unclear. We sought to investigate the effect of MIF on bone erosion in an *in vivo* model and *in vitro* osteoclastogenesis assays.

K/BXN serum transfer arthritis was induced in MIF^{-/-} and WT mice and characterised by scoring clinically, histologically, by TRAP staining (to identify

osteoclasts) and real time RT-PCR analysis. Osteoclastogenesis assays were performed using bone marrow (BM) cells or RAW 264.7 cells cultured with CSF-1 and RANKL. RAW264.7 cells stably transfected with NF κ B-luciferase and NFAT-luciferase reporters, and phosphorylation of ERK1/2 and p38 in bone marrow derived macrophages (BMM), were used to assess MIF effects on osteoclast signaling. RANKL-induced actin rings in bone marrow cells were stained with rhodamine-phalloidin.

Compared to WT mice, MIF^{-/-} mice with K/BxN serum induced arthritis, had significantly lower clinical scores, histological synovitis and bone damage. Significantly reduced TRAP⁺ osteoclast numbers, and OC-STAMP and DC-STAMP mRNA expression, was found in MIF^{-/-} joints. RANKL induction of osteoclastogenesis in BMM was accompanied by significant dose-dependent increases in MIF protein and mRNA expression. These findings were paralleled by the observation of significantly fewer TRAP⁺ osteoclasts, and significantly fewer large osteoclasts (>10 nuclei), in RANKL/CSF-1 stimulated cultures of MIF^{-/-} BM compared to WT. In addition, actin ring formation in response to RANKL was significantly less in MIF^{-/-} BMM. In RAW264.7 cells, RANKL-induced osteoclastogenesis, and NF κ B and NFATc1 reporter luciferase activity, was significantly abrogated by anti-MIF monoclonal antibody. In addition, reduced phosphorylation of ERK1/2, but not p38, was observed in MIF^{-/-} BMM. This was accompanied by higher expression of multiple dual specificity phosphatases (DUSP), including DUSP1,5,6,8,9,10,16 and 19, in MIF^{-/-} BMM.

In summary, MIF facilitates osteoclastogenesis *in vivo* and *in vitro*, and supports NF κ B, NFATc1 and ERK1/2 activation. These findings suggest therapeutic MIF neutralization as a potential strategy for both RA bone erosion as well as joint inflammation. The potential role of MIF in other forms of pathological bone loss is also suggested, and requires investigation.

Osteoclast Specific Deletion of NEMO/IKK γ in Mice Leads to Osteopetrosis. Kyuhwan Shim¹, Manolis Pasparakis², Yousef Abu-Amer³.
¹Washington University school of medicine, USA, ²Institute of Genetics, University of Cologne, Germany, ³Washington University in St. Louis School of Medicine, USA

The transcription factor NF- κ B family is central to numerous processes including bone development. Activation of this pathway depends on degradation of I κ B upon phosphorylation by I κ B kinases. This process is tightly regulated by IKK γ (also called NEMO, NF- κ B essential modulator), the regulatory subunit of I κ B kinase. Expression and function of NEMO itself is tightly regulated by poly-ubiquitination events. Nemo is X-linked, and defects in this gene result in Incontinentia Pigmenti in human hemizygous female, yet global deficiency in mouse causes embryonic lethality. Certain clinical cases manifested skeletal defects suggesting that NEMO regulates bone metabolism. To investigate such role, we used conditional deletions of *nemo* floxed mice with cre expression driven by osteoclast specific promoters cathepsin K and lysozyme M. Micro CT analysis reveals severe osteopetrotic phenotype in trabecular region in both Cat K and Lys M cre-mediated NEMO deficient male. This phenotype is more severe in females, probably reflecting lack of dosage compensation in male. Histological analysis shows that less osteoclasts (OCs) were detected in trabeculae in KO mice consistent with defective osteoclastogenesis *in vitro*. Consistently, we show that NEMO deficiency hampered activation of IKK and phosphorylation of I κ B in OC precursors (OCPs), causing arrest of osteoclastogenesis and subsequent osteopetrosis. To further explore the underlying mechanism of this phenomenon, we examined the potential role of various NEMO ubiquitinations. To this end, several viral constructs representing strategic point mutations at key residues in coiled-coil-2 and leucine zipper domains, known to be involved in oligomerization and subsequent K63 mediated or linear ubiquitination, were utilized to examine their osteoclastogenic potential in NEMO deficient OCPs. Of these mutants, K270A-NEMO (unable to undergo SUMOylation on K270) was expressed at high levels indicating increased protein stability. Introduction of this mutant protein into NEMO-deficient cells resulted with elevated osteoclastogenesis comparable to wild type levels. In contrast, expression of the mutant K319A NEMO into NEMO-deficient cells was lower and failed to restore osteoclastogenesis, indicating that K319-modification is essential for NEMO stability and function. In summary, we provide evidence that NEMO is essential for osteoclastogenesis and bone homeostasis, and that residues K270 and K319 are crucial for these functions

Ubiquitous and Osteo-chondrogenitor Specific Activation of FGFR3 Affect Endochondral and Membranous Ossification during Craniofacial Formation. Martin Biosse Duplan^{*1}, Federico Di Rocco², Catherine Benoist-Lassel², Nabil Kaci², Nadhir Litim², EMILIE MUGNIERY³, Klaus von der Mark⁴, Arnold Munnich², Laurence Legeai-Mallet⁵.
¹Faculté de Chirurgie Dentaire Université Paris Descartes AP-HP, France, ²INSERM U781, Université Paris Descartes - Sorbonne Paris Cité, Institut Imagine, Hôpital Necker-Enfants Malades, France, ³INSERM U781, France, ⁴University of Erlangen-Nürnberg, Germany, ⁵INSERM U781 - Paris Descartes university, Necker hospital, Fra

Activating FGFR3 mutations in humans result in short-limbed dwarfism and craniostenosis, implicating FGFR3 in both endochondral and membranous ossification during skeletal development. It is not well understood how FGFR3 affects the formation of the flat bone of the skull and suture homeostasis. To address this question, we generated mice expressing an activating FGFR3 mutation (*Fgfr3*^{Y367C/+}) ubiquitously (using the *CMV-cre* transgene), in osteo-chondrogenitors (*Col2al-cre*), in mature osteoblasts (*2.3kb Colla1-cre*) or in mature chondrocytes (*Coll10a1-cre*). The skull of the four mouse models were studied at 3 weeks of age using macroscopic examination of the skull after alcian blue and alizarin red staining, radiology, microCT and MRI analyses and histology of the cranial base and coronal sutures. Ubiquitous expression of the *Fgfr3*^{Y367C} resulted in dramatic morphological changes. In addition to a severe dwarfism, all mice had an impressive dome-shaped skull (33% length reduction, p<0.001), a severe malocclusion and a large midline defect. The size of nasal, frontal, interparietal and occipital bones was significantly altered. The size of the foramen magnum was reduced (38%, p<0.0001). MRI revealed significant abnormalities in the craniovertebral junction including neural compression. Most importantly both speno occipital synchondrosis and coronal sutures were prematurely fused. Targeted expression of *Fgfr3*^{Y367C/+} in osteo-chondrogenitors also induced dwarfism and morphological alterations of the skull. A brachycephalic shape (30% length reduction, p<0.0001), with a reduction of the size of the foramen (29%, p<0.0001) were observed. Neural compression was present. Fusion of the speno occipital synchondrosis and coronal suture was also present as well as defects in calvaria bones. The skull bone anomalies were less severe in these mutants. Conversely, expression of the *Fgfr3*^{Y367C} allele in mature osteoblasts or mature chondrocytes resulted in mild morphological changes. No malocclusion or anomalies of the calvarial sutures were observed. The comparative analysis of the four mouse models confirms the importance of endochondral ossification in the growth of the skull base and craniovertebral junction. These results also suggests that FGFR3 role in membranous ossification is likely mediated by early expression in a population of progenitors giving rise to osteoblast in the skull and thus affects cranial bone formation and suture homeostasis.

Hypogonadism with Estrogen Removal (HER): Differential Effects of Androgens and Estrogens on Bone Microarchitecture in Adult Men. Elaine Yu^{*1}, Alex Taylor¹, Kendra Wulczyn¹, Matthew Webb¹, Nicholas Perros¹, Mary Bouxsein², Joel Finkelstein¹.
¹Massachusetts General Hospital, USA, ²Beth Israel Deaconess Medical Center, USA

Background: Both androgens and estrogens are thought to influence bone mineral density, but the effects of testosterone (T) and estrogen (E) on bone microarchitecture are unknown.

Methods: We recruited 202 healthy men age 20-50. All men received goserelin acetate (Zoladex®, AstraZeneca LP) 3.6 mg at weeks 0, 4, 8, and 12 to suppress endogenous T and E production; anastrozole (Arimidex®, AstraZeneca LP) 1 mg daily for 16 wks to block conversion of T to E; and were randomized to treatment with 1 of 5 doses of a T gel (AndroGel®, Abbott) daily for 16 wks (Groups 1-5: placebo, 1.25g, 2.5g, 5g, 10g). Volumetric BMD (vBMD) and microarchitecture of the distal radius and tibia were assessed using high-resolution peripheral quantitative computed tomography (HR-pQCT, Scanco) in a subset of men (n=99) at wks 0 and 16. T and E levels were measured by RIA and mass spectroscopy, respectively, every 4 wks. HR-pQCT parameters were compared between groups to determine if changes occurred when T levels range from pre-pubertal to supraphysiologic while E levels are markedly suppressed in all groups. Because no important differences were seen between groups, data from all groups were then pooled to evaluate the impact of acute E suppression from wk 0 to 16. Each medication was used outside of its indications with approval.

Results: At baseline, serum levels of T and E were similar between groups (mean \pm SD for the entire cohort: T 513 \pm 158 ng/dL, E 30 \pm 10 pg/mL). Mean T levels from wk 4-16 were 43, 234, 378, 497, and 985 ng/dL in Groups 1-5, respectively and mean E levels ranged from 1.1-3.6 pg/mL. Changes in volumetric BMD and bone microarchitecture parameters were similar across groups, indicating lack of T effect on these parameters over 16 wks. In contrast, when groups were pooled to assess E effect, total, cortical, and trabecular vBMD at the radius and tibia declined from week 0 to 16 (Table). Cortical area and cortical thickness also declined while trabecular area of the radius and tibia increased.

Conclusions: In the setting of low E, short-term manipulation of T does not significantly affect vBMD or bone microarchitecture in men. Conversely, suppression

of estrogen reduces cortical and trabecular vBMD and alters cortical and trabecular architecture in a pattern consistent with "trabecularization" of the cortex. These results suggest that estrogen deficiency is the primary mediator of bone loss in hypogonadal men.

| | Radius | | Tibia | |
|----------------------|--------------|----------|-------------|----------|
| | Mean ± SD | p-value | Mean ± SD | p-value |
| Total density | -1.1 ± 1.9% | p<0.0001 | -0.9 ± 1.4% | p<0.0001 |

Cortical Porosity and Bone Loss Precede Menopause. Ashild Bjornerem^{*1}, Ali Ghasem-Zadeh², Roger Zebaze², Minh Bui³, Xiaofang Wang⁴, John L Hopper³, Ego Seeman². ¹University of Tromsø, Norway, ²Austin Health, University of Melbourne, Australia, ³Centre for MEGA Epidemiology, University of Melbourne, Australia, ⁴Endocrine Centre, Austin Health, University of Melbourne, Australia

In young adulthood, bone remodeling is balanced; equal volumes of bone are resorbed and replaced so no bone loss or structural decay occurs. Remodeling imbalance appears before menopause; less bone is replaced than was resorbed producing trabecular bone loss but cortical bone loss is held to begin after menopause even though the imbalance is global. An alternative explanation is that cortical bone loss occurs by intracortical remodeling creating small pores requiring sensitive methods of detection.

Images of the distal tibia were obtained using high-resolution peripheral quantitative computed tomography (HR-pQCT; Scanco Medical) in 200 premenopausal and 83 postmenopausal women participating in a cross-sectional study in Melbourne, Australia. Cortical porosity and volumetric bone mineral density (vBMD) were quantified using the manufacturers' software and StrAx1.0.

In premenopausal women aged 40 to 55 years (mean 45.7), tibia cortical porosity correlated positively with age while cortical vBMD correlated inversely; each standard deviation (SD) greater age (3.3 years) was associated with 0.20 SD higher porosity (p = 0.004) and 0.17 SD lower vBMD in the cortical transitional zone (p = 0.01) adjusted for BMI and height. These deficits were not detected using DXA as hip and spine aBMD were independent of age. In postmenopausal women aged 45 to 61 years (mean 55.0), each SD greater age (3.5 years) was associated with 0.38 SD higher porosity now in compact appearing cortex and 0.40 SD higher porosity in the transitional zone, and 0.42 SD lower cortical vBMD in the compact appearing cortex and 0.40 SD lower cortical vBMD in the transitional zone; twice that in premenopausal women (all p < 0.001, adjusted for BMI and height). Higher porosity was associated with high levels of remodeling markers in pre- and post-menopausal women.

We infer that cortical bone loss producing porosity starts before menopause in the transitional zone between compact appearing cortex and the trabecular compartment 'trabecularizing' the cortex. This finding has implications regarding the timing of treatment as the slow loss of the four-fold larger cortical bone volume than trabecular bone volume accounts for 70 percent of all bone loss and this loss, producing cortical porosity reduces cortical stiffness to the 7th power.

FSH Suppression in Eugonadal Men Does Not Change Bone Turnover Markers. Alexander Uihlein^{*1}, Ruchit Kumbhani¹, Erica Siwila-Sackman¹, Joel Finkelstein¹, Hang Lee¹, Benjamin Leder². ¹Massachusetts General Hospital, USA, ²Massachusetts General Hospital Harvard Medical School, USA

Background: In-vitro and animal studies have reported conflicting results regarding an independent role for FSH in the regulation of bone turnover. Furthermore, while some epidemiologic studies have reported associations between FSH and markers of bone turnover, experimental models in postmenopausal women have not confirmed a clinically relevant, gonadal-steroid-independent role for FSH. Studies in men have not been published.

Objective: To test the hypothesis that in the setting of stable gonadal steroid levels, the suppression of FSH will alter biochemical markers of bone metabolism in eugonadal men.

Design: 62 eugonadal healthy men were assigned to the following treatment groups as part of a larger trial assessing dose-response relationships between gonadal steroids and multiple outcomes:

- 1) Goserelin acetate (Zoladex®; AstraZeneca Pharmaceuticals LP) 3.6mg SC monthly and a testosterone gel (AndroGel®; Abbott Laboratories) 5 or 10 grams daily
- 2) Placebo goserelin acetate and placebo testosterone gel

In group 1, estradiol (E2) and testosterone (T) levels are maintained in the eugonadal range whereas FSH levels are suppressed. In group 2, levels of E2, T, and FSH are unaltered.

Subjects in Group 1 were individually matched with subjects in Group 2 to ensure that the mean testosterone and estradiol levels (measured every 4 weeks during the 16 week study period) for the 2 groups were equivalent. FSH, serum CTX, and osteocalcin were measured at baseline and after 16 weeks of therapy and between group changes were compared by paired t-test. Approval was obtained to use each medication outside of its indications.

Results: As shown in the table 1, subjects were well-matched at baseline. After 16 weeks of the assigned intervention, FSH was stable in the placebo group but declined by 61% in the intervention group (P < 0.0001 for the between group comparison). Despite this change in FSH, CTX and osteocalcin did not change in the intervention group nor were any between-group differences observed (table 2).

Conclusion: In the setting of equivalent levels of T and E2, significant suppression of FSH for 16 weeks does not affect bone turnover in men. These findings suggest that FSH is not a key independent regulator of male bone metabolism.

| | Group 1- Intervention (n=33) | Group 2- Placebo (n=33) | P-value |
|-----------------------------------|------------------------------|-------------------------|---------|
| Mean Testosterone wk 4-16 (ng/dL) | 605 ± 168 | 603 ± 176 | NS |
| Mean Estradiol wk 4-16 (pg/mL) | 27 ± 8 | 28 ± 9 | NS |
| FSH (% Change) | -61.3 ± 32.0 % | -2.3 ± 17.0% | <0.0001 |
| CTX (% Change) | 9.5 ± 58.7% | 9.8 ± 78.8% | NS |
| Osteocalcin (% Change) | -3.8 ± 27.3% | 2.8 ± 22.3% | NS |

Table 2

| | Group 1- Intervention (n=33) | Group 2- Placebo (n=33) | P-value |

Sclerostin/SOST, a Novel Serum and Genetic Biomarker Strongly Correlated to BMD and Fracture in Postmenopausal Women. Sjur Reppe^{*1}, Agate Noer², Runa M. Grimholt³, Bjarni V. Halldorsson⁴, Vigdis T. Gautvik², Ole K. Olstad³, Jens P. Berg³, Philippe Collas², Kaare M. Gautvik⁵. ¹Oslo University Hospital, Ullevaal, Norway, ²University of Oslo, Norway, ³Oslo University Hospital, Norway, ⁴Reykjavik University, Iceland, ⁵University of Oslo, Oslo University Hospital, Lovisenberg Deacon Hospital, Norway

Sclerostin, encoded by the *SOST* gene, is an osteocyte secreted glycoprotein that has been identified as a pivotal regulator of bone remodeling through inhibition of the anabolic Wnt signaling pathway. Mice lacking the *Sost* gene become osteopetrotic and antibodies against sclerostin (AMG 785) promote bone formation in healthy men and women.

We have analyzed *SOST* mRNA levels in iliac bone biopsies and sclerostin in serum of postmenopausal women (n=84 and 108, respectively). Furthermore, SNP analyses were performed and the genotype correlated to *SOST* mRNA/sclerostin levels. Four different areas within the *SOST* 5' upstream region were examined by bisulfite sequencing for differential CpG methylation in bone biopsies between osteoporotic (n=4) and healthy women (n=4).

Serum sclerostin and bone *SOST* mRNA correlated positively to femoral neck adjusted BMD (p<0.0001 and p=0.0003, respectively), and inversely to bone biomarker concentrations such as: bone specific ALP, BGLAP (osteocalcin), serum-1CTP and urine deoxypyrimidinium. Also, serum sclerostin levels were reduced in osteoporotic as compared to healthy women (p=0.004) corresponding to bone *SOST* mRNA changes (p< 0.0001). MicroRNA-378, has *SOST* mRNA as a putative target and was highly correlated to femoral neck BMI adjusted Z-score (r = -0.46, p=8.6E-06) as well as negatively correlated to *SOST* mRNA levels (r = -0.27, p=1.3E-02). Generally, methylation of CpG in promoter/enhancer regions leads to reduced gene expression. Analysis of CpG methylation in 4 different areas in the *SOST* upstream region showed increased methylation in one of these, closest to the *SOST* transcription start site in women with osteoporosis, concordant with their reduced

SOST mRNA levels and sclerostin serum concentrations. We also identified four different genotype markers correlating to serum sclerostin (p: 0.0016 - 0.0079) with calculated effects 0.32 to -0.42.

Serum sclerostin and *SOST* mRNA show a strong, positive correlation to age and BMI adjusted BMD. Gene heterogeneities, differential methylation patterns and miR-378 have been identified as putative regulators of *SOST* bone mRNA and sclerostin serum levels. Contrary to the current view that increased levels of sclerostin leads to osteoporosis, we propose that in humans compensatory mechanisms involving the *SOST* gene, e.g. methylation, may reduce serum sclerostin levels in situations of low BMD attempting to increase Wnt signaling and thereby promote bone formation.

RANKL Derived from Mesenchymal but not Hematopoietic Cellular Sources Is Relevant for Bone Turnover in Mice. Carmen Streicher¹, Alexandra Hevny², Paul Kostenuik³, Reinhold Erben⁴. ¹University of Veterinary Medicine Vienna, Austria, ²inst. of Physiology, Pathophysiology & Biophysics, Austria, ³Amgen Inc., USA, ⁴University of Veterinary Medicine, Austria

Receptor activator of NFκB ligand (RANKL) is an essential cytokine for osteoclast differentiation and activity. RANKL can be produced by a variety of hematopoietic (e.g. T and B-cell) and mesenchymal (osteoblast lineage, chondrocyte) cell types. However, it is still controversial to what extent RANKL derived from hematopoietic vs. mesenchymal cells contributes to the physiological regulation of bone turnover. Human RANKL knock-in (huRANKL-KI) mice were used to address this question. HuRANKL-KI mice carry the human instead of the murine exon 5 in their RANKL gene, and express a chimeric RANKL protein wherein most of the RANK binding domain is human. The anti-huRANKL antibody AMG161 blocks chimeric but not murine RANKL. To establish a model for selective blockade of hematopoietic or mesenchymal cell-derived RANKL, we lethally irradiated 16-week-old female wild-type (WT) and huRANKL-KI mice on C57BL/6 genetic background, and reconstituted them with sex-matched bone marrow from hRANKL-KI or WT mice, respectively. In irradiated WT mice reconstituted with huRANKL mouse bone marrow, mesenchymal cell-derived RANKL is exclusively murine, whereas hematopoietic cell-derived RANKL is exclusively chimeric and inhibited by AMG 161. Conversely, in irradiated huRANKL mice reconstituted with WT bone marrow, hematopoietic cell-derived RANKL is exclusively murine, while mesenchymal cell-derived RANKL is exclusively chimeric and inhibited by AMG 161. To control for the effects of irradiation on ovarian function, all mice were ovariectomized (OVX) 4 weeks after irradiation, and subcutaneously received either physiological saline or AMG161 (10 mg/kg) twice weekly. Non-irradiated OVX WT and huRANKL-KI mice treated with saline or AMG161 served as controls. All mice were killed 4 weeks post-OVX. Similar to OVX huRANKL-KI mice treated with AMG161, marked increases in bone mass were observed with AMG161 treatment of OVX huRANKL-KI mice reconstituted with WT bone marrow as evidenced by pQCT and micro-CT analysis. In contrast, AMG161 failed to increase bone mass in OVX WT mice reconstituted with huRANKL-KI mouse bone marrow. Our data indicate that RANKL derived from mesenchymal, but not from hematopoietic cells, is relevant for the physiological regulation of bone metabolism in OVX mice.

The ERα of Osteoblast Progenitors is Required for Normal Accrual of Cortical Bone Mass Independently of Estrogens. Srividhya Iyer¹, Aaron Warren², Martha Martin-Millan², Li Han¹, Shoshana Bartell¹, Elena Ambrogini¹, Jinhu Xiong¹, Julie Crawford², Robert Weinstein¹, Robert Jilka¹, Charles O'Brien¹, Maria Jose Almeida¹, Stavros Manolagas¹. ¹Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, ²Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA

The osteoclast ERα mediates the beneficial effects of estrogens in trabecular, but not cortical bone, suggesting that other cell types mediate the effects of estrogens on the latter compartment. We tested the hypothesis that the effect of estrogens on cortical bone result from cell autonomous actions on cells of the osteoblast lineage by deleting an ERα conditional allele in pluripotent mesenchymal cells expressing Prx1 (ERα-flox;Prx1-Cre), in committed osteoblast precursors expressing Osx1 (ERα-flox;Osx1-Cre), or in mature osteoblasts and osteocytes expressing collagen 1 (ERα-flox;Col1-Cre). ERα-flox;Prx1-Cre mice exhibited a decrease in the cortical thickness of the femur after puberty in both sexes; whereas trabecular bone volume was unaffected. The cortical bone decrement was maintained with advancing age in females, but not in males, and was associated with decreased bone formation rate in the periosteum, but not the endosteum. Furthermore, ERα-flox;Prx1-Cre mice did not lose cortical bone following ovariectomy. ERα-flox;Osx1-Cre mice also had decreased cortical thickness associated with decreased periosteal perimeter and no change in cancellous bone. Periosteal cells isolated from both ERα-flox;Prx1-Cre and ERα-flox;Osx1-Cre mice exhibited decreased rate of proliferation under basal conditions. More strikingly, periosteal cells deficient in ERα failed to exhibit a Wnt3-induced

increase in proliferation and differentiation that was readily seen in cells from control mice. Importantly, estradiol had no effect on untreated or Wnt3-stimulated control cells. Cortical or cancellous bone mass or their loss following ovariectomy were unaffected in the ERα-flox;Col1-Cre mice. Elucidation of decreased periosteal bone accrual in mice lacking the ERα in osteoblast progenitors- an effect that is diametrically opposite to the effects of estrogen loss on this compartment- along with an essential role of the unliganded ERα in the potentiation of Wnt signaling demonstrate that the ERα of osteoblast progenitors is required for normal accrual of cortical bone mass, independently of estrogens. In addition, our findings establish that the ERα expressed in distinct bone cell types, periosteal osteoblast progenitors involved in modeling versus osteoclasts driving remodeling, functions to increase bone mass in cortical and trabecular bone, respectively.

Blood Circulated Catabolic and Anabolic Biomarkers Associated with Skeletal Muscle Mass in Hispanic and Non-Hispanic Postmenopausal women—an Ancillary Study of the Women's Health Initiative. Zhao Chen¹, Nicole Wright², Jennifer Bea³, Walter Klimecki³, Chengcheng Hu³, Andriene Grant³, Kamal Masaki⁴, Lihong Qi⁵, Jean Wactawski-Wende⁶, Matthew Allison⁷, Patricia Thompson³. ¹University of Arizona College of Public Health, USA, ²University of Alabama at Birmingham, USA, ³University of Arizona, USA, ⁴University of Hawaii at Manoa, USA, ⁵University of California at Davis, USA, ⁶State University of New York at Buffalo, USA, ⁷University of California at San Diego, USA

Sarcopenia (low relative skeletal muscle mass and function) is common in the elderly and it may cause poor physical function and other adverse health-related outcomes, including osteoporosis in older age. Mechanisms for sarcopenia with aging are still under investigation. The objective of this study is to examine the cross-sectional relationship between skeletal muscle mass and selected catabolic and anabolic biomarkers, which may potentially contribute to the development of sarcopenia. Participants included 318 Hispanic and 683 non-Hispanic white postmenopausal women who were between 50 and 79 years at baseline from the Women's Health Initiative Observational Study. Baseline serum samples were measured to assess inflammatory cytokines and hormones, such as interleukin (IL)-6 and tumor necrosis factor (TNF)-α, as well as insulin-like growth factor (IGF)-1 and growth hormone (GH) using the Illuminex™ multiplex platform (Rules-based Medicine). DXA-derived-lean mass measurements were used to assess total body and appendicular (arms and legs) skeletal muscle mass. Quality control on biomarkers was done using a standard protocol and biomarkers with poor quality were excluded from the final analysis. For consistency, all biomarkers were log-transformed for linear regression analysis. Linear regression models and random forest statistical techniques were used for assessing the direction and strength of the association between biomarkers and lean mass. After adjusting for multiple comparisons, a number of biomarkers were significantly associated with lean mass in either the single-biomarker or multi-biomarker models. When age, weight, height, ethnicity and percent body fat were included in linear regression models, associations between some biomarkers and lean mass were substantially attenuated. In the random forest model we identified a number of biomarkers including leptin, insulin, IL-16 and C-reactive protein as the top biomarkers associated with lean mass in addition to weight, height, age, ethnicity and percent body fat (table). In summary, a number of circulating inflammatory- and obesity-associated factors were significantly associated with lean mass after adjusting for age, height, weight, ethnicity and percent body fat. These findings have suggested a number of directions for future study to longitudinally examine these relationships and to investigate possible mechanisms underlying these associations.

Table 1: Top 15 Factors Associated with Appendicular and Total Body Lean Mass Ranked by Importance Measures in Random Forest

| | Appendicular Lean Mass ¹ | Standardized Importance ² | Total Body Lean Mass ¹ | Standardized Importance ² |
|----|-------------------------------------|--------------------------------------|------------------------------------|--------------------------------------|
| 1 | Weight | 279.5 | Weight | 323.7 |
| 2 | Appendicular Percent Fat | 231.2 | Total Body Percent Fat (Corrected) | 148.6 |
| 3 | Height | 22.1 | Height | 31.4 |
| 4 | Leptin | 17.0 | Insulin | 18.7 |
| 5 | Insulin | 16.2 | Leptin | 16.6 |
| 6 | IL-16 | 7.3 | C Reactive Protein | 6.3 |
| 7 | SHRAGE | 6.4 | Age | 5.3 |
| 8 | SHBG | 5.9 | SHRAGE | 4.7 |
| 9 | Age | 5.7 | IL-16 | 4.7 |
| 10 | C Reactive Protein | 5.7 | Direct Energy | 4.6 |
| 11 | Ethnicity | 5.0 | L ² | 4.5 |
| 12 | Creative Kinase/IB | 4.8 | Appolipoprotein A1 | 4.2 |
| 13 | Adiponectin | 4.4 | TUFAIpa | 3.9 |
| 14 | IL-16 | 4.3 | Haptoglobin | 3.4 |
| 15 | Fibrinogen | 4.3 | SHBG | 3.3 |

¹ Outcomes were log2 transformed. Biomarkers were standardized with the untransformed values included as the base value of the biomarker.
² Ranking done out of a total of 28 predictors (1) biomarkers and 3 covariates. Covariates were considered individually, and were not forced into the model for linear regression models.
³ Larger number indicates higher importance in the random forest investigation.

Sarcopenia Diagnosis: Consideration of a "FRAX-like" Approach. Bjoern Buehring*, Ellen Fidler, Jessie Libber, Jennifer Sanfilippo, Bryan Heiderscheid, Diane Krueger, Neil Binkley. University of Wisconsin, Madison, USA

Sarcopenia increases falls and fracture risk. However, sarcopenia is rarely diagnosed clinically, in part because no single consensus definition exists. Current definitions are based on muscle mass alone or in combination with muscle function. However, existing definitions are imperfect in that they may not identify the same individuals as sarcopenic and do not consider fat mass. We hypothesized that an approach to sarcopenia diagnosis by combining clinically intuitive risk factors might better identify those at risk for falls and fractures. To begin evaluating this concept, this study compared sarcopenia prevalence using current definitions with that obtained using a potential alternative ("FRAX-like") scoring system based on muscle, fat and bone mass, muscle function and falls history.

Community dwelling adults age 70+ underwent DXA body composition measurement and performed a battery of muscle function tests. DXA results were used to calculate appendicular lean mass (ALM)/ht² and a potential measure of total body and muscle fat, the leg fat mass/lean mass ratio. The latter ratio is an attempt to include the effect of obesity on function (i.e. sarcopenic obesity). A fat/lean ratio ≥ 2.5 SD above the mean of 329 young athletes (178M/151F) was defined as high. Sarcopenia prevalence was determined using low ALM/ht², the European consensus approach, (low gait speed or grip strength + low ALM/ht²) and the International consensus approach (low gait speed+low ALM/ht².) An alternative ("FRAX-like") combined score with 1 point each for low ALM/ht², low grip strength or gait speed, high leg fat/lean ratio, low BMD and history falling in the last year was explored.

97 older adults (49 F/48M; mean age 81 yrs) were studied. Sarcopenia prevalence was 24%, 20% and 10% based on ALM/ht², the European and International approach respectively. Sarcopenia prevalence was 40% using a "FRAX-like" score of ≥ 3 . Percentages were significantly different ($p \leq 0.0001$).

Current approaches do not identify the same proportion of older adults as sarcopenic. A risk score combining several measures important for adverse outcomes related to sarcopenia identifies a larger proportion as potentially being at risk. As ~50% of adults over age 75 fall annually, it is possible that this "FRAX-like" approach may be a more sensitive predictor of adverse outcomes. Future research is necessary to validate proposed sarcopenia definitions.

Radiographic Knee Osteoarthritis is Associated with Genetic Loci Previously Associated with Bone Mineral Density. Rebecca Jackson*¹, Laura Yerges-Armstrong², Changwan Lu², Joanne Jordan³, Youfang Liu³, David Duggan⁴, Braxton Mitchell⁵, Marc Hochberg⁶. ¹The Ohio State University, USA, ²University of Maryland, USA, ³University of North Carolina, USA, ⁴Translational Genomics, USA, ⁵University of Maryland, Baltimore, USA, ⁶University of Maryland School of Medicine, USA

Risk for osteoarthritis (OA) is widely recognized to be heritable but few loci have been identified. Recently, longitudinal studies have shown that high bone mineral density (BMD) measured at the hip and/or spine is associated with the development of hip and knee OA. As 50-85% of the variance in BMD is genetically determined and GWAS have identified loci which influence BMD, we performed joint analyses across two cohorts with well-characterized measures of knee osteoarthritis: the Osteoarthritis Initiative (OAI) and the Johnston County Osteoarthritis Project (JoCo) to determine if single nucleotide polymorphisms (SNPs) previously reported to be associated with BMD at genome-wide significance are associated with radiographic knee OA.

Methods: Cases were required to have at least one knee with definite radiographic OA which was defined as the presence of definite osteophytes regardless of the presence of joint space narrowing. Controls were required to be free of radiographic evidence of disease (i.e. no evidence of osteophytes or joint space narrowing in either knee). There were 2014 and 658 Caucasian cases, respectively, in the OAI and JoCo studies, and 610 and 318 controls. The 81 SNPs selected for replication were identified through a review of the literature. Genotyping was carried out on the Illumina 2.5M and 1M arrays in GeCKO and JoCo, respectively. Association analyses for imputed SNPs (HapMap II CEU panel) were carried out separately in each cohort with adjustments for age and sex and then parameter estimates combined across the two cohorts in meta-analysis using a fixed effects model.

Results: We identified 4 SNPs significantly associated with prevalent radiographic knee OA. The strongest signal ($p < 0.01$, odds ratio = 1.17, 95% CI: [1.04-1.32]) maps to 12q3 which contains a gene coding for *SP7*. Additional loci map to 7p14.1 (*TXNDC3*), 7q31.31 (*C7orf58*) and 6q25 (*C6orf97*). For all but the SNP near *C6orf97*, the allele associated with higher BMD was associated with the higher odds of OA.

Conclusion: This large joint analysis demonstrates that several GWAS-identified BMD SNPs are associated with prevalent radiographic knee OA. These data further support the hypothesis that BMD may be a risk factor contributing to radiographic OA.

Vitamin D Status and Knee Pain Severity in Functionally Intact Older Adults: The Health ABC Study. Laura Tosi*¹, Robert Boudreau², Kent Kwok³, Tanushree Prasad³, Hilsa Avonayon⁴, Tamara Harris⁵, Denise Houston⁶, Stephen Kritchevsky⁶, Kushang Patel⁷, Eleanor Simonsick⁸, Jane Cauley⁹. ¹Children's National Medical Center, USA, ²University of Pittsburgh - Dept of Epidemiology, USA, ³University of Pittsburgh, USA, ⁴University of California - San Francisco, USA, ⁵National Institute of Aging, USA, ⁶Wake Forest University, USA, ⁷National Institutes of Health, USA, ⁸National Institutes of Aging, USA, ⁹University of Pittsburgh Graduate School of Public Health, USA

Background: Clinical evidence suggests that 25-hydroxyvitamin D (25(OH)D) may be important in multiple biologic processes including pain reporting, yet there exists no convincing evidence that levels of 25(OH)D are lower in individuals with chronic pain vs those pain free. The study examines the association between 25(OH)D status and reported joint pain severity in functionally intact persons aged 70-79.

Methods: Of 3,075 participants in the Health, Aging and Body Composition study, 2,793 (mean age 74.7 \pm 2.9 yrs, 51.2% women, 39.7% black) had serum 25(OH)D measures at year 2 and concurrent responses on the number of painful joints and the Modified WOMAC scale for knee pain. Quartiles of 25(OH)D were calculated based on the combined sample. Number of painful joints (0-20), joint groups (0-8: hand/wrist, hip, knee, foot/toe; left+right) and WOMAC knee pain were compared across quartiles using ANOVA and ANCOVA to adjust for covariates. The worst knee was used in the WOMAC analyses.

Results: The 25(OH)D quartile cutoffs were 18.0 ng/ml, 24.7 ng/ml and 32.3 ng/ml (min=5.0, max=186.9). The most frequently reported painful joint groups were hand/wrists (50.2%) and knees (36.2%). For both sexes, higher physical activity and dietary Vitamin-D intake were associated with higher 25(OH)D. In men, 25(OH)D status was not associated with any of the three pain measures in unadjusted or adjusted models ($p > 0.261$). For women, the highest quartile of 25(OH)D was associated with lower numbers of painful joint groups adjusted for age, race, field site, and season of serum draw ($p=0.030$), but became no longer significant ($p=0.347$) when further adjusted for education level, BMI and depressive symptoms. For WOMAC knee pain, the highest 25(OH)D quartile was strongly associated with lower knee pain in unadjusted ($p < 0.001$) and all adjusted models ($p < 0.041$). The lower three quartiles had similar WOMAC knee pain ($p=0.980$), with adjusted WOMAC knee pain of 4.05 for the lower quartiles combined vs 3.19 for the highest quartile ($p=0.004$). Dietary vitamin D attenuated this difference by 8.1%.

Conclusions: The association of 25(OH)D status with joint pain reporting is sexually dimorphic and joint specific. 25(OH)D status does not predict joint pain in men. In women, however, 25(OH)D status and WOMAC knee pain are strongly associated across all adjusted models. Clinical trials using 25(OH)D therapy to prevent/treat knee pain in women should be considered.

Progranulin Growth Factor is Protective against Osteoarthritis through Interplay with TNF α and β -Catenin Signaling. Chuanju Liu, Yunpeng Zhao*, Qingyun Tian, Shuai Zhap, Brendon Richbrough, New York University, USA

We have previously reported that Progranulin (PGRN) regulates chondrocyte metabolism and cartilage degradation in vitro and its level is elevated in the cartilage and body fluids of patients with arthritis (Guo FJ, et al, *Arthritis Rheum.* 2010; 62(7):2023-36; Feng JQ, et al, *FASEB J.* 2010; 24(6):1879-92). Additionally, our recent findings revealed that PGRN antagonizes TNF and protects cartilage loss and bone erosion in inflammatory arthritis (Tang W, et al, *Science.* 2011; 332(6028):478-84). Furthermore, our genome-wide screen for novel, differentially expressed genes in osteoarthritis (OA) led to the isolation of PGRN as an OA-associated growth factor. This study is, thus, to determine the potential role of PGRN in the pathogenesis of OA as well as the molecular events involved. The deletion of the *PGRN* gene led to the spontaneous development of an OA-like phenotype in "aged" mice (Note that the phenotype could be observed in as early as a 6-month old). A Micro-CT of the hind knees showed osteophyte formation in aged knockout mice. Safranin O staining demonstrated a remarkable loss of proteoglycan staining and meniscus ossification. High power photography revealed clear chondrocyte clustering and migration of the irregular tide mark to the superficial zone. Surgically-induced OA models, including both DMM (destabilization of medial meniscus) and ACL (anterior cruciate ligament) transection models, demonstrated that the deficiency of PGRN accelerated the degradation of cartilage matrix molecules (e.g. Aggrecan and COMP) and OA progression, while the intra-articular injection of recombinant PGRN delayed these processes. Molecular mechanistic studies revealed that PGRN activated Akt and Erk1/2 signaling and that PGRN-induced expressions of its target genes primarily depended on TNFR in chondrocytes. In addition, PGRN inhibited TNF α -induced ADAMTS cleavage of COMP. Furthermore, the deletion of the *PGRN* gene exacerbated, whereas recombinant PGRN prevented, the loss of cartilage in TNF transgenic mice. Activation of β -catenin signaling in articular chondrocytes was reported to induce OA-like phenotype in mice (Zhu, M, et al, *JBM.* 2009, 23; 12-21), and progranulin was recently found to inhibit Wnt/ β -catenin signaling in the central nervous system (Rosen EY, et al, *Neuron.* 2011; 71(6):1030-42). We also found the mutual inhibition of PGRN and Wnt/ β -catenin signaling in chondrocytes and OA. Collectively, PGRN is a novel chondroprotective growth factor that inhibits OA development, probably through interacting with TNF α /TNFR and Wnt/ β -catenin signaling pathways. These findings not only provide novel insights into the role of

PGRN in cartilage homeostasis and arthritis in vivo, but may also lead to the development of novel therapeutic intervention strategies for osteoarthritis.

Sclerostin Plays a Key Role in Abnormal Wnt/ β -catenin Signalling in Human Osteoarthritic Subchondral Osteoblasts Leading to Reduced Mineralization. Elie Abed^{1*}, Denis Couchourel², Aline Delalandre³, Daniel Lajeunesse⁴. ¹Crchum-hôpital Notre-dame, Canada, ²Danone, , ³CRCHUM, Canada, ⁴CHUM, Hôpital Notre-Dame, Canada

Objectives: Clinical and *in vitro* studies suggest that subchondral bone sclerosis due to abnormal osteoblast (Ob) function, is involved in the progression and/or onset of osteoarthritis (OA). Moreover, human OA subchondral Ob show a phenotype of very differentiated cells, however they fail to mineralize normally *in vitro* as *in vivo*. Wnt signaling plays a key role in osteogenesis by promoting the differentiation and mineralization of Ob mainly via the canonical Wnt/ β -catenin (cWnt) signaling pathway. Sclerostin (SOST) has been shown to alter cWnt signaling, however the regulation of SOST in OA Ob remains unknown. Here we investigated the role of SOST in OA Ob.

Material and Methods: We prepared primary human subchondral Ob using the sclerotic medial portion of the tibial plateaus of OA patients undergoing knee arthroplasty, or from tibial plateaus of normal individuals at autopsy. SOST expression and production were evaluated by qRT-PCR and WB analysis. The regulation of SOST expression was determined in response to transforming growth factor- β 1 (TGF- β 1) and as a function of the growth of OA Ob. SOST inhibition was performed using siRNA techniques. cWnt signaling was evaluated by measuring the activity of the TOPflash Tcf/lef luciferase reporter assay and intracellular β -catenin levels by WB. Mineralization was evaluated by Alizarin red staining. TGF- β 1 levels were determined by ELISA.

Results: SOST expression and production were elevated in OA Ob compared to normal Ob. SOST expression increased in post-confluent OA Ob and normal Ob, however its increase was more pronounced in OA Ob. SOST levels also remained always higher in OA Ob than in normal Ob. TGF- β 1 expression was high in OA Ob, and TGF- β 1 stimulated SOST expression in both normal and OA Ob whereas siRNA for TGF- β 1 reduced SOST expression about 5-fold in OA Ob. cWnt signaling and mineralization were reduced in OA Ob compared to normal Ob. SOST inhibition increased cWnt signalling, β -catenin levels and also corrected the abnormal mineralization in OA Ob.

Conclusions: This is the first demonstration of elevated SOST levels in OA Ob. High SOST levels in OA Ob are responsible, at least in part, for the reduced cWnt signaling of these cells and abnormal mineralization. As SOST is a secreted protein, this could lead to potential new avenues of treatment of OA to correct their abnormal bone phenotype and thereof contribute to reduce the burden of OA

Prevention of Bone Loss during Spaceflight by Bisphosphonate. Toshio Matsumoto^{1*}, Adrian LeBlanc², Jeffrey Jones², Jay Shapiro³, Thomas Lang⁴, Linda Shackelford⁵, Scott Smith⁶, Harlan Evans⁷, Elisabeth Spector⁷, Robert Ploutz-Snyder², Jean Sibonga⁸, Toshitaka Nakamura⁹, Kenjiro Kohri¹⁰, Hiroshi Ohshima¹¹. ¹University of Tokushima Graduate School of Medical Sciences, Japan, ²Baylor College of Medicine, USA, ³Kennedy Krieger Institute, Johns Hopkins, USA, ⁴University of California, San Francisco, USA, ⁵NASA JSC, USA, ⁶Wyle/nasa Jsc, USA, ⁷Wyle, USA, ⁸NASA Johnson Space Center, USA, ⁹University of Occupational & Environmental Health, Japan, ¹⁰Nagoya City Univ, Japan, ¹¹JAXASpace Biomedical Research Office, Japan

The Mir and ISS long-duration missions documented losses in bone mineral density (BMD) from critical skeletal regions, including the most clinically important BMD losses from the hip. These studies demonstrated the wide range in individual BMD loss from -0.5% to -5.1% per a month, averaging about -1.6% per a month. A secondary consequence to uncoupled bone remodeling is hypercalciuria and the associated increase in the risk of renal stone formation.

The present study was undertaken to determine if the combination of bisphosphonate administration and an in-flight exercise regimen would have a measurable effect on preventing space flight-induced changes in bone remodeling and loss of bone mass, and reducing renal stone risk. There were a total of 10 astronauts who signed NASA consent forms to participate. One of these ultimately decided not to participate and 2 experienced stomach discomfort or dyspepsia before or during flight and did not participate or discontinued the drug. Seven crewmembers completed the protocol taking a 70-mg alendronate tablet once/week before and during flight, starting 17 days before launch. Controls are 14 previous ISS crewmembers with DXA and QCT measurements. Change in pre and post flight DXA and QCT were analyzed by random-intercept mixed-model regression analyses that included a continuously scaled covariate to accommodate flight duration (days), a group indicator for comparing the bisphosphonate cohort to controls and an interaction term to compare relative change.

The significant loss in QCT-determined bone strength and trabecular BMD in the untreated group was almost completely prevented in the treated group. Similarly, the reduction in DXA hip BMD was also prevented and lumbar BMD was significantly increased from pre-flight in the treated group (Table). Bone resorption marker, NTX, was decreased compared to preflight, in contrast to typical increases of 50% to 100% above preflight in previous crewmembers. Urinary calcium showed no increase compared to baseline levels, also distinct from the elevated levels of 50% or greater above preflight in previous crewmembers. These results are consistent with the notion that bisphosphonate administration during spaceflight will be beneficial in preventing bone loss and maintaining bone strength.

Cortical Porosity and Estimated Bone Strength in Healthy Postmenopausal Women Treated with Exemestane for the Primary Prevention of Breast Cancer: Analyses from the nested bone strength substudy of the MAP.3 trial (MAP3BSS). Angela Cheung*¹, John Robbins², Sandhya Pruthi³, Paul E. Goss⁴, Savannah Cardew⁵, Sharmila Majumdar⁶, Sundeep Khosla⁷, Steven Boyd⁸, Andrew Burghardt⁶, Louise Bordeleau⁹, James Ingle¹⁰, Eva Szabo¹, Marta Erlandson⁵, Hanxian Hu¹, Judite Scher¹¹, Harriet Richardson¹², Karen Gelmon¹³, LIANNE TILE⁵, George Tomlinson¹. ¹University Health Network, Canada, ²University of California, Davis Medical Center, USA, ³Mayo Clinic College of Medicine, USA, ⁴Massachusetts General Hospital, USA, ⁵University of Toronto, Canada, ⁶University of California, San Francisco, USA, ⁷College of Medicine, Mayo Clinic, USA, ⁸University of Calgary, Canada, ⁹McMaster University, Canada, ¹⁰Mayo Clinic Rochester, USA, ¹¹University Health Network, Canada, Canada, ¹²Queens University, Canada, ¹³BC Cancer Agency, Canada

Background and Purpose: The MAP.3 trial, an international double-blind placebo-controlled trial of exemestane involving 4560 healthy postmenopausal women at risk of breast cancer demonstrated a 65% reduction in invasive breast cancer after a median follow-up of 35 months. Exemestane lowers circulating estrogen levels. In a nested non-inferiority bone strength substudy of the MAP.3 trial (MAP3BSS), we recently showed that exemestane reduced total volumetric BMD and decreased cortical thickness at the distal radius and distal tibia by high resolution peripheral quantitative computed tomography (HRpQCT), and areal BMD at the lumbar spine and total hip by DXA over two years. To gain further insights, we assessed the effect of exemestane on cortical porosity and estimated bone strength using finite element analysis (FEA).

Methods: We included postmenopausal women eligible for MAP.3 from 5 centers (2 US and 3 Canadian), who were not osteoporotic, not on bone medications, with baseline lumbar spine, total hip and femoral neck T-scores above -2.0. For cortical porosity, we used an automated segmentation technique to identify the periosteal and endosteal margins of the distal radius and distal tibia, and determined the intracortical pore space morphologically. For estimation of bone strength, uniaxial compression testing was performed using FEA (FAIM, Numerics88 Solutions Ltd). We performed 2 sample t-tests on the change over time. Results are presented as absolute and percent changes from baseline to one and two years.

Results: Three hundred and fifty one women participated in the MAP3BSS. At baseline, median age was 61.3 years, median areal BMD T-scores at the lumbar spine and total hip by DXA were -0.23 and 0.14, respectively, and median WHO FRAX 10-year risk for major osteoporotic fractures and hip fractures were 6.0% and 0.3%, respectively. 108 women on exemestane and 105 women on placebo had evaluable scans at 2 years. Exemestane significantly increased cortical porosity at both the distal radius and distal tibia at 1 and 2 years (Table). There is considerable heterogeneity among women. Our estimated bone strength results using FEA are pending.

Conclusions: Two years of exemestane increased cortical porosity. Taken together with the decrease in cortical thickness and the decrease in total volumetric bone density, we can conclude that exemestane has a negative effect on bone microarchitecture at the distal radius and distal tibia over the first 2 years of therapy.

Determinants of Low Bone Mineral Density (BMD) in Young Women with Severe Anorexia Nervosa. Karine Briot*¹, Marie-Raphael Thiebaut², Simon Paternotte³, Sami Kolta³, Nicole Barthe⁴, Alain Daragon⁵, Yves Maugars⁶, Thierry Thomas⁷, Nathalie Godart², Christian Roux³. ¹Paris Descartes University, Cochin hospital, Rheumatology Hospital, France, ²Inserm U669, Universités Paris 5 ; Psychiatry Unit, Institut Mutualiste Montsouris, France, ³Cochin hospital, France, ⁴Médecine Nucléaire, Centre Hospitalier de Bordeaux & Université de Bordeaux 2-Victor Segalen, France, ⁵INSERM U 905, France, ⁶Hôpital Dieu Et Hme, France, ⁷INSERM U1059, Service de Rhumatologie, CHU de St Etienne, France

Background: Low bone mineral density (BMD) is a known consequence of anorexia nervosa but there are few data concerning the prevalence of low BMD in young patients (adolescents and young adults) with severe disease, who require a hospitalization.

Objectives: to assess bone mineral density (BMD) at lumbar spine and hip in a large cohort of young patients with severe anorexia nervosa (AN), and to assess determinants of low BMD.

Patients and methods: the main inclusion criteria were as follows: women with severe anorexia nervosa (AN) admitted to inpatient treatment units recruited from 11 centers in France (cohort EVHAN (EValuation of Hospitalisation for AN)). Current AN diagnosis was based on the DSM-IV criteria obtained by the Eating Disorder Examination and the CIDI 3.0 with the following BMI (Body Mass Index) criteria of: BMI <10th percentile up to 17 years of age, and BMI <17.5 for 17 years of age and above. Clinical variables were assessed during the first 2 weeks after hospitalization. Lumbar spine and femoral bone mineral density (BMD), body composition (lean and fat masses) were performed during the hospitalization using dual-energy x-ray absorptiometry (DXA). Low BMD was defined by Z ≤ -2 (at least one site). Determinants associated with low BMD were tested using univariate and multivariate analysis.

Results: 150 women were the basis of this study: mean age 20.5 years, mean disease duration of 48.4 months, 90.5% were amenorrheic and mean BMI of 14.3kg/m². 34 (24.1%) reported a previous fracture. Mean Z score was -1.82 at lumbar spine and -1.34 at femoral neck; 72 (49%) had low BMD. None of them received anti-osteoporotic treatment. Univariate analysis showed that parameters significantly associated with low BMD were lifetime lowest BMI (p<.0001), BMI measured at the admission (p=0.004), low appendicular lean mass (p= p=0.034) and low appendicular fat mass (p=0.07). When using multivariate analysis, the lifetime lowest BMI remained the only determinant of low BMD (OR=1.83, CI 95% 1.40-2.50, p=0.001) while age, disease duration, amenorrhea, BMI measured at the time of admission and body composition were no longer significantly associated.

Conclusion: this study showed that 1 out of 4 patients with severe anorexia nervosa had a previous fracture, low BMD is frequent, and that among all potential risk factors tested, the lifetime lowest BMI was the only determinant.

Disclosures: Karine Briot, None.

Bone Loss After Bariatric Surgery: Not Just Skeletal Unloading. Emily Stein¹, Angela Carrelli², Polly Young³, Mariana Bucovsky³, Donald McMahon¹, Chiyuan Zhang³, Bin Zhou³, Ji Wang³, X Guo³, Elizabeth Shane¹, Shonni Silverberg³. ¹Columbia University College of Physicians & Surgeons, USA, ²Columbia University Medical Center, USA, ³Columbia University, USA

The mechanism of bone loss after bariatric surgery and whether it is associated with increased skeletal fragility is unknown. We studied 22 women (age 45±10) undergoing Roux-en-Y gastric bypass (RYGB; n=14) and restrictive procedures (n=8). We measured calciotropic hormones, bone turnover markers, areal BMD (aBMD) by DXA at the lumbar spine (LS), total hip (TH), femoral neck (FN) and 1/3 radius (1/3R), and trabecular (Tb) and cortical (Ct) volumetric BMD (vBMD) and microstructure at the distal radius and tibia by high resolution peripheral quantitative CT (HRpQCT) before and 12 months after surgery. Subjects were 23% Caucasian and 59% Latina with a mean BMI of 44±5 kg/m² and normal baseline T-scores (LS:-0.1±0.2, TH:0.6±0.2, FN:0.1±0.2; 1/3R:0.1±0.2). Before surgery, average daily intake of calcium was 873 mg and vitamin D 5188 IU. Mean weight loss was 28±3 kg (Table; p<0.0001). Serum calcium fell and PTH rose despite a 50% increase in calcium (p<0.02) and stable vitamin D intake, and no change in serum 25OHD. Serum CTX increased by 136%. aBMD declined at the TH (5.4%) and FN (4.5%), but not the LS or 1/3R. By HRpQCT, Tb parameters were stable while Ct Area (CtAr), Ct thickness (CtTh) and Ct density deteriorated, particularly at the tibia. By multivariate regression, weight loss predicted 52% of variance in hip bone loss (p<0.001), while PTH increase was not a significant predictor. In contrast, PTH increase predicted the decline in Ct parameters at both radius (CtAr 26% p<0.04; CtTh 27% p<0.03) and tibia (CtAr 23% p<0.02; CtTh 16% p<0.04; Ct density 32% p<0.01), while the contribution of weight loss was less (18%, 17% and 9%, p= 0.10-0.18). RYGB patients lost more weight and had more bone loss by DXA and HRpQCT than those with restrictive procedures, which was associated with a decline cortical load share estimated by finite element analysis. In summary, our results suggest at least 2 mechanisms for bone loss after bariatric surgery. Weight loss is a more important cause of hip than tibial bone loss, likely because the load carried by the hip (2-3 x body weight) is greater than that carried by the tibia (1x body weight). In contrast, cortical losses at the tibia reflect secondary hyperparathyroidism (SHPT). In conclusion, hip bone loss after bariatric surgery reflects skeletal unloading, while deterioration of cortical microstructure is due to SHPT. The decline in cortical load share after RYGB raises concern for future increases in skeletal fragility.

Changes Following Bariatric Surgery (mean±SE)

Evaluation of Bone Turnover During Lactation in African-Americans: A Comparison to Caucasian Lactation. Mara Horwitz¹, Raquel Carneiro^{2*}, Linda Prebehala³, Mary Beth Tedesco³, Susan Sereika³, Caren Gundberg⁴, Andrew Stewart⁵. ¹University of Pittsburgh Div of Endocrinology - EMRC, USA, ²The University of Fortaleza, School of Medicine, Brazil, ³University of Pittsburgh, USA, ⁴Yale University School of Medicine, USA, ⁵University of Pittsburgh School of Medicine, USA

Background. Lactational bone turnover, which is mediated by PTHrP in the setting of low estrogen, has not been studied in African-American (AA) women. The AA skeleton is known to be resistant to PTH; whether it is also resistant to PTHrP and the hormonal changes of lactation are unknown. We hypothesized that AA women may be resistant to PTHrP and therefore display lower levels of bone turnover markers during lactation than Caucasians (C).

Objectives. To assess AA bone turnover during lactation and to compare this to C.

Design and Participants. This was a prospective cohort study with repeated measures of bone metabolism in 60 healthy AA women age 21-45 (three groups of 20: lactating, bottle feeding, and healthy controls) studied at 6 and 12 weeks postpartum. AA subjects were compared with a previously published identical study in C women.

Outcome Measures. Biochemical markers of bone turnover and calcium metabolism.

Results. All three AA groups displayed 30-50% lower 25OHD and two-fold higher PTH values compared to C (p<0.001, p<0.002) but similar 1,25(OH)₂D values. Formation markers (PINP and BSAP) were comparable in AA and C controls, but resorption (CTX and NTX) was lower in the AA vs. C controls (p=0.003, p<0.01). PINP and BSAP increased significantly (2-3 fold) in lactating and bottle-feeding AA women (PINP, p<0.001; BSAP, p<0.001) as did both CTX and NTX (both p<0.01). AA lactating mothers displayed quantitatively similar bone formation, but slightly lower bone resorption, compared to C women (p= 0.036).

Conclusions. Bone turnover, measured using current sensitive and specific markers, is uncoupled in favor of formation in young adult AA women when compared to C. Despite resistance of the AA skeleton to PTH, the AA skeleton appears to respond to the hormonal milieu of lactation with a robust three-fold increase in bone turnover. This is quantitatively similar to that observed in C. Whether this is associated with similar losses of bone in AA vs C during lactation has not been studied and requires further investigation.

The Skeletal Effects of Reducing Inflammation in Type 2 Diabetes Mellitus. Daniel Donovan¹, Serge Cremers¹, Donald McMahon², Elzbieta Dworakowski¹, Allison Goldfine³, Steven Shoelson³, Mishaela Rubin^{4*}. ¹Columbia University, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Joslin Diabetes Center, USA

The skeleton is now recognized, epidemiologically, to be adversely affected in Type 2 Diabetes Mellitus (T2D), with an increased risk of fractures. Previous studies have identified reduced bone formation as a contributing factor, but the mechanisms remain speculative. One possible explanation is chronic inflammation, which negatively influences bone remodeling by reducing bone formation and increasing bone resorption. The Targeting Inflammation using SALSALATE in Type 2 Diabetes (TINSAL-T2D) trial found that a salicylate, which reduces inflammation by decreasing NF-κB, improved glycemic control in patients with T2D. We hypothesized that reducing inflammation in T2D would additionally lead to a rebalancing of the bone remodeling process. In TINSAL-T2D patients were randomized to placebo (PLB) or salsalate, at doses of 3.0, 3.5 or 4.0 g/d tid for 14 weeks. We measured markers of bone turnover (PINP, BAP, osteocalcin, s-CTX and TRAP-5b) in samples from TINSAL-T2D at 0 and 14 weeks.

76 subjects with T2D (56 ± 1yr, 51 men, BMI 33 ± 1 kg/m², 43% Caucasian, HbA1c 7.6 ± 1%; none on TZDs or insulin) were analyzed. At baseline, corrected serum calcium was 9.2 ± 1 mg/dl; PTH 35 ± 1 pg/ml; 25OHD 21 ± 2 ng/dl. Baseline PINP was 36.8 ± 2 ng/ml (nl: 16-83), BAP 28.3 ± 1 IU/L (nl: 11.6-29.6), osteocalcin 10.7 ± 1 ng/ml (nl: 8.4-33.9), s-CTX 0.29 ± 0.1 ng/ml (nl: 0.11 - 0.74) and TRAP-5b 3.2 ± 0.1 U/L (nl: 1.03-4.15). With salsalate treatment, PINP, BAP and TRAP-5b did not change, but osteocalcin increased from 0 to 14 wks at the highest dose as compared with PLB (PLB: -3% ± 9% vs. 4 mg dose: 34% ± 8%, p=0.003). Moreover, s-CTX levels increased from 0 to 14 wks at the 3.5 mg dose (PLB: 7 ± 3 vs 3.5 mg dose: 95 ± 19%, p=0.003), tending also to increase at the 4 mg dose (31 ± 22%; p=0.16 vs PLB).

These data suggest that along with reductions in inflammation and glycemic burden in TINSAL-T2D, there is an increase in bone remodeling, as reflected by increases in osteocalcin and s-CTX. Although one would not expect that bone resorption would increase with a concomitant reduction in NF-κB, there may be a coupled rise in bone remodeling in T2D as inflammation is reduced. This study provides proof of concept for a relationship between the inflammatory process and skeletal dynamics in T2D. Further studies would shed light on mechanistic approaches to the skeletal complications of T2D.

A FoxO1/ATF4 Synergism in Osteoblasts Adversely Affects Glucose Metabolism by Promoting Osteocalcin Carboxylation. Aruna Kode*, Ioanna Mosialou, Stavroula Kousteni, Columbia University Medical Center, USA

Osteoblasts beneficially regulate energy metabolism through secretion of the undercarboxylated form of osteocalcin. At the transcriptional level, *FoxO1* cooperates with *Atf4* in osteoblasts to suppress glucose metabolism, insulin production and insulin sensitivity. To understand the molecular mechanism of the insulin sensitizing properties of these two transcription factors, we examined an array of insulin regulated genes in compound mice lacking one allele of *Atf4* and *FoxO1* in osteoblasts (*FoxO1^{osb}+/-; Atf4+/-* mice). Expression of the insulin-sensitizing hormone *adiponectin* was upregulated in gonadal fat of *FoxO1^{osb}+/-; Atf4+/-* mice. In contrast, expression of *Resistin*, associated with insulin resistance, or *Leptin* were not affected. Consistent with increased adiponectin, expression of the adiponectin targets *Acyl-CoA Oxidase*, peroxisome proliferator-activated receptor- α (*Ppar α*) and Uncoupling Protein 2 (*Ucp2*) was increased in the muscle of *FoxO1^{osb}+/-; Atf4+/-* mice. Also in the muscle, expression of the insulin target *Pgcl α* and its transcriptional effectors *Nrf1* and *Mcad* was upregulated. In the liver, expression of *FoxA2* was increased whereas expression of *G6Pase* and *Pepck1* was decreased in *FoxO1^{osb}+/-; Atf4+/-* mice. The expression profiling of the metabolic phenotype of *FoxO1^{osb}+/-; Atf4+/-* mice pointed towards Osteocalcin as a potential mediator of the combined function of the 2 transcription factors. Indeed, serum levels of undercarboxylated osteocalcin were increased in *FoxO1^{osb}+/-; Atf4+/-* mice. Expression of *Esp*, the tyrosine phosphatase promoting osteocalcin carboxylation, was reduced in the bone of these animals. *FoxO1* and *Atf4* each stimulated *Esp* transcriptional activity in osteoblast cultures. Combination of both transcription factors resulted in synergistic, highly induced transcriptional activation of *Esp*. Mutation of either an *ATF4* or a *FoxO1* binding site in the *Esp* promoter abolished binding of the respective transcription factor to *Esp*. It also ablated *Esp* activation by each transcription factor. Combination of *FoxO1* and *ATF4* also failed to induce activation of *Esp* when either the *ATF4* or *FoxO1* binding site was mutated. Thus, synergistic activation of *Esp* by *ATF4* and *FoxO1* requires both factors to be bound simultaneously to DNA. Collectively, these observations indicate that *FoxO1* and *ATF4* interact in osteoblasts to control glucose homeostasis by promoting *Esp* expression and subsequent carboxylation and inactivation of osteocalcin.

Age-Related Impairment of the Mechanostat is Sex Specific and Associated with Impaired Cell-Cycle Progression and Decreased Mechanosensitivity. Lee Meakin*, Gabriel Galea¹, Toshihiro Sugiyama², Lance Lanyon³, Joanna Price¹. ¹University of Bristol, United Kingdom, ²Yamaguchi University School of Medicine, Japan, ³Royal Veterinary College, United Kingdom

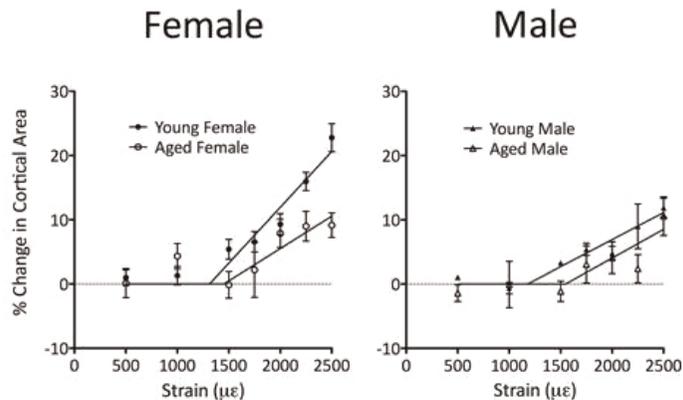

One hypothesis for the cause of age-related bone loss is decreased effectiveness of "the mechanostat". The higher prevalence of bone fragility fractures in women suggests a gender-related influence. In the present study we used the axial tibial *in vivo* loading model¹ to compare bones' adaptive responses in young and aged, male and female mice and compared the proliferative response to strain of osteoblast-like cells derived from the long bones of these mice *in vitro*.

Minimum Effective Strain (MES; x-intercept in Figure) was determined by μ CT in cortical bone and, in females, was similar in young adults (17-week) and aged mice (19-month; $p=0.54$). In contrast, in males the MES was significantly higher in aged than young mice ($p=0.04$). The slope of the strain-response curves (bone response per unit strain) was similar in young and aged males ($p=0.64$) but lower in aged than young females ($p<0.01$).

Proliferation of long bone-osteoblasts (LOBs) derived from these mice was investigated *in vitro* by Ki-67 *in situ* cell cycle analysis and showed that young male and female LOBs were recruited to the cell cycle within 1h of exposure to a single short period of dynamic strain change (peak 3400me, 600 cycles, 0.6Hz) in their substrate². Aged female LOBs were also recruited within 1h, but showed delayed progression through G2-phase with a consequential reduced increase in cell number after 48hrs. Aged male LOBs were not recruited to the cell cycle by strain. Expression of EGR2, an early marker of osteoblasts' strain responsiveness², measured by quantitative PCR, was up-regulated 1h following strain in LOBs from all groups except aged males.

In conclusion, this study demonstrates, for the first time, that ageing is associated with impaired cell cycle progression in osteoblast-like cells; in this case in response to strain. This impaired proliferative response is gender specific. *In vivo*, bones' adaptive responsiveness was less in aged than young females whereas it was similar between young and old males, although their sensitivity (MES) was different. These data implicate both age- and sex-related differences in mechano-responsiveness and sensitivity, as well as cell cycle progression. These age-related impairments of the mechanostat may be recapitulated in humans.

Differential Expression of MicroRNAs in Human Mesenchymal Stem Cells with Age May Be Related to Musculoskeletal Disorders. Sudharsan Periyasamy-Thandavan*¹, Sergi Mas², Sadanand Fulzele³, Mark Hamrick³, Xingming Shi³, Carlos Isales⁴, Norman Chutkan³, Randy Ruark³, John Hinson³, Monte Hunter³, Raymond Corpe³, Hongyan Xu³, William Hill⁵. ¹Georgia Health Sciences University & Charlie Norwood VAMC, USA, ²Universitat de Barcelona, Spain, ³Georgia Health Sciences University, USA, ⁴Medical College of Georgia, USA, ⁵Georgia Health Sciences University & Charlie Norwood VAMC, USA

Age-associated osteoporosis is one of the most common and debilitating types of bone disease. Although the mechanisms involved remain poorly defined, recent studies suggest that age-associated osteoporosis is a stem cell disease. Human mesenchymal stromal/stem cells (hMSCs) are multipotent stem cells that can differentiate into osteoblasts. MicroRNAs (miRNAs), a class of short single-stranded noncoding RNAs are post-transcriptional regulators that can modulate the homeostasis of multiple genes and associated pathways simultaneously. Changes in miRNA expression have been linked to the development of numerous disorders, including musculoskeletal disorders. While miRNAs are emerging as critical modulators of cell function and phenotype development little work has been done to determine their role in hMSC differentiation or in the regulation of bone metabolism with aging. Here, we directly isolated hMSC CD271⁺ cells by using a kit (CD271 (APC) MicroBead Kit, Miltenyi Biotec Inc. CA.) from surgical bone marrow specimens of three young (under 40 yrs old) and three old (over 75 yrs old) patients, without plastic adhesion or culturing that might alter miRNA and gene expression. Total RNA was isolated from the hMSC CD271⁺ cells and microarrays were performed using an Affymetrix GeneChip[®] miRNA 2.0 Array, normalized using robust multichip average (RMA), and assessed by 2-way ANOVA analysis of young vs old hMSCs (with sex and age as the variables) using the Partek Genomics Suite. This genome-wide assessment of miRNA expression revealed multiple miRNAs whose expressions were altered with age. We identified six miRNAs (miR-579, -1244, -374ab, -671-5p, -370, -29abcd) that were significantly up-regulated in aged hMSCs. Predicted bone homeostasis targets of these miRNAs include SDF-1, BMP2, β arrestin, SOX4, Leptin, IGF-1, VEGF, Collagen type 1 $\alpha 1$ and $\alpha 2$. Similarly, we identified 11 miRNAs including miR-1231, -517-ac, -3180-5p that were significantly reduced in aged hMSCs. Predicted targets of these miRNAs included adipogenic genes such as PPAR- γ or- α , AP2- α , and CD36. These results suggest that the differential miRNA expression in hMSCs with age may regulate age-associated changes that reduce osteogenic capacity and increase the adipogenic fate of these stem cells, and may help drive the development of osteoporosis. Targeting these miRNAs may be a potential therapeutic strategy to treat age-related musculoskeletal disorders.

Levels of Serum Sclerostin Are Related with Atherosclerotic Disease in Type 2 Diabetes. Rebeca Reyes-Garcia^{*1}, Pedro Rozas-Moreno², Antonia Garcia-Martin¹, Sonia Morales-Santana³, Beatriz Garcia-Fontana¹, Manuel Muñoz-Torres¹. ¹Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Spain, ²Endocrinology Division, Hospital General de Ciudad Real, Ciudad Real, Spain, ³Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio; Proteomic Research Service, Fundación para la Investigación Biosanitaria de Andalucía Oriental - Alejandro Otero- (FIBAO), Spain

In vitro studies have shown that calcification induces vascular smooth muscle cells (VSMCs) to undergo an osteocytic phenotype transition and *in vivo* studies in diabetic murine models have demonstrated that sclerostin, an osteocyte-derived negative regulator of bone formation, is up-regulated during calcification of VSMCs. Our aim was to explore the hypothesis that increased circulating sclerostin levels are associated with atherosclerotic disease in patients with type 2 diabetes mellitus (T2DM). We performed a cross-sectional study of 75 patients with T2DM (female: 45.3%, mean age 59±5.7 years and male: 54.7%, mean age 57.4±6.7 years) and we evaluated intima-media thickness, and the prevalence of ischemic heart disease atherosclerotic plaques and aortic calcifications. Serum sclerostin levels were determined by ELISA immunoassay.

Overall 58.6% of T2DM patients had atherosclerotic disease (AD), 37.3% had ischemic heart disease, 54.6% had abnormal intima-media thickness, 28.1% had carotid plaques and 34.7% had aortic calcifications. SMean serum sclerostin was significantly higher (P=0.006) in patients with AD (59.0±26.2 pmol/L) compared with those without AD (44.8±16.5 pmol/L). Sclerostin serum levels remained significantly higher in male patients with vs without AD (68.4±25.0 pmol/L vs 51.6±21.6 pmol/L; P=0.042). Also, higher concentrations of sclerostin were found in male patients with abnormal intima-media thickness (68.9±26.7 pmol/L vs 47.1±16.0 pmol/L; P=0.004), carotid plaques (79.0±23.7 pmol/L vs 49.0±20.5 pmol/L; P<0.001) and aortic calcifications (70.2±28.9 pmol/L vs 50.7±21.2 pmol/L; P=0.034). Serum sclerostin levels were significantly higher in female patients with vs without abnormal intima-media thickness (44.5±12.2 pmol/L vs 36.1±8.05 pmol/L; P=0.029) and aortic calcifications (48.7±13.9 pmol/L vs 36.3±7.74 pmol/L; P=0.004). In summary, serum sclerostin levels were positively related with parameters of atherosclerosis, suggesting that sclerostin is up-regulated during the progress of atherosclerotic disease in T2DM patients

The Adipokine Leptin Enhances the Proliferation and Differentiation of Aged Primary Myoblasts in vitro. Matthew Bowser^{*1}, Sadanand Fulzele², William Hill³, Xingming Shi², Carlos Isaacs⁴, Mark Hamrick². ¹Georgia Health Science University, USA, ²Georgia Health Sciences University, USA, ³Georgia Health Sciences University & Charlie Norwood VAMC, USA, ⁴Medical College of Georgia, USA

The long form of the leptin receptor is abundant in human skeletal muscle, and we have previously shown that recombinant leptin therapy increases skeletal muscle mass and fiber size in aged mice. Here we sought to determine whether or not leptin may have direct effects on either the proliferation or differentiation of primary myoblasts isolated from the hindlimb muscles of young (12 mo) and aged (24 mo) mice. Primary cells were isolated and cultured and then serum-starved prior to leptin treatment (0 ng/ml, 100 ng/ml, 1000 ng/ml). MTS assays showed that leptin treatment significantly (P<.01) increased proliferation of myoblasts from both young and aged mice. Leptin did not significantly alter the expression of myogenic markers MyoD and myogenin in young myoblasts, but leptin significantly (P<.01) increased the expression of both MyoD and myogenin in myoblasts from aged mice. In addition, primary myoblasts from POUND (Lepr^{db/db}) mice, which lack both the short and long form of the leptin receptor, showed decreased proliferation and decreased expression of both MyoD and myogenin compared to myoblasts from normal mice. Together, these data provide further evidence that leptin is important for the regulation of both muscle and bone mass, and that leptin can act directly on its receptors in peripheral tissues to regulate cell proliferation and differentiation.

The Role of Ramp3 in Development of an Aging Phenotype. Fiona McGuigan^{*1}, Kristina Akesson², Peter Grabowski³, Gareth Richards³, Timothy Skerry⁴. ¹University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, ²Skåne University Hospital, Malmö, Sweden, ³University of Sheffield, United Kingdom, ⁴University of Sheffield Medical School, United Kingdom

The Receptor activity modifying proteins (RAMPs) are a group of 3 accessory proteins which interact with a number of G-protein coupled receptors (GPCR). These interactions of a RAMP with a GPCR have several roles in regulation of endocrine signalling. They alter the selectivity of a receptor for different ligands, so a calcitonin receptor (CTR) becomes a receptor for amylin when associated with a RAMP. Secondly, they are required for trafficking of the calcium sensing receptor (CaSR) and calcitonin-like receptors (CLR) to the cell surface. We have also shown that they alter the G-protein activation response of a single receptor to a single ligand. For example, a PTH1 receptor associated with a RAMP activates a different spectrum of G-proteins and second messengers from a PTH1 receptor alone stimulated by the same ligand. It is known that RAMPs associate with CTR, CLR, PTH1&2Rs, CaSR, and the glucagon, secretin and VPAC1 receptors, so effects of altered signaling in vivo are complex. Studies in RAMP3 KO mice reveal an age related phenotype with altered metabolic regulation and high bone mass. To translate these findings into a clinically relevant perspective, we investigated the relationship between RAMP3 gene variants, body composition, BMD, serum biomarkers and hormone levels in two population-based cohorts of Swedish women. Five single nucleotide polymorphisms (SNP) in the vicinity of the RAMP3 gene (rs1294935; rs11982639; rs3757575; rs12702121 and rs2074654) were genotyped in two populations; the PEAK25 cohort consisting of 1061 25 year old women and OPRA consisting of 1044 75 year-old women. BMD, fat mass and lean mass (total body; regional) were measured by DXA. Genotype distributions were the same in both cohorts (p>0.05). BMD was not significantly different between genotypes. rs2074654 showed association with body composition in older but not younger women: fat and lean mass was not significantly different in PEAK25, but 3-10% higher in OPRA women carrying the variant allele (p<0.05). In the older women this was reflected in a trend towards a lower lean/fat ratio (less-lean phenotype). After correction for covariates contributing to body composition (weight, height, smoking) the results suggest that the effect of the polymorphism is through an effect on body size. These results provide the first link between the biology of RAMPs in vitro and in mice and effects in humans.

Inter and Intramuscular Adiposity Explains Only a Proportion of the Association between Muscle Density and Fractures. Andy Kin On Wong^{*1}, Karen Beattie¹, Aakash Bhargava¹, Sami Shaker¹, Colin Webber², Christopher Gordon¹, Laura Pickard¹, Alexandra Papaioannou², Jonathan Adachi³, The CaMos Research Group⁴. ¹McMaster University, Canada, ²Hamilton Health Sciences, Canada, ³St. Joseph's Hospital, Canada, ⁴McGill University, Canada

Objectives:1) To determine the association between MRI-derived inter- and intramuscular fat (IMF) in the calf and fragility fractures, 2) to determine whether IMF explains part of the association between volumetric muscle density (vMD) and fractures.

Methods:A cohort of women ≥ 50 years old from the CaMos Hamilton site underwent a 1T peripheral (p) MRI (T1-weighted fast spin echo) and pQCT (20 mm/s, 38 kVp) scan of the 66% site of their calf muscle as measured proximally from the medial malleolus to the medial tibial plateau. IMF was segmented semi-automatically from muscle on single slice MR images (1.0 mm thick, 195 µm resolution) using a region-growing algorithm. Total and percent IMF area (A), as a function of muscle area, were determined. Muscles on pQCT image slices (2.3 ± 0.5mm thick, 500 µm resolution) were manually segmented from subcutaneous fat and bone using a watershed algorithm to yield a measure of vMD computed using a fixed density calibration. Number of prevalent fragility fractures (excluding skull, toes, fingers) over the last 15 years was acquired from the CaMos database. Pearson correlations determined the percentage variance of vMD and total hip aBMD explained by IMF.A. A binary logistic regression analysis measured the association between IMF.A and odds for fragility fractures. A similar model quantifying the association between vMD and prevalent fractures further adjusted for IMF.A. All models were examined with and without age, BMI and total hip aBMD as covariates. Missing values were imputed 10 times and saturated by the regression method.

Results:IMF.A explained 53.9% of the variance in vMD, with adjustment for BMI (p<0.001), and 6.7% of variance in total hip aBMD (p=0.036). Odds for fragility fractures were significantly increased with vMD alone but only marginally with IMF.A. The association with fractures remained significant for vMD after adjusting for absolute or percent IMF.A but was decreased when total hip aBMD was included in the model (Table II).

Conclusion: Visible muscle adiposity on MRI represents only a portion of muscle density. Associations of muscle density and fractures independent of inter and intramuscular fat could be explained by the quality of muscle fibres or intra/extra

myocellular lipids which cannot be quantified using the technique employed here. Variability in IMF.A could arise from partial volume effects and subjectivity in histogram-based threshold selection.

Table I. Comparison of participant characteristics between those with and without at least one fragility fracture. P-value indicates significant difference between groups from analysis of variance tests adjusted for multiple comparisons. Percent (perc) inter and intra-muscular fat (IMF) area (A) represent all visible muscle adiposity on T1-weighted MR images.

| Variable | No Fracture (N=23) | Fractured (N=47) | P-value |
|---------------------------|--------------------|------------------|---------|
| Age (years) | 67.04 ± 5.24 | 75.55 ± 8.27 | <0.001 |
| BMI (kg/m ²) | 26.31 ± 4.57 | 28.38 ± 6.26 | 0.163 |
| IMF.A (mm ²) | 601.16 ± 264.36 | 779.08 ± 410.57 | 0.063 |
| Perc IMF.A (%) | 0.163 ± 0.094 | 0.155 ± 0.076 | 0.715 |
| vMD (mg/cm ³) | 71.85 ± 1.72 | 68.76 ± 4.7 | 0.003 |

Table I

Table II. Odds for fragility fractures based on vMD and IMF information. Models were adjusted by covariates (covars): age, BMI, total hip aBMD where indicated. All odds ratios (OR) were expressed per standard deviation (SD) increase (+) or decrease (-) in the primary variable.

| Model | pMRI/pQCT Variable | OR | Lower 95% CI | Upper 95% CI | Per SD +/- |
|---------|---------------------------|-------|--------------|--------------|------------|
| Model1A | IMF.A (mm ²) | 1.84 | 0.95 | 3.57 | + |
| Model1B | Perc IMF.A (%) | 0.91 | 0.56 | 1.49 | + |
| Model1C | vMD (mg/cm ³) | 7.16 | 2.19 | 23.42 | - |
| Model2A | IMF.A + Covars | 1.63 | 0.60 | 4.44 | + |

Prevalent Fractures are Associated with Frailty: Baseline Data from the Canadian Multicentre Osteoporosis Study. Courtney Kennedy^{*1}, George Ioannidis¹, Jonathan Adachi², Kenneth Rockwood³, Lehana Thabane¹, Laura Pickard¹, Alexandra Papaioannou⁴. ¹McMaster University, Canada, ²St. Joseph's Hospital, Canada, ³Dalhousie University, Canada, ⁴Hamilton Health Sciences, Canada

Background: A Frailty Index is a composite measure of impairments, reflecting the concept that the more things people have wrong the more frail they are. We created a "cumulative deficits" Frailty Index utilizing baseline data from the prospective, population-based Canadian Multicentre Osteoporosis Study (CaMos) and examined the relationship with prevalent fractures, falls, and BMD. Methods: A clinical panel identified candidate Index variables (i.e., related to health status; biological plausibility) which were assessed for inclusion according to pre-defined criteria: prevalence ≥ 1% and <80%, accumulates with age, does not saturate too early, and ≤5% missing data. The final Frailty Index consisted of 31 variables. For dichotomous variables, a deficit value of "1" (present) or "0" (absent) was assigned; multi-level variables were assigned deficit values in equal cut-points. Frailty scores were computed as the sum of deficit values/total number of deficits. Osteoporosis (OP) was considered a BMD t-score ≤ -2.5. Falls (past month) and prevalent fractures were self-reported, or detected via x-ray for vertebral fractures (>3 SD below the mean normal ratio). Associations were examined with ANOVA, Dunnett's C post-hoc tests, and age-adjusted ANCOVA. Mean frailty scores (95% confidence intervals [CI]) according to prevalent fracture and falls status were graphed by 5-year age categories. Results: In CaMos men (n=2884) and women (n=6539) aged 25-103 years (mean 62.6, SD 13.4), frailty scores increased significantly with age (3.4% increase per year of age on a logarithmic scale) and were significantly higher for women than men across the life-span. In men and women ≥ 65 years: 1) Participants with a prevalent fracture had greater frailty than those without (only significant <75 years; Figure 1a); 2) Participants with a recent fall (versus non-fallers) had significantly greater frailty (Figure 1b); 3) Men with OP at the femoral neck were significantly frailer than men without. A relationship with OP was not observed for women. Conclusion: In every age decade, women had greater frailty than men. Participants with a prevalent fracture were more likely to be frail than those without, particularly at younger ages. A relationship between OP and frailty was only observed for men, which could indicate that OP has more serious consequences for men and/or is often due to secondary causes.

Effect of a Multifactorial Fall-and-Fracture Risk Assessment and Management Program on Gait and Balance and Disability in Hospitalized Older Adults: a Controlled Study. Andrea Trombetti^{*}, Mélanie Hars, François Herrmann, René Rizzoli, Serge Ferrari. Division of Bone Diseases, University Hospitals & Faculty of Medicine of Geneva, Switzerland

Purpose: Falls and fragility fractures among older adults are common, devastating and costly. Hospitalization affords a major opportunity for identifying high-risk individuals and for interdisciplinary cooperation to manage fall and fracture risk factors. We assessed the effects on physical performances and the level of independence in activities of daily living (ADL), of a multifactorial fall-and-fracture risk assessment and management program including targeted exercise applied in a specific geriatric hospital setting.

Methods: We conducted a controlled study among 122 geriatric in-patients (mean ± SD age, 84 ± 7 years) admitted with a fall-related diagnosis to an acute rehabilitation ward. Among them, 92 were admitted to a dedicated unit and enrolled into a multidisciplinary, multifactorial program addressing risk factors for fall and fracture, including intensive targeted exercise, who constituted the intervention group. Thirty age-matched patients who received standard usual care in a general geriatric unit formed the control group. Primary outcomes included gait and balance performances, as assessed by instrumental gait analysis and functional tests, and the level of independence in ADL, measured on two separate occasions during stay (11.6 ± 6 days apart). Secondary outcomes included length of hospital stay, incidence of in-hospital falls, hospital readmission and mortality rates.

Results: Compared to the usual care group, the intervention group improved their Timed Up & Go (P=0.017), Tinetti (P<0.001), and Functional Independence Measure (P=0.027) tests performances, as well as several gait parameters (comfortable gait velocity: adjusted mean difference, 8.6 cm/s; 95% CI, 3.0-14.1; P=0.003). Furthermore, this program favourably impacted three-month hospital readmission rate (HR, 0.30;

95% CI, 0.1-0.9; P=0.02). Three patients in both groups (10% and 3% of control and intervention patients, respectively) were readmitted for fall-related causes (P=0.14), two control patients (7%) with a fall-related fracture.

Conclusions: A multidisciplinary, multifactorial fall-and-fracture risk-based intervention program incorporating targeted exercise, delivered during hospitalization in a dedicated unit, was effective and more beneficial than usual care in improving physical parameters related to the risk of fall and reducing disability among high-risk oldest old patients.

Effects of High-Impact Training on Femoral Neck Structure in Postmenopausal Women with mild osteoarthritis: 12-Month Randomized Controlled Exercise Intervention (ISRCTN58314639). Ari Heinonen^{*1}, Eija Janhunen¹, Juhani Multanen², Timo Jamsa³, Urho Kujala¹, Miika Nieminen⁴, Ilkka Kiviranta⁵, Arja Häkkinen¹. ¹Department of Health Sciences, University of Jyväskylä, Finland, ²University of Jyväskylä, Finland, ³University of Oulu, Finland, ⁴Department of Medical Technology, Institute of Biomedicine, University of Oulu, Finland, ⁵Department of Orthopaedics & Traumatology, University of Helsinki, Finland

Exercise seems to be a promising action to promote bone health also in adulthood. Total bone strength is known to be a combination of material and structural properties. However, most of the exercise studies have focused on measuring only bone mineral mass as an outcome of the exercise intervention. This study evaluated the training effects of a 12-month exercise intervention on femoral neck structure in postmenopausal women who had mild knee osteoarthritis (OA).

Women with Kellgren-Lawrence (K/L) radiographic grading of knee OA 1-2 were included to the study. Eighty eligible women (mean age: 58 (SD 4) yrs, height: 165 (6) cm, weight: 72 (11) kg) were randomly assigned to undergo a supervised progressive high-impact exercise 3 times a week for 12-months (n=40) or to a non-intervention control group (n=40). At baseline and 12 months, dual-emission X-ray absorptiometry (DXA) data on 36 trainees and 40 control participants were available for hip structural analysis. The section modulus (Z), cross-sectional area (CSA), and subperiosteal width (W) at the femoral neck were analyzed from the higher K/L grade knee side. Besides the DXA scans, the dynamic balance was measured with a figure-of-eight running test, maximal isometric knee extension force was measured with a dynamometer, and cardiorespiratory fitness (VO₂ max) was evaluated by a standardized 2-kilometer walking test at baseline and 12 months. In addition, subscores for self-perceived knee pain, stiffness, and self-rated physical functioning were assessed with the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC). The univariate general linear model (GLM) was used to calculate the between-group differences at 12 months.

The baseline adjusted between-group differences were observed after the 12-month intervention in favour of trainees in Z (4.4%, p = 0.003) and CSA (1.2%, p = 0.078), while there were no change in W. The exercise group improved 7% more their isometric leg extension force (p=0.009), 3% dynamic balance (p = 0.022) and 4% estimated VO_{2max} (p=0.027) than in the control group. There were no between-group differences in WOMAC subscores.

The results of this study indicate that high-impact type of exercise can increase the femoral neck strength by improving the structural properties of bone in postmenopausal women.

The Effects of Whole-Body Vibration and High Impact Aerobic Training on Bone Metabolism and Fall Risk in Postmenopausal Women. EKIN ILKE SEN^{*1}, Sina Esmailzadeh¹, NURTEN ESKIYURT². ¹ISTANBUL UNIVERSITY, ISTANBUL FACULTY OF MEDICINE, Turkey, ²Istanbul University, Turkey

Purpose: The aim of this study was to determine the effects of six months of supervised whole-body vibration (WBV) and high-impact aerobic (HIA) exercises on bone mineral density (BMD), serum bone turnover markers, fall risk and health-related quality of life (QoL) in postmenopausal women.

Methods: Fifty-eight eligible postmenopausal women were assigned to a WBV training group (n=19), a HIA training group (n=19), or a control group (n=20). All participants received calcium and vitamin D supplementation. The patients in both training groups participated in a supervised training program, which consisted of the one-hour exercise session three times a week for six months. The WBV groups received vibration (30–35 Hz, 2–2.8g) in five different static positions. The HIA group jumped rope (10-50 jumps/day). In all participants, baseline and six month BMD at the lumbar spine (L2-L4) and femoral neck was measured. Serum osteocalcin (OC) and C-terminal telopeptide of type I collagen (CTX) were measured at baseline, three, and six month intervals. Fall risk and health-related QoL were assessed using the Timed Up and Go (TUG) test and Quality of Life Questionnaire of the European Foundation for Osteoporosis (QUALEFFO) at baseline and sixth month of the study, respectively.

Results: At baseline, there was no significant difference between the three groups in respect to demographic and clinical characteristics of the participants (p>0.05). The BMD at the L2-L4 and femoral neck increased significantly in the WBV group (p<0.01) compared to the HIA and the control groups (p<0.05). Over six months, the serum OC significantly decreased in the WBV group and significantly increased in both HIA and control groups (p=0.001). There was no statistically significant change in serum CTx levels in the three groups (p<0.05). Finally, the TUG and QUALEFFO scores decreased in both training groups (p<0.001) compared to the controls.

Conclusions: Our data suggest that the six month supervised WBV training can be effective in the prevention of bone loss in postmenopausal women. These findings also indicate that supervised WBV and HIA training programs reduce fall risk and fractures related to osteoporosis, while at the same time improving health-related QoL in postmenopausal women.

Is the Relationship Between Spine Bone Mineral Density (BMD) and Prevalent Vertebral Fractures In Children Impacted by the Choice of BMD Reference Data? Leanne M. Ward^{*1}, Nathalie Alos², Stephanie Atkinson³, David Cabral⁴, Robert Couch⁵, Elizabeth A. Cummings⁶, Ronald Grant⁷, Paivi M. Miettunen⁸, Helen Nadel⁴, Celia Rodd⁹, Robert Stein¹⁰, David Stephure⁸, Shayne Taback¹¹, Mary Ann Matzinger¹, Nazih Shenouda¹, Brian Lentle⁴, Frank Rauch⁹, Kerry Siminoski⁵, and the Canadian STOPP Consortium¹². ¹University of Ottawa, Canada, ²Université de Montréal, Canada, ³McMaster University, Canada, ⁴University of British Columbia, Canada, ⁵University of Alberta, Canada, ⁶Dalhousie University, Canada, ⁷University of Toronto, Canada, ⁸University of Calgary, Canada, ⁹McGill University, Canada, ¹⁰University of Western Ontario, Canada, ¹¹University of Manitoba, Canada, ¹²Canadian Pediatric Bone Health Working Group, Canada

Background: Several reference databases are available to generate Z-scores for pediatric lumbar spine bone mineral density (LSBMD). When raw spine density for an individual is normalized on the various databases, different Z-scores are produced.

Aim: To evaluate whether the relationship between LSBMD Z-scores and vertebral fractures (VF) differs depending on the LSBMD reference database that is implemented.

Methods: VF were diagnosed by the Genant semi-quantitative method on lateral spine radiographs. LSBMD was measured by dual-energy x-ray absorptiometry with machines cross-calibrated using a spine phantom. Subjects' raw LSBMD values were converted to age-, gender-, and race-specific Z-scores for 13 sets of reference data. Various age groups were defined according to the age ranges specified by the reference databases. BMD Z-scores and the odds for VF associated with reductions in BMD Z-scores (expressed as increased odds of VF per 1 SD reduction in BMD) were compared across databases within each of the age groups.

Results: We studied 186 children through a national research program with recently diagnosed acute lymphoblastic leukemia (median age 5.3 years, range 1.3 to 17.0 years; 59% boys). Of these, 29 children (16%; 95% CI, 11% to 22%) had prevalent VF using a consensus paradigm for three experienced pediatric radiologists. The medians and ranges of the LSBMD Z-scores generated from each of the databases for the different age groups are presented in the Table. There were statistically significant differences among LSBMD Z-scores produced by the different databases within each age group. There were, however, no significant differences among the databases in the odds of VF associated with reductions in LSBMD Z-scores.

Conclusions: Although LSBMD Z-scores varied substantially among reference databases within a given age subset, the odds of VF associated with reductions in LSBMD Z-scores were similar regardless the database used to generate the Z-scores. These results highlight that the use of a LSBMD Z-score threshold as part of the pediatric osteoporosis definition is challenging, given varying results for different reference databases. On the other hand, the more consistent odds of VF in relationship to LSBMD Z-scores demonstrates that spine BMD as a risk factor for VF in children is not dependent on the choice of BMD reference database.

| Age Group (yrs) | Number of Reference Databases | LSBMD Z-score Median (range)* | Odds of VF for every 1 SD reduction in LSBMD Z-Score, Median (range)** |
|-----------------|-------------------------------|-------------------------------|--|
| 0 to 18 | 2 | -1.6 (-2.0, -1.2) | 2.2 (2.1, 2.3) |
| 0 to 5 | 2 | -1.7 (-2.0, -1.4) | 5.5 (5.1, 6.0) |
| 3 to 18 | 5 | -0.6 (-2.1, -0.3) | 2.1 (1.9, 2.1) |
| 5 to 18 | 8 | -1.0 (-2.0, -0.1) | 1.6 (1.5, 1.8) |
| 8 to 16 | 11 | -0.4 (-1.9, 0.2) | 1.9 (1.6, 2.3) |
| 9 to 14 | 13 | -0.7 (-2.0, 0.03) | 2.7 (1.7, 4.1) |

*Within each age group, LSBMD Z-scores differed significantly (p<0.001)
**Within each age group, odds ratios did not differ significantly (p>0.05)

Maternal Vitamin D Levels in Pregnancy and Offspring Bone Mass at Age 9: Findings from a UK Prospective Birth Cohort Study. Andrew Wills, Adrian Sayers*, Jon Tobias, Debbie Lawlor. University of Bristol, United Kingdom

Introduction: There is a suggestion that higher levels of maternal vitamin D (as measured by dietary intake or circulating 25(OH)D) during pregnancy are related to higher offspring bone mineral density (BMD) in later childhood, and that the 3rd trimester may be the important period of exposure. To address this question we examined whether, in the Avon Longitudinal Study of Parents and Children (ALSPAC), maternal 25(OH)D is associated with skeletal phenotypes measured by total body less head (TBLH) DXA at age 9.9 years.

Methods: Data are from 2840 mother-offspring pairs from the ALSPAC study. 25(OH)D₂ and 25(OH)D₃ were measured by HPLC on serum obtained from blood samples routinely collected during clinic attendances throughout pregnancy. Total 25(OH)D was adjusted to the respective trimester midpoint (6, 20 & 34 weeks). Whole body DXA scans were carried out in the offspring (mean age: 9.9y). The association between total 25(OH)D and TBLH bone mineral density, content, area and bone area adjusted bone mineral content was assessed using multivariable linear regression.

Results: There was no evidence for an association between maternal 25(OH)D and any of the offspring childhood DXA outcomes in minimally adjusted models (offspring age at DXA, sex, and maternal age at pregnancy) or a series of adjusted models ($p > 0.3$ for all tests). There was no evidence of non-linearity ($p > 0.05$) in these associations, or any evidence that deficient compared to replete 25(OH)D mothers had offspring with different bone outcomes. In addition we could find no evidence for an association after restricting analyses to those mothers with measures in the 3rd trimester (p for trimester 25(OH)D interactions > 0.05), or after accounting for seasonal variation in 25(OH)D in an attempt to measure habitual vitamin D levels.

Conclusion: Our study does not support the hypothesis that later childhood bone mass might be directly affected by prenatal exposure to varying levels of vitamin D.

The Response of Cortical Bone to High Impact Activity is Attenuated in Girls: Findings from a Cross-sectional PQCT Study in Adolescents. Kevin Deere¹, Adrian Sayers^{*2}, Joern Rittweger³, J.H. Tobias⁴. ¹Bristol University, United Kingdom, ²University of Bristol, United Kingdom, ³Division of Space Physiology, Institute of Aerospace Medicine, Germany, ⁴Avon Orthopaedic Centre, United Kingdom

Abstract: Background: The factors which govern skeletal responses to physical activity remain poorly understood, conceivably because accelerometers measuring physical activity are calibrated against energy expenditure rather than mechanical strain. We investigated whether a more precise understanding of these factors, including gender and fat mass, can be gained based on measurement of exposure to defined levels of impact using a Newtest device (Newtest Oy, Finland).

Methods: Participants attending the ALSPAC research clinic underwent total body DXA and pQCT of the mid-tibia, and were subsequently invited to wear a Newtest accelerometer for seven days. Accelerometer results were partitioned into low (0.5-2.1g), medium (2.1-4.1g) and high (>4.1g) impact activity.

Results: 675 participants (272 boys) had valid accelerometer recordings and information on pQCT data and other covariates (mean age=17.7 years). In our fully adjusted model (for age, height, fat mass and lean mass), moderate impact activity was positively related to periosteal circumference (PC) in boys but negatively related in girls [0.039 (95%CI -0.013, 0.090, $p=0.14$) and -0.023 (-0.023, 0.017, $p=0.26$) respectively. $p=0.03$ for gender interaction, coefficient= SD change per doubling in activity]. High impact activity showed a stronger positive association with PC in boys but no association was seen in girls [0.054 (0.007, 0.100, $p=0.024$) and 0.007 (-0.028, 0.041, $p=0.707$) respectively]. In further analyses additionally stratified by fat mass, an independent interaction was observed, such that the positive relationship between high impact activity and PC was greatest in those with highest fat mass [high impact versus PC in boys: 0.01 (-0.064, 0.085, $p=0.783$), 0.045 (-0.040, 0.131, $p=0.298$), 0.098 (0.012, 0.185, $p=0.027$); high impact versus PC in girls: -0.041 (-0.101, 0.020, $p=0.187$), -0.028 (-0.077, 0.022, $p=0.271$), 0.082 (0.015, 0.148, $p=0.017$) ($p=0.01$ for fat mass interaction); lower, middle and upper fat-tertiles respectively].

Conclusions: Female gender and low body fat are associated with reduced periosteal expansion in response to high impact activity, via independent pathways. Our results suggest that skeletal response to high impacts is particularly impaired in girls with low body weight, which may partly explain the excess of stress fractures observed in this group after undergoing strenuous exercise.

FR0034

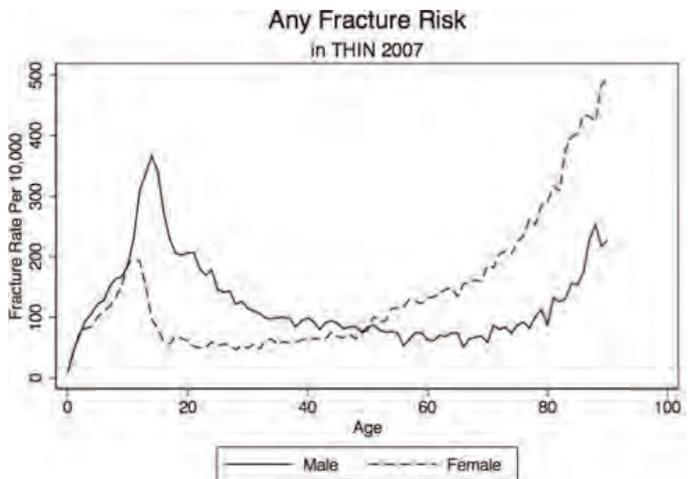

The Greater Fracture Risk in Adolescent Males Extends Through Mid-Adulthood in the United Kingdom. Kevin Haynes¹, Michelle Denburg^{*2}, Justine Shults³, Mary Leonard⁴. ¹University of Pennsylvania, USA, ²The Children's Hospital of Philadelphia, USA, ³Children's Hospital & Philadelphia, USA, ⁴Children's Hospital of Philadelphia, USA

Background: The gender differences in fracture risk in adolescent and elderly populations are well known. The greater fracture risk in adolescent males, compared with females, has been attributed to rapid growth with transitory low cortical thickness and bone density in boys but not girls. However, sex differences in fracture rates have not been evaluated in late adolescence through mid-adulthood. The objective of this study was to examine gender differences in fracture risk across the life-span in the United Kingdom.

Methods: We used The Health Improvement Network (THIN) database, which is an electronic medical record database in the United Kingdom comprising 495 General Practices. We identified 3,870,062 patients who were registered with a practice in 2007 and the 46,059 patients with a fracture code in 2007. We excluded 27,563 patients over the age of 90. We limited the study to the first fracture in 2007 in order to avoid counting follow-up visits for the same fracture as a new onset fracture. We examined incidence rates per 10,000 and determined the 95% confidence interval across all ages.

Results: The median age of the cohort in 2007 was 39 years (IQR 21-57). The Figure summarizes fracture incidence rates according to age and gender for any fracture. In patients 20 years of age, the fracture rate was 206 per 10,000 (95% CI 188, 225) for men and 61 per 10,000 (95% CI 51, 72) for women. For patients 50 years old, the fracture rate was 84 per 10,000 (95% CI 73, 95) for men and 79 per 10,000 (95% CI 68, 90) for women. For patients 80 years old, the fracture rate was 87 per 10,000 (95% CI 68, 109) for men and 290 per 10,000 (95% CI 261, 322) for women. When analyzing hip fracture separately risk began to rise after age 65 and was higher in women. In an analysis of forearm fracture both boys and girls had a similar peak childhood incidence, 71 per 10,000 (95% CI 60, 83) for girls at age 10 and 77 per 10,000 (95% CI 67, 89) for boys at age 13.

Conclusions: These data demonstrate that the greater fracture risk previously reported in the UK in adolescent boys extends into young and mid-adulthood, followed by a steady increased fracture risk in women after age 65. The results have implications to target public health interventions to both of these high risk groups. Future studies are needed to examine gender difference in bone quality, as well as behaviors that may contribute to these fracture rates across different fracture sites.

FR0037

Sclerostin has Differential Effects on Bone Mineral Density and Strength Parameters in Adolescent Athletes Compared with Non-Athletes. Pounch Fazeli^{*1}, Kathryn Ackerman², Lisa Pierce³, Gabriela Guereca³, Mary Bouxsein⁴, Anne Klibanski⁵, Madhusmita Misra³. ¹Massachusetts General Hospital & Harvard Medical School, USA, ²Brigham & Women's Hospital, USA, ³Massachusetts General Hospital, USA, ⁴Beth Israel Deaconess Medical Center, USA, ⁵Massachusetts General Hospital Harvard Medical School, USA

Sclerostin is a potent inhibitor of bone formation via WNT signaling inhibition and increases in hypogonadal states. In obese adults, sclerostin levels increase with diet-induced weight loss; however, this increase is not observed when weight loss is mediated by both diet and exercise. Therefore a mechanism whereby exercise may preserve bone mineral density (BMD) is by lowering sclerostin levels. Exercise is common in adolescents and we have previously shown that excessive athletic activity

causing amenorrhea leads to lower bone density and impaired microarchitecture parameters in amenorrheic athletes (AA) compared to eumenorrheic athletes (EA) and non-athletes (NA). Sclerostin has not been investigated in adolescent athletes, and its relationship to BMD, amenorrhea and exercise in this group is unknown. We hypothesized that AA would have higher sclerostin levels than EA and NA, and that higher sclerostin levels would be associated with lower BMD and strength parameters. We studied 49 adolescents 14-21 years old: 16 AA, 17 EA and 16 NA. We measured spine and hip BMD by DXA, failure load and stiffness at the radius using microfinite element analysis and measured fasting sclerostin levels (ELISA, TECO/Quidel). AA, EA and NA did not differ in bone age (AA: 17.7 ± 0.7 , EA: 17.5 ± 0.9 , NA: 17.7 ± 0.9 yrs; $p=0.25$), BMI (AA: 20.8 ± 2.2 , EA: 22.1 ± 2.2 , NA: 21.5 ± 2.4 kg/m²; $p=0.16$) or height (AA: 166.3 ± 5.6 , EA: 164.8 ± 6.7 , NA: 163.2 ± 6.2 cm, $p=0.34$). Sclerostin was higher in AA and EA compared with NA (AA: 0.42 ± 0.15 , EA: 0.44 ± 0.09 , NA: 0.33 ± 0.14 ng/ml; $p=0.047$). In NA, sclerostin was inversely associated with LBMD and its Z-score ($R=-0.61$, $p=0.01$), LBMAD ($R=-0.60$, $p=0.01$), hip BMD and its Z-score ($R=-0.55$, $p=0.03$) and stiffness and failure load ($R=-0.65$ and -0.65 , $p=0.001$ for both). However, in EA, sclerostin was positively associated with LBMD and its Z-score ($R=0.52$ and 0.55 , $p=0.03$ and 0.02) and LBMAD ($R=0.71$; $p=0.001$). The associations in EA remained significant after controlling for estradiol. Therefore sclerostin may have different effects in adolescent athletes compared to NA. In NA, sclerostin is inversely associated with BMD and strength parameters whereas in EA, sclerostin is positively associated with BMD. Sclerostin was also higher in both groups of athletes (not just AA) vs NA. Additional studies are needed to further delineate the role of sclerostin in mediating BMD and microarchitecture with exercise.

FR0040

Osteoimmunology in Adolescent Obesity: Delay of Trabecular Bone Development is Paralleled by Shift of Bone Marrow Immune Cells to Adipose Tissue. M. Ete Chan^{*1}, Danielle Green¹, Benjamin Adler¹, Gabriel Pagnotti¹, Denis Nguyen¹, Clinton Rubin². ¹Stony Brook University, USA, ²State University of New York at Stony Brook, USA

Obesity, which increases lifetime susceptibility to osteoporosis and fracture, may also confound skeletal development during adolescence, which depends on the viability of both the MSC and HSC progenitors. To determine the impact of obesity on bone development and bone marrow stem cells, this study tested the hypothesis that obesity compromises trabecular bone quantity and quality, paralleled by a disturbance in the neighboring bone marrow niche. Twenty 5 week old male C57BL/6J mice were weight matched into two groups ($n=10$). High fat diet (HF) and regular diet (RD) mice were fed with 45 and 10 kcal% fat diet, respectively, for a total of 8 weeks. At 2, 5 and 8w, proximal tibial metaphyses were scanned *in vivo* with μ CT at 17 μ m resolution (970 μ m thick region 480 μ m distal to the growth plate). At sacrifice (8w), cellular composition of bone marrow and gonadal adipose tissue were evaluated by flow cytometry. The obese phenotype was evident in HF by 2w with +7% higher body mass and +29% larger abdominal adipose tissue relative to RD ($p=0.01$). Longitudinal μ CT indicated that HF delayed trabecular bone development compared to RD (Fig. 1). Although the overall change of trabecular bone volume fraction (BV/TV) over the 8w experiment appeared similar between groups, HF showed a trend of -8% lower BV/TV at 2 weeks relative to RD ($p=0.09$), which dropped to -13% by 5w ($p<0.05$). Perhaps reflecting a compensatory mechanism, cortical volume in HF was +4% larger than RD at 5w ($p<0.05$), with consistent, but not significant, higher cortical volume at other time points. In parallel with a +152% higher adipose tissue mass ($p<0.001$) in HF at 8 w, flow cytometry analysis indicated that HF enabled infiltration of immune B-cell (+199%) and T-cells (+207%) into adipose tissue of HF relative to RD ($p<0.05$), but -15% and -31% ($p<0.01$) reductions of these immune cells in the bone marrow. In summary, these results suggest that obesity rapidly and profoundly disturbs the bone marrow niche, a consequence, perhaps, of the recruitment of immune cells into the enlarging adipose tissue from the bone marrow. Whether this shift in B- and T-cells is responsible for the delay of trabecular bone development has not yet been determined, but it does indicate that the metabolic or developmental demands of obesity put numerous systems at risk.

Differential Impacts of Obesity on Trabecular and Cortical Bone

Pharmacological Evaluation of a CNP Analogue for the Treatment of Achondroplasia. Florence Lorget^{*1}, Nabil Kaci², Jeff Peng¹, Catherine Benoist-Lassel², Emilie Mugniery², Todd Oppeneer¹, Dan Wendt¹, Sherry Bullens¹, Stuart Bunting¹, Laurie Tsuruda¹, Charles O'Neill¹, Federico Di Rocco², Arnold Munnich², Laurence Igeai-Mallet². ¹BioMarin Pharmaceutical Inc, USA, ²INSERM, U781 - Hopital Necker-enfants malades, France

Achondroplasia (ACH), the most common form of dwarfism, is caused by a gain of function mutation in the fibroblast growth factor receptor 3 gene (FGFR3). The C-type natriuretic peptide (CNP) antagonizes FGFR3 downstream signaling by inhibiting the mitogen-activated protein kinase (MAPK) pathway. The use of CNP as a therapeutic agent for ACH is impracticable due to its short half-life. Here, we are presenting an update on the pharmacological activity of BMN 111, a novel CNP analogue with an extended plasma half-life allowing once daily subcutaneous (SC) administration. In ACH growth plate chondrocytes, we demonstrated that BMN 111 decreased MAPK pathway activation but did not affect STAT pathway activation. In *Fgfr3^{Y367C/+}* mice mimicking ACH, daily SC administration of BMN 111 led to the attenuation of the dwarfism phenotype. With 20 days of daily SC dosing of BMN 111 (800 μ g/kg) beginning at seven days of age, we observed a significant increase in the axial and appendicular skeleton length with improvements in ACH related clinical features including flattening of the skull, reduced prognathism and straightening of the tibias and femurs. The growth plate defect (reduced height of the pre-hypertrophic/hypertrophic zones and lack of columnar arrangement) was corrected along with the normalization of the size and shape of the proliferative and hypertrophic chondrocytes. A rescue of the height and architecture of the different zones of the growth plate was observed. The height of the proliferative zone was increased; the replicating chondrocytes were organized into columns parallel to the long axis of the bone. In the hypertrophic zone, the terminally differentiated chondrocytes recovered a columnar alignment. These data support further development of BMN 111 for the treatment for ACH and hypochondroplasia (HCH).

Alendronate and PTH Dose-Dependent Improvements in Microarchitecture Lead to Improved Bone Strength despite Reductions in Tissue Material Properties. Andrea Trinward^{*1}, Steven Tommasini², Sarah Manske¹, Alvin Acerbo³, Lisa Miller⁴, Stefan Judex¹. ¹Stony Brook University, USA, ²Yale University School of Medicine, USA, ³Brookhaven National Laboratory, USA, ⁴Brookhaven National Laboratory, USA

Osteoporosis is associated with bone loss and deterioration in tissue quality. Drugs such as alendronate (ALN) and parathyroid hormone (PTH) differentially counteract bone loss, leading to drug-specific changes in measures of bone quality including bone strength. To determine how drug-induced changes in bone quality relate to mechanical strength, we subjected OVX rats to 6mo of varying doses of ALN and PTH. Morphologic (μ CT), chemical (FTIR), and mechanical properties (nanoindentation and finite element modeling) of cortical and trabecular bone in the femoral metaphysis were determined. Six mo old SD rats ($n=10$ /gp) were assigned to age-matched controls (AM), OVX controls, OVX treated with high(H), medium(M) or

low(L) doses of hPTH (75, 15, 0.3µg/kg/d), or ALN (100, 10 or 1µg/kg/2xwk). At 12mo, OVX rats had 81% less trabecular bone than AM ($p<0.001$). There were dose-dependent improvements to architecture: L-PTH had similar BV/TV as OVX, while M- and H-PTH had 2x, and 7x more BV/TV and L-, M- and H-ALN had 1x, 2x and 4x more BV/TV than OVX. Compared to AM, H-PTH and H-ALN maintained or improved both trabecular and cortical architecture, but decreased cortical tissue mineral density by 6% and 3% ($p<0.01$). There were no differences in cortical bone crystallinity, collagen cross-linking, mineralization or carbonate substitution across groups. Nanoindentation of the cortical bone showed that H-PTH and H-ALN had a 9% and 14% smaller elastic modulus and a 10% and 11% lower tissue hardness than AM ($p<0.01$). Incorporation of tissue morphology and measured elastic moduli into the finite element model demonstrated differences in structural mechanical properties. When the femoral metaphysis was subjected to a given compressive load, compared to AM, OVX had 12% lower stiffness while H-PTH and H-ALN were 46% and 18% stiffer ($p<0.05$). When combined via multiple linear regressions, CtTh, TbBV/TV and TbTh explained 91% of the variability in stiffness ($p<0.001$) while chemical or tissue mechanical properties did not enhance this association. These data show that despite deteriorated tissue properties in ALN and PTH treated rats, the improved bone architecture resulted in a structure that was able to withstand a greater mechanical load. While these results emphasize the importance of preserving bone structure during osteoporosis, the reductions in tissue material properties with ALN and PTH treatment may cause complications with long term use.

Cortical Porosity and Bone Strength Assessment in Postmenopausal Women with Atypical Fractures of the Femur and Long Term Bisphosphonate Therapy. Maria Belen Zanchetta^{*1}, Vanesa Longobardi², Fernando Silveira², Maria Dielh², Mirena Buttazzoni², ANA GALICH³, Cesar Bogado⁴, Jose Ruben Zanchetta¹. ¹Instituto de Investigaciones Metabolicas (IDIM), Argentina, ²MD, Argentina, ³Instituto De Investigaciones Metabolicas, Argentina, ⁴Idim, Argentina

In recent years, concern has been raised about atypical femoral fractures of the femur (AFF) as a possible complication of long-term bisphosphonate therapy. The pathophysiology of these events remains unknown. Previously, we had assessed bone volumetric density and architectural parameters measured by HR-pQCT in 14 postmenopausal women with atypical fractures during long term bisphosphonate treatment. The purpose of the present study was to describe cortical porosity and bone strength in these patients. All major features defined by the ASBMR Task Force - subtrochanteric or femoral shaft location, transverse or oblique orientation, no trauma or comminution, a medial spike in complete fractures - were present to designate a femoral fracture as atypical. We recorded, whenever possible, all minor features.

Methods: Cortical porosity and µFE analysis were based on HR-pQCT images of distal radius and tibia (XtremeCT; Scanco Medical).HR-pQCT scans were analyzed using an automated segmentation technique developed to identify the periosteal and endosteal margins and detect intracortical pore space morphologically consistent with Haversian canals. µFE analysis assessed quantitatively the biomechanical properties that result from bone microarchitecture. We analyzed the following parameters: Cortical thickness (Ct.Th (mm)), cortical pore volume (Ct.Po.V (mm³)), intracortical porosity (Co.Po %), cortical pore diameter (Ct.Po.Dm (µm)), estimated failure load and stiffness. We compared the results with a group of 19 postmenopausal women with similar age, BMD and BMI who had never received treatment selected from our database.

Results: Minor features are described in table 1. There were no statistically significant differences in any of the parameters measured (table 2).

In this cross-sectional study, using a noninvasive and high-resolution bone imaging device, we could not find any distinctive microarchitecture deterioration in the radius and tibia of women who had suffered an atypical fracture of the femur. Our results suggest that, if there is an alteration in bone microarchitecture or strength in these atypically fractured patients, it is not generalized through the skeleton. The compromise may be specific and limited to the femoral shaft, a site of maximum tensile stress.

Evidence of Narrower Tibiae with Increased vBMD in Stress Fractured Royal Marine Recruits Compared with Matched Controls: An Investigation of Radius and Tibia Bone Mass using pQCT. Trish Davey^{*1}, Susan A. Lanham-New², Adrian J. Allsopp¹, Pat Taylor³, Cyrus Cooper⁴, Joanne L. Fallowfield¹. ¹Institute of Naval Medicine, United Kingdom, ²Nutrition & Metabolism Department, University of Surrey, United Kingdom, ³University Hospital Southampton, United Kingdom, ⁴University of Southampton, United Kingdom

Royal Marine (RM) recruits (aged 16-32 y) undertake a strenuous 32-week military training programme. The prevalence of stress fracture (SF) is of the order of 5%. Peripheral Quantitative Computed Tomography (pQCT) provides a method of investigating structural bone parameters that may be important in the pathogenesis of SF. We have previously shown that lumbar spine and femoral neck BMD is lower in SF recruits [1]. The aim of this case-control study was to identify differences in bone structure and strength using pQCT in relation to SF during RM training as part of the UK Surgeon General's Bone Health Project. Fifty-eight SF Royal Marine (RM) recruits and 58 well-matched, un-injured RM recruits underwent pQCT scanning of the non-dominant radius and tibia. Cases and controls were matched for body weight, BMI, age and aerobic fitness. Differences between cases and controls were assessed using T-tests. At the 4% radius, SF recruits had lower total bone mineral content (BMC), trabecular BMC and trabecular volumetric bone mineral density (vBMD) than matched controls ($P<0.05$). Differences between SF recruits and controls were apparent at all slices of the tibia (4%, 16%, 38% and 66%) ($P<0.05$). SF recruits had lower: total cross-sectional area (CSA) and total BMC; cortical (cort) CSA and cort BMC; periosteal and endosteal circumferences; and polar strength-strain index (SSI)

at the 38% tibial segment than their matched controls ($P < 0.05$). Total (but not cortical) vBMD was higher in SF recruits than matched controls (38% tibia) ($P < 0.05$). There was no difference in tibial muscle area between SF recruits and controls (assessed at the 66% tibial slice). To the authors' knowledge this is the first case-control study on stress fractures within the UK military to have utilised pQCT with the close matching of injured and non-injured recruits allowing for robust comparisons to be made. Thus, narrower tibiae appear to be a risk factor for SF during military training, independent of body size; this agrees with a cohort study in military recruits using different technologies [2]. The theory of increased mineralisation as a compensatory mechanism for narrower tibiae [3] is supported by the findings from the present study, where vBMD was higher in SF recruits than matched controls.

Losing Trabecular Plates and Axial BV/TV in Hip Fractures. Bin Zhou¹, Ji Wang¹, Ian Parkinson², Xiaowei Liu³, C. David L. Thomas⁴, John G. Clement⁴, Nick Fazzalari⁵, X. Guo¹. ¹Columbia University, USA, ²SA Pathology & Hanson Institute, Australia, ³University of Pennsylvania, USA, ⁴Melbourne Dental School, Australia, ⁵Institute of Medical & Veterinary Science, Australia

Decreased bone mineral density is an important risk factor of hip fractures. However, it remains controversial regarding the relative contributions of trabecular vs. cortical components in fracture risks. Alterations in microstructures and mechanical properties of trabecular bone in the hip fracture are not well documented. We hypothesized that patients with hip fracture have distinctly weaker trabecular bone microstructure and severely compromised mechanical properties at the hip fracture site. To address this hypothesis, we applied individual trabecula segmentation (ITS) morphological analysis and micro finite element (μFE) analysis to micro computed tomography (μCT) images of inter-trochanteric trabecular bone biopsies from hip fracture patients.

Ten-mm diameter inter-trochanteric trabecular bone cores were obtained from 23 patients (age 73 ± 13, 9 male/14 female) who underwent hip replacement surgery for inter-trochanteric hip fracture. Twenty-two bone cores from cadavers (age 80 ± 11, 13 male/9 female) served as controls. Bone cores were scanned at 15 μm resolution using a μCT system (Skyscan 1174, Belgium). A cube of 4.44 × 4.44 × 4.44 mm³, corresponding to 296 × 296 × 296 voxels, was extracted from the middle of the cylinder for morphological and mechanical analysis. ITS analysis revealed interesting and distinct microstructural differences between groups (Fig. 1). The fracture group had a 33% lower plate bone volume fraction (pBV/TV) and 31% lower axial bone volume fraction (aBV/TV) than the non-fracture group (Fig. 2). The fracture group had a lower plate trabecular surface (pTb.S) and longer trabecular rods (rTb.I) than the control group. No differences were found in rod bone volume fraction (rBV/TV), plate and rod trabecular number and thickness (pTb.N, rTb.N, pTb.Th, rTb.Th). From standard μCT morphological analysis, the fracture group had 27% lower BV/TV compared with the non-fracture group. Similar results were found for Tb.N and Tb.Th, with values for the fracture group lower than the non-fracture group by 21% and 9%, respectively. Consequently, the fracture group had drastically lower Young's moduli than the control group (up to 53%) by μFE analysis.

These results suggest that there is a drastic and distinct conversion from plate-like to rod-like microstructure and a significant loss of axial trabecular bone in hip fracture patients. These microstructural changes result in a significant decrease in trabecular bone mechanical properties.

Major Gender-related Differences in Bone Mass and Strength in Aged Sost Knockout Mice. Behzad Javaheri¹, Amber Stern^{2*}, Nuria Lara², Mark Dallas³, Alexander Robling⁴, Mark Johnson⁵. ¹School of Dentistry The University of Missouri-Kansas City, USA, ²University of Missouri - Kansas City, USA, ³UMKC School of Dentistry, USA, ⁴Indiana University, USA, ⁵University of Missouri, Kansas City Dental School, USA

Previous studies have shown that canonical Wnt signaling regulates bone mass. Sclerostin (Sost) is a negative regulator of Wnt signaling and consequently bone formation and is produced mainly in osteocytes. Mice with homozygous deletion of *Sost* (*Sost* KO or KO) have high bone mass compared with WT mice at 4-6 months of age. We recently showed greater bone mass loss in female vs. male mice with a deletion of one allele of the β-catenin gene targeted to osteocytes and that these differences increase with aging. We now address the question of whether deletion of the *Sost* gene, which causes the opposite effect of increased bone mass and strength, also displays age and gender dependence. We assessed whole body bone mineral content (wBMC) and areal bone mineral density (wBMD) using PIXImus mouse densitometry; BV/TV and other cortical and trabecular parameters by microCT, and bone biomechanical properties by 3 point bending in male and female KO and WT mice at 70-90 weeks of age. We observed no differences in body weight between male and female KO mice. wBMD and wBMC were 25% and 60% higher, respectively, in female KO compared to male KO mice (p<0.001). MicroCT analysis of the femur showed that midshaft cortical thickness was 34% higher in female KO vs. male KO mice (p<0.001) and both were higher compared to WT mice of either gender. Interestingly, no gender differences in cortical bone density or BV/TV were observed in KO mice. However, in female KO mice the proximal trabecular compartment had significantly higher BV/TV (5-fold) and trabecular thickness (70%) (p<0.001) and lower trabecular spacing compared to male KO mice. Mechanical testing of the femur showed significantly stronger bones in female KO vs. male KO mice. Both genders of KO mice were stronger than their WT counterparts. Female KO mice had significantly higher total

bone volume and cross sectional area compared to male KO, but Young's Modulus was the same between the sexes and significantly lower compared to WT. These data clearly demonstrate that the regulation of the Wnt/ β -catenin signaling pathway and its role in bone are strongly influenced by gender and aging. The mechanism(s) underlying this phenomenon are currently unknown. Importantly, these findings in *Sost* KO mice support an important role of sclerostin on bone mass that is age and sex dependent and point to the need for further studies that explore the role of sex hormones as possible mediators/regulators of sclerostin function.

Muscle Strength Predicts Radial Bone Structure and Strength in Adolescent Boys and Girls. Vina Tan^{*1}, Heather Macdonald², SoJung Kim², Christine Voss³, Joan Wharf Higgins⁴, Patti-Jean Naylor⁴, Heather McKay².
¹Robert HN Ho Research Centre, Canada, ²University of British Columbia, Canada, ³Center for Hip Health & Mobility, Canada, ⁴University of Victoria, Canada

Muscle contractions exert the largest physiological loads on the skeleton; however, we know little about the influence of muscle on bone structure and strength in adolescent boys and girls. Thus, we aimed to determine the independent contribution of muscle strength to bone strength and structure of the radius in adolescent boys and girls. Participants in this cross-sectional study were 148 (87 boys) healthy Grade 10 students, aged 15.3 ± 0.3 yrs who volunteered for the Health Promoting Secondary Schools (HPSS) study. We obtained peripheral quantitative computed tomography (pQCT) scans at the distal (7%) and shaft (30%) sites of the non-dominant radius. Primary outcomes were: 1) bone strength index (BSI, mg^2/mm^4) at the distal radius and 2) polar strength-strain index (SSI_p , mm^3) at the radial shaft. Secondary outcomes were total bone area (Tt.Ar, mm^2), and density (Tt.BMD, mg/cm^3) at the distal radius, and cortical area (Ct.Ar, mm^2), density (Ct.BMD, mg/cm^3), and thickness (Ct.Th, mm) at the radial shaft. We measured forearm muscle strength using a maximal isometric hand-grip strength test. We assessed stretch stature, body mass and forearm length using standard anthropometric techniques. We also determined ethnicity and maturity status (boys: Tanner stage; girls: age at menarche) using self-report questionnaires. We developed sex-specific multivariable regression models to determine the independent contribution of muscle strength to each bone outcome after adjusting for forearm length, body mass, ethnicity and maturity status. In adolescent boys and girls, muscle strength was a significant predictor of BSI and SSI_p , and explained 10-19% and 18-19% of the variance ($p < 0.01$), respectively (Figure 1 & 2). At the distal radius, muscle strength predicted 9-20% of the variance in boys' and girls' Tt.Ar ($p < 0.001$). In contrast, muscle strength did not predict Tt.BMD in girls, but explained 8% ($p = 0.007$) of the variance in boys. Similarly, at the radial shaft, muscle strength explained 17-20% of the variance in Ct.Th and Ct.Ar ($p < 0.001$) in boys and girls, but did not predict Ct.BMD in either sex. Our findings are consistent with a functional model of bone development in which bone primarily adapts its cross-sectional geometry, rather than its mineral density, to withstand loads from muscle forces. The specific adaptation of bone strength to increased muscle strength achieved through an exercise-training program warrants further investigation.

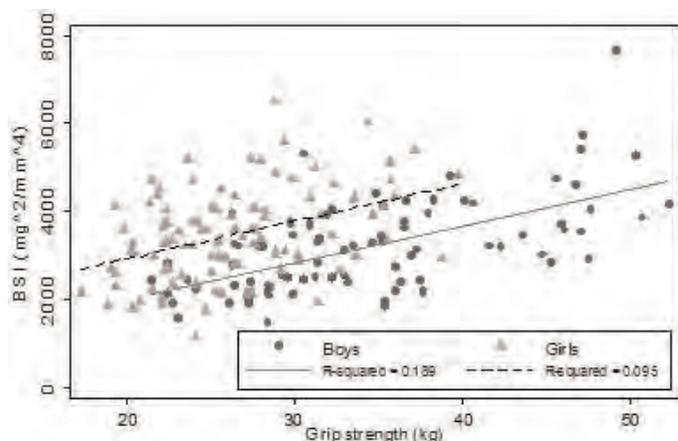

Figure 1. Relationship between bone strength index (BSI) at the distal radius and grip strength in boys and girls, $p < 0.01$.

Lower Osteocyte Lacunar Density in Osteons of Alendronate Treated Canine. Joseph Geissler^{*1}, Devendra Bajaj², Shahir Monsuruddin³, Matthew Allen⁴, David Burr⁴, J. Fritton⁵. ¹New Jersey Institute of Technology New Jersey Medical School, USA, ²NJ Medical School Orthopaedics, USA, ³NJ Institute of Technology Biomedical Engineering, USA, ⁴Indiana University School of Medicine, USA, ⁵New Jersey Medical School, USA

Bisphosphonates (BPs) are effective drugs that decrease fragility fracture risk through actions on decreasing individual osteoclast tunneling, and increasing and decreasing apoptosis of osteoclasts and osteocytes, respectively. The emergence of very rare, atypical fractures with their defining characteristics (long-term anti-resorptive use, low-energy cortical shaft fracture, bilaterality) has renewed interest in the effects of drugs on tissue-level mechanical properties and the mechanisms behind bone tissue damage. In canine rib bone we found that long-term alendronate (ALN) treatment reduces both stiffness (20% lower) and resistance to failure (3x fewer cycles to failure) under cyclic fatigue loading of cortical tissue beams ($1.5 \times 0.5 \times 10$ mm) at a dose associated with the treatment of Paget's. This adds to data that long-term BP treatment results in reduced toughness. This study investigated possible microstructural differences behind these mechanical differences in 3-year ALN-treated cortical tissue. Skeletally mature (1-2 yrs), female beagles ($n = 12/\text{group}$) were treated daily with ALN (1.0 mg/kg BW) or vehicle control. After 4-point bending to determine stiffness and fatigue life, beams were stained with basic fuchsin and plastic embedded. Three cross-sections from each beam were cut and polished to constant thickness, and imaged by light microscopy. Histomorphometry revealed that the average cross-sectional area of cortical osteons and their osteocyte lacunar density were lower in ALN beams by 17% and 20%, respectively ($p < 0.05$). Most interestingly, within both groups linear correlations existed between osteonal lacunar density and initial beam stiffness such that the regression equations were similar ($r = 0.54$ for combined data). This relationship might offer a means of predicting mechanical properties of osteonal bone. Reductions in osteon size are likely due to decreased individual osteoclast tunneling as recently described by Hazelwood et al. Reduced osteon size and associated lower cement line surface area may allow for larger microcracks to accumulate in interstitial spaces accounting for the reductions in mechanical properties observed. Reduced osteonal osteocyte lacunar density likely has a more purely biological origin not directly associated with the effects of BPs on osteocyte apoptosis. Since the rate of remodeling is reduced with BPs fewer osteoblasts are required to refill tunnels and available to become matrix-bound osteocytes.

Mechanical Strain Downregulates C/EBP β in MSC and Decreases Endoplasmic Reticulum Stress. Maya Styner^{*1}, Mark Meyer², Kornelia Galior³, Natasha Case¹, Buer Sen⁴, Zhihui Xie⁵, William Thompson⁶, J. Pike², Janet Rubin¹. ¹University of North Carolina, Chapel Hill, School of Medicine, USA, ²University of Wisconsin-Madison, USA, ³UNC-CH School of Medicine, USA, ⁴University of North Carolina At Chapel Hill, USA, ⁵University of North Carolina, Department of Medicine, USA, ⁶University of Delaware, USA

Exercise prevents marrow mesenchymal stem cell (MSC) adipogenesis, reversing trends that accompany aging and osteoporosis. Mechanical input, analogous to exercise, limits MSC adipogenesis through activation of β -catenin, preserving MSC potential for osteogenic differentiation. C/EBP β , a transcription factor upstream of PPAR γ , is critical for adipogenesis and interestingly, has also been shown to upregulate ER stress. We thus hypothesized strain would target C/EBP β and that the targeting of this transcription factor would benefit the skeleton, not only from a lineage- perspective, but also by decreasing ER stress. Both C3H10T1/2 pluripotent stem cells as well as mouse marrow derived MSC were cultured in adipogenic medium in the presence or absence of mechanical strain applied via Flexcell device. We demonstrate herein that mechanical strain represses C/EBP β expression and activity in MSC. siRNA silencing of β -catenin prevented mechanical repression of C/EBP β . ChIP-seq demonstrated no significant association of β -catenin and its target TCF4 with the *Cehpb* gene, suggesting that mechanical repression of C/EBP β via β -catenin is indirect. Furthermore, C/EBP β overexpression did not override strain's inhibition of adipogenesis, indicating that mechanical induction of β -catenin blocks adipogenesis at multiple loci. Overexpression of C/EBP β in MSC induced a dose-dependent increase in the pro-apoptotic CHOP as well as a dose-dependent reduction in the chaperone BiP, changes consistent with increased ER stress. Application of a daily strain regimen, in addition to decreasing C/EBP β , increased ER capacity as measured by a significant increase in BiP. ChIP-seq demonstrated a significant association between C/EBP β and the *CHOP* and *BiP* genes. In conclusion, mechanical downregulation of C/EBP β not only accompanies a reduction in adipogenesis, but also limits ER stress, adding a novel mechanism whereby exercise improves MSC/skeletal health.

Planar Cell Polarity Signaling directs Osteoblast Proliferation and Wolff's Law for Dynamic Strain. Gabriel Galea^{*1}, Lee Meakin¹, Hanna Taipaleenmaki², Noureddine Zebda¹, Toshihiro Sugiyama³, Gary Stein², Lance Lanyon², Andre Van Wijnen², Joanna Price¹. ¹University of Bristol, United Kingdom, ²University of Massachusetts Medical School, USA, ³Yamaguchi University School of Medicine, Japan, ⁴Royal Veterinary College, United Kingdom

Bone is a mechanically-responsive tissue with a structural hierarchy of cytoskeletal proteins, extracellular matrix proteins and minerals. The macroscopic organization of these components into a skeletal architecture occurs along the direction of load-engendered dynamic strain (Wolff's Law). Here, we investigated the cellular and molecular basis of Wolff's Law.

We first examined the direction of cell division in mouse primary osteoblasts, NIH-3T3 fibroblasts, as well as human osteoblastic SaOs-2 or chondrocytic 28I2 cells that were briefly exposed to dynamic strain by four-point substrate bending. Within 24 hrs following strain, a significantly greater proportion of osteoblastic and fibroblastic but not chondrocytic cells, divided in parallel to the strain direction, but mitotic division in unstrained cells was random. Initiating proliferation with 1 μ M estradiol before strain did not alter strain-dependent polarization of SaOS-2 division. Thus, strain orients mitotic division independently of initiating cell cycle progression.

We then addressed whether the direction of cell division is controlled by the planar cell polarity (PCP) pathway through Rho-associated coiled-coil kinase (ROCK), which mediates centriole positioning¹. ROCK-dependent centriole realignment towards the principal strain direction relative to the center of G1/S-phase nuclei was observed within 1 hr following strain as visualized by immunofluorescence microscopy for the centriole component PCM-1. ROCK blockade 1 hr before strain with the ROCK inhibitor GSK269962 prevented reorientation of division, but blockade 1 hr after strain had no effect.

Mutation of the PCP component Vangl2 (Vangl2^{-/-}), which generates loop-tail mice, alters femoral architecture (e.g., lower eccentricity, greater trabecular structure model index). The Vangl2^{-/-} mutation also compromises the polarization of long bone-derived osteoblast division in response to strain *ex vivo*.

Thus, limited acute dynamic strain influences the cell-type dependent orientation of mitotic division in osteoblasts and fibroblasts by rapid ROCK-mediated centriole realignment. These data suggest that Wolff's Law includes PCP dependent polarization of cell division as a strain-adaptive response in bone and connective tissue.¹Chevrier V et al, J Cell Biol, 2007 ;157(5):807-17

Bone Density and Strength Differences Among Elite Female Athletes in Weight-Bearing Versus Non Weight-Bearing Sports. Brett Bruininks¹, Lesley Scibora^{*2}. ¹Concordia College (Moorhead), USA, ²University of Minnesota, USA

High-impact weight-bearing sports, generating large ground reaction forces, are positively associated with bone density and strength. Since muscle-generated forces exert the greatest physiological load on bone, sports that involve muscle contraction with little or no ground reaction forces should also be associated with enhanced strength of the loaded bone. Differences in areal and volumetric bone mineral density and parameters of bone geometry and strength were explored in elite female athletes. Fifty-three female (age 18-25 years) soccer (n=15), ice hockey (n=21), and swimming (n=17) athletes and 19 non-active controls were measured. Total body bone mineral content (BMC) and total body, lumbar spine and femoral neck areal bone mineral density (aBMD) was assessed using dual energy X-ray absorptiometry. Peripheral quantitative computed tomography was used to examine bone volumetric density (vBMD), total (ToA) and cortical bone area (CoA), and estimates of bone compressive (BSI) and bending strength (Z, SSIp) at tibia (4, 66%) and radius (4, 50%) sites. Upon adjustment for age, height/bone length and body weight, soccer and ice hockey groups exhibited significantly greater lumbar spine aBMD (both +9.6% and +8%, respectively) compared to swimmers and non-active controls. There were no significant differences among groups at the femoral neck. At the distal (4%) tibia, only soccer athletes showed 15-26% higher BSI ($p<0.05$) compared to all other groups and exhibited 13-15% greater bending strength (Z, SSIp, $p<0.05$) compared to swimmers and controls at the proximal (66%) tibia; with greater bending strength due to more robust bone geometry (CoA, +10-13%, $p<0.05$). At the distal (4%) radius only ice hockey athletes showed 24-25% greater BSI ($p<0.05$) compared to swimmers and controls. Results are consistent with previous research suggesting weight-bearing sports are associated with greater bone density and strength than non weight-bearing sports. Both elite ice hockey and soccer female athletes exhibited greater aBMD and bone strength parameters at weight-bearing sites compared to swimmers and controls. Thus, both may be bone-strength enhancing activities in females. Unexpectedly, muscle-generated forces in elite female swimmers did not appear to exert bone density or strength benefits beyond that of non-active females. Future research is needed to further investigate the role of non weight-bearing sports on bone structure and strength in females.

Diffuse Microdamage Induced in Cortical Bone in vivo Repairs without Bone Remodeling. Zeynep Seref-Ferlengez^{*1}, Oran Kennedy², Mitchell Schaffler¹. ¹City College of New York, USA, ²The City College of New York, USA

Physiological loading produces two types of microdamage in bone: linear microcracks (LCr, ~ 50-100mm) and diffuse damage (DDx, cluster of cracks <1mm). LCr induce local osteocyte apoptosis that evokes remodeling of damaged bone. However DDx foci neither induce apoptosis nor activate resorption. The biological response of bone to DDx is unknown. Therefore we examined time-dependent changes in DDx content and bone mechanical properties after inducing DDx *in vivo*.

Methods: Under anesthesia, ulnae from 3 groups of adult (4-5 mo, n=24) female SD rats underwent creep loading to a predetermined displacement that induces only DDx. In Group 1, right ulnae were loaded on Day 0 after which rats resumed normal cage activity for 14d (Survival). On Day 14, left ulnae (Acute) were loaded identically after which rats were killed and both ulnae were harvested for histology. In Groups 2 & 3, mechanical properties of creep-loaded damaged ulnae were tested by loading to failure, either immediately after loading or after 14d (Survival) and compared to non-damaged ulnae of the same rat. DDx area fraction in Acute Loaded and Survival ulnae was measured from basic fuchsin-stained diaphyseal sections using fluorescence microscopy. DDx area fraction in Survival vs. Acute-Loaded ulnae and stiffness of creep-loaded vs. intact control ulnae were compared using paired t-tests.

Results: DDx in Survival bones was reduced ~30% compared to Acute-Loaded ulnae (Fig. 1 & 2, $p<0.02$). Moreover, no resorption or woven bone formation was seen. The stiffness of Acute-Loaded ulnae was 14% less than intact control bones ($p<0.02$) but was restored to normal levels in Survival ulnae ($p>0.6$ Fig 3).

Conclusion: These findings reveal for the first time that small crack damage in bone (DDx) undergoes some form of repair, resulting in both microscopically and mechanically demonstrable recoveries evident by two weeks after induction of DDx in living bone. This damage reduction and mechanical recovery occurred without remodeling or changes in bone architecture. These findings suggest that alternative repair mechanisms exist in bone to deal with small crack damage. The nature of such mechanisms is currently unknown, but it seems reasonable to postulate that a combination of physicochemical remineralization and/or osteocyte-mediated processes involving local production of structural or adhesive proteins play roles in such repair.

Muscle Volume does not Affect the Osteogenic Response to Compressive Loading in the Distal Radius of Young Women. Karen Troy*, Varun Bhatia, William Edwards. University of Illinois at Chicago, USA

Bone is typically well suited for its habitual loading environment because of its ability to adapt. Although animal studies have been valuable tools for studying this process, prospective human bone adaptation data are lacking. In addition to externally applied mechanical forces, muscle forces may play an important role in bone adaptation. Greater muscle volume suggests larger habitual muscle forces

applied to the bone. Given that bone adaptation is understood to be “error signal” driven, muscle volume may be inversely related to osteogenic response magnitude. Our purpose was to use a human *in vivo* loading model to determine whether voluntary compression of the radius is osteogenic, and whether baseline muscle volume affects the response.

Eight women (20 ± 1 years) participated in an institutionally approved 28-week mechanical loading regime that targeted the distal radius. Seven women (22 ± 2 years) served as controls. Subjects applied a 300 N force by leaning onto the palm of the hand 50 cycles per day, three days per week, with each cycle being separated by two seconds. All subjects gave written informed consent prior to their participation and received QCT scans of their forearm at weeks 0, 14, and 28. Cortical, trabecular, and integral BMC, BMD, and BV in the 45 mm region proximal to the subchondral plate were computed. Muscle volume was quantified in the distal-most 10 cm region of the radius. Repeated measures ANOVAs were used to compare main effects of group and time. Pearson correlations were used to relate baseline muscle volume to 28-week changes in bone.

Loading increased the integral BMC by 54 ± 35 mg at 28 weeks. This 1.3% relative increase from baseline was significantly different from zero ($p=0.005$) and from the control group (change: -45 ± 23 mg, $p<0.001$). At 28 weeks trabecular and cortical compartments contributed 19 ± 32 and 35 ± 41 mg to the net increase, respectively. Muscle volume was not significantly correlated with changes in bone.

Compression of the radius is osteogenic in young women and can be used to prospectively study bone adaptation. In our small sample, osteogenic response was not related to muscle volume. This task can be used to determine the degree to which animal data may be translated to humans, thereby providing a validated theoretical framework within which exercise interventions to increase bone mass and prevent osteoporosis may be systematically designed and evaluated.

Directed Differentiation of Embryonic Stem Cells to Chondrocyte and Osteoblast lineages: The Role of RhoA/ROCK Signaling. Dalea Bukhary*, Fraser McDonald², Agamemnon E Grigoriadis³. ¹King's College London/UKKing Abdulaziz University/Saudi Arabia, United Kingdom, ²King's College London Dental Institute, United Kingdom, ³Dept Craniofacial Dev & Stem Cell Biology, King's College London, United Kingdom

Treatment of bone and cartilage tissue defects caused by disease, trauma or aging is therapeutically challenging. Pluripotent stem cell-based approaches to regenerative therapies have been strengthened by a better understanding of embryonic skeletal development and how bone and cartilage lineage specification and differentiation occur. It is now well-established that *in vitro* differentiation of Embryonic Stem Cells (ESCs) and induced Pluripotent Stem Cells (iPSCs) can recapitulate embryonic development through germ layer induction followed by enrichment and expansion of specific lineages. We have developed a novel, step-wise mESC differentiation system using specific recombinant factors in the absence of serum to investigate (a) the mechanisms of pluripotent stem cell commitment to somitic mesoderm and bone/cartilage cell lineages, and (b) the role of Rho GTPase signaling in ESC-derived osteoblast/chondrocyte differentiation. Activation of the Nodal/Activin and canonical Wnt pathways together with inhibition of BMP signaling (Noggin) directed ESCs to form a primitive streak-like population expressing Brachyury, and further to somitic mesodermal subpopulations expressing PDGFR α with reduced hematopoietic/osteoclastic and cardiac potential, that subsequently differentiated efficiently in monolayer culture to osteoblast and chondroblast lineages. Inhibition of Rho/ROCK signaling using the ROCK inhibitor, Y-27632, at different developmental stages of ESC differentiation showed up to a 2 to 3-fold increase in chondrogenesis and osteogenesis, suggesting that Rho/ROCK signaling regulates the fate of bipotential chondro-osteoprogenitor cells. This was confirmed by qPCR analysis of osteoblast (Runx2, ALP, BSP) and chondrocyte (Sox9, Coll2)-specific genes, as well as by Alcian blue staining and Coll2 antibody staining of differentiated chondrocyte monolayers. Preliminary data also suggest that exposure to BMP4 together with stage-specific inhibition of ROCK signaling may play a role in maturation of hypertrophic chondrocytes. Finally, renal capsule grafting studies showed that the ESC-generated cells have endochondral ossification potential *in vivo*. Thus, the ESC model system provides defined, manipulatable and expandable chondro-osteoprogenitor populations that will provide insights into the molecular basis of bone/cartilage development and disease, as well as for generating specific populations for bone and cartilage tissue repair and replacement.

Ethanol Modulates Canonical Wnt Signaling And FoxO Activation In Acute and Chronic Binge Models of Ethanol-Induced Deficient Fracture Repair. Philip Roper*, Rachel Nauer¹, Kristen Lauing¹, John Callaci². ¹Loyola University Medical Center, USA, ²Loyola University of Chicago, USA

Alcohol abuse is a risk factor for impaired bone fracture healing, and binge drinking is the predominant alcohol abuse pattern associated with traumatic orthopedic injury. The mechanism behind this effect is unknown. The canonical Wnt signaling pathway is important in fracture healing because it drives mesenchymal

stem cell (MSC) differentiation towards osteoblasts and chondrocytes that are required for callus formation. Wnt signaling relies on activation of β -catenin to upregulate specific target genes necessary for differentiation. However, in times of increased oxidative stress, as with alcohol exposure, another family of transcription factors, the FoxO transcription factors, becomes active. Once active, FoxOs require β -catenin as a cofactor for proper function. We hypothesize that alcohol exposure may be able to activate FoxOs within the fracture callus, thereby suppressing Wnt signaling through β -catenin competition. To test this hypothesis, we devised two clinically relevant models of alcohol administration in which 7 week old male C57BL/6 mice received intraperitoneal injections of ethanol (2g/kg) or saline for three consecutive days per week for two weeks prior to injury. One hour after the last alcohol exposure, the left tibia was stabilized with an intramedullary pin and surgically fractured. Animals in the acute binge group ceased further injections, while animals in the chronic binge group continued once daily i.p. ethanol injections until the animals were euthanized. Callus tissue was examined for the effects of alcohol on tissue composition, FoxO oxidative stress signaling, and Wnt signaling. Both acute and chronic binge alcohol administration led to deficient fracture repair, however administration of alcohol during healing produced greater defects in repair as measured by decreased callus size and perturbed callus tissue composition, namely a reduction in the cartilaginous callus and the presence of mature, hypertrophic chondrocytes. FoxO1 activation was significantly increased in the fracture callus of alcohol animals as compared to saline ($p < 0.01$), with a concomitant decrease in active β -catenin ($p < 0.05$). The callus tissue of chronic binge animals also exhibited increases in total FoxO1 protein levels ($p < 0.05$). Alcohol-induced activation of FoxO signaling with the concurrent decrease in canonical Wnt signaling provides a plausible mechanistic explanation for the observed effects of alcohol on fracture healing.

Runx2 Control Chondrocyte Proliferation through Direct Regulation of Cell Cycle Genes. Haiyan Chen^{*1}, Farah Ghori-Javed¹, Rosa Serra¹, Soraya Gutierrez², Amjad Javed¹. ¹University of Alabama at Birmingham, USA, ²Universidad De Concepcion, Chile

Runt related protein-2 (Runx2) is essential for skeletogenesis. Coordinated activity of multiple cell types including chondrocyte and osteoblast are required for skeletogenesis. To elucidate Runx2 regulatory control distinctive to chondrocyte cell population, we generated mice with a conditional ablation of Runx2 in chondrocyte. Selective deletion of Runx2 in chondrocyte by Col2a-Cre was confirmed with Rosa26-tomato mice. Homozygous mice exhibited developmentally failed endochondral ossification and dies shortly after birth. Chondroprogenitors in the hyaline cartilage of wild type mice showed uni-directional differentiation to hypertrophic chondrocytes. Runx2 deficiency resulted in disruption of chondrocyte differentiation as determined by absence of pre/hypertrophy and Collagen type X expression. To our surprise, chondrocyte proliferation which is an integral component of endochondral ossification was severely impaired. We observed a dramatic decrease (50%) in the total cell number in both proliferative and pre-hypertrophic zones of homozygous mutant compared to wild type. Similar reduction in chondrocyte cell number was noted in hyaline cartilage of trachea. Furthermore, *in vivo* BrdU labeling confirmed this reduction results from a decreased mitotic activity of chondrocyte. This unique role of Runx2 to enhance chondrocyte proliferation is consistent with the growth failure and primordial dwarfism in mutant mice. To mechanistically understand alteration in chondrocyte proliferation rate, we determined genes associated with cell cycle cascade in the Runx2 null growth plate. Our gene microarray identified 5 genes with reproducible differences in expression levels ranging from 3-50 folds. In Runx2 null chondrocytes Sfn mRNA was upregulated, while expression of Gpr132, c-Myb, cyclin A1, A2 were strongly inhibited. Interestingly, the differentially expressed gene set encompass functional grouping across cell cycle from G1/S phase to cell cycle check points and arrest. To assess if Runx2 directly regulate their transcription, we cloned 2kb promoter of all five genes. Multiple high affinity Runx recognition motifs were noted in these promoters. Chromatin immunoprecipitation revealed that in chondrocytes Runx2 is bound to these sites. Consistent with *in vivo* promoter occupancy, promoter activity of these genes was enhanced by Runx2. Our results establish for the first time that Runx2 is obligatory for chondrocyte proliferation and regulate cell cycle genes.

Smad2/3 Mediated TGFbeta Signaling Regulates Chondrocyte Proliferation and Differentiation in Postnatal Growth Plate and Maintains Articular Cartilage Integrity. Weiguang Wang^{*}, Karen Lyons, Buer Song. University of California, Los Angeles, USA

Previous findings on mouse models with TGF- β type II receptor or ligand knockout revealed that TGF- β signaling plays important roles in axial skeleton formation, joint development, and long bone growth. However, it is unknown whether it is the Smad2/3 or noncanonical pathway that mediates the functions of TGF- β signaling. To study the role of Smads 2 and 3 in the process of cartilage formation and maintenance, we generated mice with conditional deletion of Smad2 in chondrocytes using Col2cre, mice with Smad3 globally deleted, and the cross of these two strains to obtain mice with both Smad2 and 3 deleted in chondrocytes (the double

mutant mice). In prenatal stages, when compared with WT littermates, none of these single and double mutant mice showed defects in axial skeleton and joint formation, but differences were observed in long bones. By P0, both *Smad2^{cko}* and *Smad3^{-/-}* mice exhibited defects in the growth plate, including an increase in proliferation of resting chondrocytes and an expansion of the hypertrophic zone. These defects were much more severe in *Smad2/3* double mutant. By 2-weeks, the double mutant mice developed a severe postnatal dwarfism, associated with a delay of secondary ossification in the resting zone, decreased proliferation in the proliferative zone, and an increase in apoptosis in the growth plate and articular chondrocytes. In addition, the double mutant mice showed a much earlier onset of an osteoarthritis-like phenotype (1 month) than previously reported for *Smad3^{-/-}* mice (Ref). Meanwhile, *Smad2^{cko}* mice showed minor but reproducible differences in growth plate morphology, demonstrating a role for Smad2 in growth plate cartilage. Analysis of articular cartilage in *Smad2^{cko}* mice is ongoing. By 4 months, the *Smad3^{-/-}* mice developed postnatal dwarfism as well as an osteoarthritis-like phenotype, as reported previously (Ref). These observations suggest that both Smad2 and Smad3 mediated TGF- β signaling is important for the regulation of postnatal growth plate chondrocyte differentiation and for maintenance of articular cartilage, and that Smad2 and 3 have overlapping function. Smad2/3 mediated signaling is not critical at prenatal stages, yet is indispensable postnatally for chondrocyte proliferation, differentiation and maintenance of cartilage in adult.

Reference: Yang et al., *J Cell Biol.* 2001 Apr 2;153(1):35-46

Figure. *Smad2/3* double mutant mice have an earlier onset and more severe OA-like phenotype than do *Smad3^{-/-}* mice. H&E staining of 1 month knee sections. Double mutants exhibit thinner superficial, middle and deep zones (yellow double head arrow) compared to *Smad3^{-/-}* null or WT mice. An increased number of hypertrophic cells are seen (blue arrow heads) in the deep zone in *Smad3^{-/-}* null mice. This is exacerbated in the double mutants (right). Chondrocyte clusters (green arrowheads) and hypercellularity are evident in the midzone of double mutants, but are not seen in *Smad3^{-/-}* null or WT mice.

Smad2/3 double mutant mice have an earlier onset and more severe OA-like phenotype than do *Smad3^{-/-}*

The FOP R206H Alk2 Mutation Enhances BMP-Induced Chondrogenic Differentiation. Andria Culbert^{*}, Salin Chakkalakal, Robert Caron, Eileen Shore. University of Pennsylvania, USA

Fibrodysplasia ossificans progressiva (FOP) is a rare genetic disease characterized by heterotopic endochondral ossification within soft connective tissues and is caused by mutations in ALK2/ACVR1, a BMP type I receptor. The most common mutation, R206H, causes dysregulation of canonical BMP signaling, a key regulator of chondrocyte commitment, proliferation, and maturation. Primary mouse embryonic fibroblasts (MEFs) were harvested from wild-type and heterozygous knock-in *Alk2^{R206H/+}* embryos to examine the effects of the mutation on chondrogenic differentiation. Consistent with previous results, *Alk2^{R206H/+}* MEFs have increased canonical BMP signaling in both the presence and absence of BMP ligand, as detected by phosphorylation of Smad1/5/8. Chondrogenic media containing BMP ligand was used to induce differentiation as TGF β alone did not induce chondrogenesis of wild-type or mutant MEFs. In the absence of BMP, *Alk2^{R206H/+}* MEFs did not spontaneously differentiate, despite increased BMP signaling; however, in the presence of BMP show increased sensitivity toward chondrogenesis. *Alk2* mRNA is most abundant in undifferentiated MEFs and decreases upon differentiation, suggesting a role in early differentiation events. Consistent with our results, *Alk2^{R206H/+}* MEFs have accelerated onset and increased abundance of early chondrogenic transcripts during differentiation corresponding to the earlier appearance of chondrocyte morphology. Proliferation was quantified but showed no differences between wild-type and *Alk2^{R206H/+}* MEFs either prior to or during early chondrogenesis. Implants of MEFs into hind limbs of wild-type mice demonstrate that robust *in vivo* heterotopic endochondral ossification is induced by the combination of BMP ligand with *Alk2^{R206H/+}*, but not wild-type, MEFs. Our data demonstrate that heterozygous expression of R206H Alk2 enhances chondrogenic differentiation of progenitor cells and suggests Alk2 plays an important role early during chondrogenic differentiation. The requirement for BMP ligand to activate differentiation of *Alk2^{R206H/+}* MEFs both *in vitro* and *in vivo* suggests that an increased sensitivity to BMP signals during early stages of chondrogenesis is a critical mechanism to promote heterotopic endochondral ossification in the presence of the R206H Alk2 FOP mutation.

The Transcription Factor FoxC1 Regulates Chondrogenesis Together with Gli2 through Induction of PTHrP. Michiko Yoshida*¹, Kenji Hata¹, Rikako Takashima², Sachiko Iseki³, Teruko Takano-Yamamoto⁴, Riko Nishimura¹, Toshiyuki Yoneda¹. ¹Osaka University Graduate School of Dentistry, Japan, ²Osaka University, Japan, ³Section of Molecular Craniofacial Embryology, Graduate School, Tokyo Medical & Dental University, Japan, ⁴Tohoku University, Japan

Endochondral bone formation, which is an essential event for mammalian skeletal development, is regulated by various transcription factors through harmonious organization of transcriptional networks. Identification of transcription factors involved in the development of these networks would facilitate to uncover the molecular basis of endochondral ossification. Here we attempted to identify a novel transcription factor that takes a part in chondrogenesis via transcription network development. To approach this, we generated transgenic mice carrying Venus driven by Col2a1 promoter, thereby GFP is selectively expressed in chondrogenic cells. Venus-positive chondrogenic cells dissociated from E12.5 limb buds were sorted using the FACS Aria without expansion in culture. Subsequent differential microarray between Venus-positive and -negative cells led us to identify FoxC1 (Forkhead Box C1) as a candidate transcription factor. Of note, the mutation of *FOXC1* is shown to cause Axenfeld-Rieger syndrome (ARS) in human that is characterized by the anterior segment dysgenesis and diverse skeletal abnormalities. Whole mount *in situ* hybridization demonstrated evident co-expression of *FoxC1* mRNA and Col2a1 in the developing limbs. Overexpression of FoxC1 induced alcian blue-positive chondrogenesis in limb bud cells in microculture. These results collectively suggest that FoxC1 plays a role in chondrogenesis.

To further verify the functional role of FoxC1 in chondrogenesis, we searched for transcriptional target of FoxC1. FoxC1 had no effects on Col2a1 and Sox9 mRNA expression. On the other hand, FoxC1 increased PTHrP mRNA expression in conjunction with promoted chondrogenesis. Moreover, FoxC1 together with Gli2 further up-regulated PTHrP expression. IP-Western analysis revealed a physical interaction between FoxC1 and Gli2. DNA pull-down assay and ChIP experiments showed direct binding of FoxC1 to the FoxC1 binding element (CTAAATAAC) in the PTHrP gene promoter. Finally, pathogenic missense mutation (Ile126Met) of FOXC1, which is responsible for ARS, suppressed PTHrP expression induced by IHH. In conclusion, we identified a novel transcription factor FoxC1 that promotes chondrogenesis through directly up-regulating PTHrP expression in collaboration with Gli2. Further determination of FoxC1 function in transcription network and chondrogenesis should lead us to obtain deeper insights into the molecular mechanism of endochondral ossification.

Knockdown of Tribbles Homolog 3 (TRIB 3) Results in Cell and Context Specific Effects on Bone, Fat and the Hematopoietic System. Rakesh Verma*¹, Anne Breggia², Phuong Le¹, Sheila Bornstein², Donald Wojchowski¹, Clifford Rosen². ¹Maine Medical Center Research Institute, USA, ²Maine Medical Center, USA

TRIB 3 (Tribbles homologue 3 Drosophila) is a pseudokinase which regulates diverse cellular functions including insulin signaling, adipogenesis and bone formation via cell survival and stress signaling pathways. Importantly, TRIB 3 suppresses adipocyte differentiation by negative regulation of peroxisome proliferator-activated receptor gamma (PPAR γ). Bone marrow irradiation prior to transplantation induces trabecular and cortical bone loss. Interestingly, following bone marrow irradiation there is a transient period of marrow adipogenesis (days 5-10) prior to hematopoietic reconstitution and recovery of bone mass. However, the role of adipogenesis during bone marrow recovery remains unclear. In this study, we hypothesized that a reduction in TRIB 3 might promote marrow adipogenesis and alter hematopoiesis and skeletal mass. As such, we first phenotyped TRIB 3^{-/-} mice on a B6 background and B6 WT mice at 12 weeks of age by DXA and found increased % body fat, lower total body weight, decreased areal BMD, but no hematopoietic phenotype. Next we sought to investigate the role of TRIB 3 in bone marrow recovery following lethal irradiation and bone marrow transplantation. LY5.1+ WT recipient mice were lethally irradiated (10Gy) and transplanted with either LY5.2+ TRIB 3 KO or LY5.2+ WT donor cells. At 8 weeks post transplant, >90% of peripheral blood (PB) cells of all recipient mice were LY5.2+ indicating successful engraftment. Surprisingly, mice engrafted with TRIB 3^{-/-} donor cells had increases in total body weight (36%), % body fat (26%), total bone mineral density (BMD, 2%), total bone mineral content (BMC, 6%), and femoral (BMD, 7%) compared to WT receiving WT donor cells. Importantly, as compared to LY5.1 WT mice transplanted with WT donor cells, LY5.1 WT mice transplanted with TRIB 3^{-/-} donor cells exhibited marked increases in red blood cells and reticulocyte production. Interestingly, the CD11b+ myeloid population, a precursor to the osteoclast lineage, was also markedly increased in the recipient mice. Thus transplantation of donor cells without TRIB 3 led to an increase in hematopoietic elements as well as enhancement of bone mass suggesting that the target of this pseudokinase within the bone marrow includes all three major cell types. These data also highlight the cell and context specific nature of Tribbles Homolog 3 in the bone marrow and its potential role in regulating body composition and bone mass. NIH-1R24 DK092759-01

HIF-1 α is Essential for the Development of the Nucleus Pulposus. Laura Mangiavini*¹, Tremika LeShan Wilson², Alexander Robling³, Irving Shapiro⁴, Makarand Risbud⁵, Ernestina Schipani¹. ¹Indiana University School of Medicine, USA, ²Department of Medicine, Indiana University School of Medicine, USA, ³Indiana University, USA, ⁴Thomas Jefferson University, USA, ⁵Department of Orthopedics Surgery, Thomas Jefferson University, USA

The intervertebral disc consists of an outer ring of fibrous cartilage called the annulus fibrosus, and an inner gelatinous structure known as the nucleus pulposus. The annulus fibrosus derives from the sclerotome, whereas it has been recently shown that the nucleus pulposus cells originate from the notochord. Notably, however, the molecular mechanisms that control differentiation of notochordal cells into cells of the nucleus pulposus are still largely unknown.

The nucleus pulposus is hypoxic and express the transcription factor Hypoxia Inducible Factor -1 α (HIF-1 α), which is a major mediator of cellular adaptation to hypoxia. In this study, we analyzed the role of HIF-1 α in the development of the nucleus pulposus by conditionally ablating HIF-1 α in the notochord. For this purpose, FOXA2-Cre transgenic mice were bred with mice homozygous for a floxed HIF-1 α allele (HIF-1 α ^{fl}) in order to generate FOXA2-Cre; HIF-1 α ^{fl/fl} mutant mice and control littermates. Mutant mice were viable with no macroscopic abnormalities. Development of the nucleus pulposus was studied from E15.5 up to 4 months. E15.5 mutant nucleus pulposus was considerably smaller than control. This phenotypic feature was not due to decreased cell proliferation or to cell death, but was, at least in part, a consequence of the reduced size of the cells forming the nucleus pulposus, which did not display the classical hypertrophic appearance shown by control cells. Our finding thus suggests that HIF-1 α deficiency had altered the differentiation of notochord cells into cells of the nucleus pulposus. Conversely, at birth, Tunel assay revealed massive cell death in the mutant nucleus pulposus. The nucleus pulposus eventually disappeared completely in postnatal mutant mice, and was replaced by cells of the annulus fibrosus. Interestingly, morphology of the vertebral bodies was normal at all time points examined, which further supported the high degree of specificity of expression of Cre recombinase in cells of the nucleus pulposus. Taken together, our findings indicate that deficiency of HIF-1 α in the notochord alters the differentiation process of notochord cells into cells of the nucleus pulposus, which then eventually die. Moreover, our study supports the notion that the nucleus pulposus originates from the notochord.

In conclusion, HIF-1 α is a differentiation and survival factors for cells of the nucleus pulposus and has an essential role in the development of the nucleus pulposus.

Manipulating the Notch Pathway to Accelerate Fracture Repair. Cuicui Wang*¹, Jie Shen¹, Kiminori Yukata², Michael Zuscik³, Regis O'Keefe¹, Hani Awad⁴, Matthew Hilton⁴. ¹University of Rochester, USA, ²University of Tokushima Graduate School, Japan, ³University of Rochester School of Medicine & Dentistry, USA, ⁴University of Rochester Medical Center, USA

Bone fractures are one of the most common problems observed in clinical orthopaedics. During fracture repair, mesenchymal stem cells (MSCs) are recruited to the fracture site and undergo differentiation to form chondrocytes and osteoblasts that aid in repairing and strengthening the bone. The process of MSC differentiation during fracture repair is reminiscent of events that occur during skeletal development. Recently, several breakthrough discoveries in our lab have identified the Notch pathway as a critical regulator of MSC differentiation during skeletal development. Specifically, our genetic data demonstrated that loss of Notch signaling accelerates cartilage and bone formation from the common mesenchymal progenitor during limb development. In our current study, we investigated whether Notch inhibition (via DAPT treatment) would accelerate and enhance fracture repair by inducing more cartilage and bone formation from MSCs recruited to the fracture site. Following the generation of an open tibial fracture in mice, DAPT (50mg/kg/day) or DMSO (vehicle) was delivered via I.P. injection for one or 4 consecutive days. Treatments began two days following fracture to ensure normal initiation of MSC recruitment and proliferation. Radiographs collected from 14 days post-fracture (14dpf) suggested greater volume of bony callus in DAPT treated mice, particularly in the 4 consecutive day treatment group. MicroCT quantification established a significant increase in mineralized callus volume in DAPT treated mice at 14dpf. Additionally, the strength of the newly formed fracture callus in DAPT treated mice, as measured by biomechanical torsion testing, was dramatically enhanced compared to controls. Histological analyses further revealed that Notch inhibition enhanced the size of the cartilage and bony callus at early time-points (4dpf and 7dpf) during fracture repair. To verify these results at the molecular level, real-time RT-PCR analyses were performed to assess changes in chondrogenic and osteogenic gene expression of callus tissue (4dpf). Consistent with our histological findings, cartilage (*Col2a1*, *Col10a1*) and bone markers (*Coll1a1*, *Bsp*, *Oc*) were significantly up-regulated. Taken together, our findings revealed that Notch inhibition accelerated fracture repair by enhancing MSC differentiation to generate a more robust cartilaginous and bony callus, therefore, the Notch pathway may serve as an important therapeutic target in the context of fracture repair.

FR0100**Periosteal PTHrP Regulates Cortical Bone Modeling During Linear Growth.**Meina Wang^{*1}, Joshua VanHouten², Randy Johnson³, Arthur Broadus².¹Yale University, USA, ²Yale University School of Medicine, USA, ³M.D. Anderson Cancer Center, USA

PTHrP is highly expressed in the periosteum (PO) and fibrous ligament and tendon insertion sites during linear growth. Here, we tested the hypothesis that PTHrP in the fibrous layer at the PO might regulate the modeling of cortical bone surfaces during growth. We studied this question in mice in which *PTHrP* was conditionally deleted via *sclex* (*Scx*)-Cre; *Scx* is a bHLH transcription factor that is highly expressed in the connective tissues of bone. Concordance of *Scx* and *PTHrP* expression was determined in *Scx-Cre/R26R* and *PTHrP-lacZ* reporter mice.

We focused on two regions: 1) the proximal posterolateral tibia (PL tibia), a well-known site of metaphyseal modeling or cut-back and 2) the neck and diaphysis of the fibula, chosen because it has a profoundly abnormal structure by μ CT in the *PTHrP* cKO mouse. Findings in the PL tibia included: a) abundant PTHrP expression in the fibrous PO overlying a dense population of osteoclasts (OCs) resorbing the subjacent metaphyseal cortex, b) a 75% reduction in these OCs in the *PTHrP* cKO mouse, together with a much thickened cortex in a site with concordant *R26R* and *PTHrP-lacZ* expression, and c) a striking increase in endosteal osteoblasts (OBs) at this site together with a 3-fold increase in double-label BFR by histomorphometry at 7 weeks. This thickening distorted the PL tibia on 3D μ CT in 10/10 cKO mice at 12 weeks. In the control fibular neck, we found an extraordinary rate of modeling of a curious "trabecularized cortex" that lacked a true cortical surface. Here, OCs and OBs were at work on opposing trabecular surfaces, and the entire region lit up by double label at 7 weeks. In the cKO mouse, we saw a decrease in OC bone resorption, an inside-out or endosteal pattern of double-labeling, and at 12 weeks total volumes and cross-sectional areas that were twice those seen in the control mice ($TV = 0.27 \pm 0.03$ vs 0.55 ± 0.06 mm³ and $TA = 0.17 \pm 0.02$ vs 0.33 ± 0.03 mm², $M \pm SEM$, control vs cKO/ $n = 5$ pairs, t test < 0.003). The result of this abnormal modeling was a fibular diaphysis that was markedly thickened and misshapen throughout. Clearly, the remarkable increase in the cKO fibular bone mass was the result of the uncoupling of OC and OB activities during modeling.

We conclude that PTHrP in the PO regulates cortical modeling during linear growth. Since the PO is anchored proximally in the bone collar, we propose that PO PTHrP expression may be driven in the fibrous PO by growth-induced loading.

FR0103**SULF1/SULF2 Expression in Osteochondral Cells and Their Role in Bone Development and Fracture Repair.**Gul Zaman^{*1}, Mittal Shah¹, Jaish Dudhia¹, Chantal Chenu², Andrew Pitsillides¹, Gurtej Dhoot¹. ¹The Royal veterinary College, United Kingdom, ²Royal Veterinary College, United Kingdom

Heparan sulfate 6-O-endo-sulfatases (SULF1 and SULF2) are a relatively novel family of extracellular sulfatases that selectively remove 6-O-sulfate groups from HSPGs, co-receptors for many growth factors and cytokines thereby altering their binding characteristics crucial for cell signaling. Cartilage and bone homeostasis are regulated by specific growth factors and cytokines and skeletal abnormalities have been reported in SULF1/2 double knockout mice. The role of resident osteochondral cells through SULF1/2-mediated cell signaling has not, however, been examined and the aim of this study was to examine the expression patterns of Sulfi/2 at mRNA and protein level in cartilage and bone cells during normal development and fracture repair in rat limbs using RT-PCR, immunohistochemistry and *in vitro* assays designed to determine their functional significance.

SULF1/2 expression using immunohistochemistry was observed in chondrocytes undergoing endochondral bone development in both primary and secondary ossification centres in fetal day 17 and postnatal days 5-11 rat femurs. Examination of epiphyseal growth plates revealed that compared to quiescent or hypertrophic chondrocytes, the columns of proliferating chondrocytes expressed higher levels of SULF1/2. Markedly higher levels of both SULFs, however, were expressed in osteoblasts actively forming bone when compared with proliferating pre-osteoblasts in the periosteum or the entombed osteocytes expressing the lowest levels.

A fracture model that comprised a mid-diaphyseal transverse osteotomy in the rat femur showed elevated levels of SULF1/2 in the periosteal layer adjacent to the fracture site during the early inflammatory phase. Chondrocytes, identified by Alcian blue positive staining of their extracellular matrix, were more prevalent one week after fracture and, as in growth plates, those undergoing active proliferation expressed higher SULF1/2 levels than chondrocytes exhibiting overt differentiation or hypertrophy. Active osteoblasts involved in bone accrual and osteoclasts in closely allied resorbing sites also expressed elevated levels of SULF1/2 during the fracture repair process.

Sulf1 and Sulf2 mRNA was also expressed in the osteoblast-like cell line SAOS2 and RNA extracted from calvaria, long bones and cartilage samples. In preliminary gain or loss of function analyses, the addition of SULF1 neutralizing antibodies to SAOS2 cells *in vitro* resulted in a small (15%) but significant ($p < 0.05$) increase in osteoblast-like cell (SAOS2) proliferation.

This study shows that cartilage and bone cells have distinct SULF1/2 expression profiles during development, which are recapitulated during fracture repair. Our ongoing dissection of the signaling pathways active in cells expressing these elevated

levels of SULF1/2 will provide important insight into the regulation of growth and development in osteochondral tissues.

FR0105**Computational Simulation of Osteopontin ASARM Peptide Binding to Crystal Faces of Hydroxyapatite.**Ahmad Mansouri¹, David L. Masic², Jeffrey J. Gray², Marc McKee^{*1}. ¹McGill University, Canada, ²Johns Hopkins University, USA

Matrix extracellular phosphoglycoprotein (MEPE) and osteopontin (OPN) contain an acidic, serine- and aspartate-rich motif (ASARM) which, when phosphorylated, potently inhibits mineralization of osteoblast cultures. ASARM peptides accumulate in hypophosphatemia patients whose distinguishing clinical feature is soft bones (osteomalacia). To investigate the mechanism by which ASARM peptides inhibit mineralization, we have modeled using energy-minimization computational simulations human OPN-ASARM peptide (DDSHQSDSHHSDESDEL) binding to hydroxyapatite mineral at the atomic scale. To examine peptide binding to different hydroxyapatite atomic planes having different chemical terminations, we used RosettaSurface, a computational structure-prediction algorithm for peptide-solid surface interactions. We have determined the binding affinities, specificities and structure for ASARM-Sp0 (without phosphoserine) and two phosphorylated forms of ASARM (ASARM-Sp3 and ASARM-Sp5, with 3 and 5 phosphoserines, respectively). Peptides were constructed using PyMOL software. {100}, {001} and {010} monoclinic hydroxyapatite planar surfaces having different calcium-to-phosphate ratios were constructed using CrystalMaker software. Each surface was generated by "cutting" along a specific Miller indices (hkl) plane, and each mineral construct had a thickness of at least 8 angstroms. P-O and O-H bonds are strong and their breaking is energetically unfavorable, so we tailored the terminations to leave intact interfacial phosphate and hydroxyl ions. Different mixed-charge surfaces were constructed to reflect surfaces likely sampled during crystal growth. The RosettaSurface protocol predicted low-energy conformations for these peptides in solution and bound to mineral (adsorbed). Adsorption data revealed highly significant differences in binding energies between the 3 peptides for all crystal surfaces examined, with increased binding correlating with increased phosphorylation. All peptides were generally unstructured both in solution and upon adsorption, and phosphate and carboxylate groups coordinated with surface calcium with some degree of lattice matching. The highest binding energies were for the phosphorylated peptides on (100) and (010) terminations. In conclusion, these computational simulations provide mechanistic data on how OPN and its phosphorylated peptides act as potent biomineralization inhibitors. Support from the CIHR and the Arnold and Mabel Beckman Foundation.

FR0116**Critical Role of PTH Receptor Phosphorylation in Regulating Acute Effects of PTH on Renal Hemodynamics.**Akira Maeda^{*1}, Makoto Okazaki², Hiroko Segawa¹, Abdul Abou-Samra³, Harald Jueppner¹, John Potts¹, Thomas Gardella¹. ¹Massachusetts General Hospital, USA, ²Chugai Pharmaceutical. Co., Ltd., Japan, ³Wayne State University, School of Medicine, USA

Phosphorylation of seven serine residues on the PTHR1 C-terminal tail is thought to play a key role in controlling signaling responses induced by PTH ligands. Cells expressing a phosphorylation-deficient mutant PTHR1 (PD), having the seven serines replaced by alanine, exhibit prolonged cAMP signaling responses to PTH ligand treatment. Knock-in mice expressing this PD-PTHR1 in place of the normal PTHR1 exhibit prolonged increases in blood cAMP levels after single acute PTH(1-34) injection (Bounoutas et al., Endocrinology 2006). Last year we reported that the expected responses of decreased blood phosphate levels and increased blood 1,25(OH)₂D₃ levels following acute PTH(1-34) injection were unexpectedly blunted in the PD mice. Furthermore, whereas levels of cAMP in urine of WT mice increased robustly following PTH injection, they did not increase in urine of PD mice. These altered responses of blood and urine markers of PTH action suggested a defect in PTH function in kidneys of PD mice.

We investigated the effects of PTH injection in WT and PD mice on NaPi2a protein levels in renal brush-border membranes (BBMs) using western blot analysis. Surprisingly, NaPi2a expression was down-regulated in renal BBMs of PD mice to the same extent that it was in renal BBMs of WT mice. Moreover, real-time PCR analysis revealed that PTH injection increased 1 α -OHase mRNA expression in kidneys of PD mice to the same extent that it did in kidneys of WT mice. Thus, key molecular responses in renal proximal tubule cells were normal in PTH-injected PD mice. We then investigated effects on renal filtration. We injected (iv) WT and PD mice with FITC-inulin, along with PTH(1-34) (50 nmol/kg) or vehicle, and measured the disappearance of fluorescence from the blood over time. The values for T_{1/2} of FITC-inulin in vehicle- and PTH-injected WT mice were 17 \pm 2 and 21 \pm 5 minutes, while the corresponding values in PD mice were 14 \pm 2 and >75 minutes. Thus, renal clearance following acute PTH injection was markedly impaired in PD mice. These data show that phosphorylation of the PTHR1 plays a key role in regulating the effects of PTH on renal clearance mechanisms. Whether these effects involve direct actions of the

PTHr1 specifically within the kidney, the systemic vasculature, or elsewhere, is currently under investigation.

Induction of Bone Marrow Apoptosis Impacts PTH Anabolic Actions in Bone. Amy Koh¹, Sun Wook Cho², Glenda Pettway¹, Laurie McCauley³. ¹University of Michigan, USA, ²Seoul National University Hospital, South Korea, ³University of Michigan School of Dentistry, USA

PTH has multifaceted effects in the skeleton, a prominent one being its potent anabolic actions. Irradiation increases bone marrow cell apoptosis, TGF β activity, and mesenchymal progenitor cell numbers which are associated with augmented PTH anabolic actions. The purpose of this study was to determine whether targeted bone marrow cell apoptosis impacts PTH anabolic actions. The pro-apoptotic agent, etoposide (ETOP) (20mg/kg) or vehicle (VEH) control, was used to treat 16wk old mice daily for 5d then 3d/wk for 6wks. PTH (50mg/kg/d) or VEH was also administered daily resulting in 4 treatment groups: VEH, PTH, ETOP and PTH+ETOP. Mice were sacrificed 24h after last injections and skeletal phenotyping, flow cytometric analyses (FACS) of the bone marrow, and serum bone turnover markers analyzed. MicroCT analysis and histomorphometry of tibiae revealed a significant increase in bone volume with PTH vs. VEH, and a significant decrease with ETOP vs. VEH. PTH administration in the ETOP treated mice had a significantly higher ratio of increase versus PTH without ETOP. At 5 days of ETOP treatment there was a significant increase in early apoptotic cells (AnnexinV+PI-) as well as MER⁺CD11b⁺F4/80⁺ and MER⁺CD68⁺F4/80⁺ cells via FACS. At 6 wks, FACS analysis revealed significantly increased percentages of CD68⁺ and Gr1⁺CD11b⁺F4/80⁺ (macrophage markers), CD45⁺ (leukocyte marker) and Lin⁺CD29⁺sca1⁺ (mesenchymal stem cell marker) cells with ETOP or PTH+ETOP treatment. Serum TRAcP5b was significantly increased with PTH and PTH+ETOP similarly whereas PINP levels were increased to a greater extent with PTH than PTH+ETOP. PTH+ETOP significantly reduced numbers of osteoclasts per bone perimeter after 6 wks of treatment when compared to VEH or ETOP but not compared to PTH alone. In another experimental model, luciferase⁺ bone marrow stromal cells (BMSCs) were implanted subcutaneously to form ectopic ossicles and their growth tracked over time using bioluminescent imaging. Mice were administered VEH, ETOP, PTH, or PTH+ETOP daily starting 7d after implantation. PTH increased BMSC luciferase signals at d6. ETOP increased signal similarly to PTH and greater than VEH while PTH+ETOP had the greatest increase in luciferase BMSC signal suggesting that the induction of apoptosis provided an environment more conducive for PTH anabolic actions. Taken together, these data suggest that targeted apoptosis augments the ability of PTH to evoke anabolic actions in bone.

Proton Generation by Osteoblasts/Osteocytes in Response to PTH/PTHrP. Katharina Jähn¹, Matt Prideaux², Hong Zhao², Sarah Dallas¹, Lynda Bonewald¹. ¹University of Missouri - Kansas City, USA, ²University of Missouri-Kansas City, USA

PTH activates bone remodeling and elevated PTHrP during lactation has been shown to induce osteocytes to remove mineral from their perilacunar matrix (Qing *et al.* 2012). Genes associated with the production and export of protons i.e. carbonic anhydrase and ATP/H⁺ transporters, and proteins active under acidic conditions i.e. TRAP and Cathepsin K are elevated with lactation. To determine if osteocytes can acidify their microenvironment, the IDG-SW3 cell line, which recapitulates early to late osteocyte differentiation, was used. Addition of 100nM PTHrP rapidly and significantly reduced pH in the media of IDG-SW3 cultures at day 3 and 6 (representative of late osteoblasts/early osteocytes) as detected by the pH indicator dye SNARF. Similar, but less pronounced effects were observed using 100nM PTH. This effect was specific for the osteoblast lineage as similar effects were observed with osteoblastic but not fibroblastic cells. However, the effects of PTH on genes associated with proton production were dependent on stage of differentiation. PTH (50nM) treatment for 24h significantly increased gene expression of ATP6V0B, ATP6V0d2, TRAP and Cathepsin K in mature osteocyte (day15-29) IDG-SW3 cultures but not in late osteoblast/early osteocyte (day1-8) cultures. Therefore, late osteoblasts/early osteocytes are primed to release protons in response to activation by a potentially different mechanism from that of mature osteocytes. To further examine osteocyte perilacunar remodeling *in vivo*, mice expressing an α 2(I)-collagen-GFP fusion protein were allowed to lactate. The prominent green fluorescence around osteocyte lacunae and within the bone matrix in virgin mice was absent in lactating mice but reappeared with 1 week recovery after force weaning. Whereas the absence of GFP-collagen in the osteocyte perilacunar matrix with lactation may be due to proteolytic degradation of collagen, this is an unlikely explanation for the absence of fluorescence throughout the surrounding bone matrix. Using a cell lysate containing GFP, decreasing pH quenched GFP fluorescence which was partially recovered at pH>6, but not at pH<5. Therefore, recovery of GFP in the bone matrix of α 2(I)-collagen-GFP mice post-lactation suggests a reduction in pH of no more than 6 during lactation. These

data provide evidence that osteocytes may have the capacity to lower pH in their local environment, thereby affecting activation of proteases and removal of mineral.

FGF23 Suppresses Chondrocyte Proliferation and Maturation in the Presence of Soluble Alpha-klotho both in vitro and in vivo. Masanobu Kawai¹, Saori Kinoshita², Yasuhisa Ohata³, Kazuaki Miyagawa⁴, Miwa Yamazaki¹, Keiichi Ozono⁵, Toshimi Michigami⁶. ¹Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, ²Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, ³Osaka University, Japan, ⁴Osaka Medical Center, Japan, ⁵Osaka University Graduate School of Medicine, Japan, ⁶Osaka Medical Center, Research Institute for Maternal & Child Health, Japan

Fibroblast growth factor-23 (FGF23) is well established to play a crucial role in the regulation of phosphate homeostasis. X-linked hypophosphatemic rickets (XLH) is one of the FGF23-related disorders characterized by the impaired mineralization and growth retardation. Similar to XLH, FGF23 levels are elevated in patients with chronic kidney disease (CKD) and one of the complications of childhood CKD is growth retardation. However, it remains unclear as to whether the elevated levels of FGF23 have any direct effects on chondrocyte biology with respect to the development of growth retardation. To answer this question, we performed *in vitro*, *ex vivo* and *in vivo* analyses to determine the effect of FGF23 on chondrocyte biology. *In vitro* studies revealed that FGF23 induced ERK phosphorylation and up-regulated *Egr1* expression in the presence of soluble alpha-klotho (sKL) both in ATDC5 cells and primary chondrocytes. *Ex vivo* organ culture of metatarsal rudiments showed that FGF23/sKL suppressed the linear growth of metatarsals in a dose dependent manner, which was antagonized by the co-incubation with neutralizing antibodies raised against FGF23. Calcium deposition detected by calcein labeling in the hypertrophic zone was impaired in metatarsals treated with FGF23/sKL, suggesting that chondrocyte maturation is impaired in FGF23/sKL-treated metatarsals. Histologically, the length of proliferating zone was diminished associated with decreased proliferation of chondrocytes. FGF23/sKL did not affect the expression of Sox9 and Col2a1, but significantly suppressed Indian hedgehog (Ihh) expression. Importantly, administration of Ihh protein partially rescued the suppressive effect of FGF23/sKL on metatarsal growth. *In vivo*, three-consecutive days of intraperitoneal administration of sKL in *Hyp* mice (P7) caused a decrease in the length of proliferating zone associated with a decline of proliferation of chondrocytes, but did not alter circulating phosphate levels. In adenine-induced CKD models, the length of proliferating zone was decreased in association with elevated serum FGF23 levels despite of the comparable circulating phosphate levels compared to controls. These lines of evidence suggest that FGF23 may have a direct influence on chondrocyte biology such that it suppresses proliferation and maturation of chondrocytes in the presence of sKL and blockade of FGF23 signaling could have a therapeutic potential to improve linear growth in CKD and XLH patients.

Persistent Hyperparathyroidism Is a Major Risk Factor for Fractures in the Five Years after Renal Transplantation. Rose-marie Javier¹, Peggy Perrin², Sophie Caillard², Laura Braun², Françoise Heibel², Bruno Moulin³. ¹University Hospital, France, ²Nephrology-Transplantation Department, France, ³Nephrology-Transplantation Department, Strasbourg, France

Persistent hyperparathyroidism (HPT) contributes to bone loss after renal transplantation (RT) but its impact on fracture in the early course of RT is not documented. This longitudinal study was designed to evaluate persistent HPT and its association with mineral disorders and fractures in the five years after RT.

Methods. 152 consecutive patients undergoing RT at our center between August 2004 and April 2006 were included. Bone and metabolism biochemical parameters were determined at RT, at 3, 12 and 60 months after RT (D0, M3, M12, M60). Patients characteristics, treatments and symptomatic fractures were recorded.

Results. 143 patients were analysed (age 47 ± 12 years, 59% male, 89% deceased donor, 18% RT range >1, 12% diabetic nephropathy, 37 ± 42 dialysis months, 79% haemodialysis, 17% peritoneal dialysis). Pretransplant osteopenia (BMD T-score < -1 to -2.5 at hip and/or at spine) concerned 44% of patients and osteoporosis (T-score < -2.5) 23%. At D0, intact parathormon serum concentration (PTH) was 447 ± 395 pg/mL. Incidences of persistent HPT (PTH > 130 pg/mL) at M3 and M60 were respectively 49 and 34 %, of hypercalcemia (Ca > 10.4 mg/dL) 13 and 8% and of hypophosphatemia (Ph < 2.5 mg/dL) 22 and 20 %. At M60, 12% of patients with GFR > 60 ml/min had PTH > 130 ng/L.

Recipients with PTH > 130 ng/L at M3 had decreased survival (7 vs 0, p=0.03), higher BMI, bone turnover markers (bAP, crosslaps) and calcemia and lower phosphatemia, 25OHD and GFR.

During the five post transplant years, 22 patients (15.4%) presented 30 fractures (spine:10, foot:6, forearm:6, leg:4, rib:2, hand:1, hip:1); 24 fractures were spontaneous. Mean time to first fracture was 15.9 ± 15.7 months. Six patients presented several

fractures. Fractures were significantly associated with: M3 and M12 PTH>130 pg/mL, M3 and M12 hypercalcemia, M3 hypophosphatemia, M3 albuminemia<40 g/dL and a trend for female gender and pretransplant osteopenia. Fractures were not associated with 25OHD at D0, M3 and M12 bAP, diabetes, age, M3 GFR. By ROC curve analysis, we showed that cut-off of M3 PTH of 130 pg/mL predicted fractures occurrence with a sensibility of 82% and a specificity of 58%.

Conclusion: This first longitudinal study demonstrates that persistent HPT is an important risk factor for fractures after RT. A better control of hyperparathyroidism before and after kidney transplantation should be beneficial, particularly in patients with pretransplant bone disease.

FR0129

Rapid Decrease in Plasma Calcium Concentration by Treatment with ONO-5334, a Cathepsin K Inhibitor, in the Rabbit Hypercalcemia Model Induced by PTHrP. Yasuo Ochi¹, Hiroyuki Yamada², Yasutomo Nakanishi¹, Satoshi Nishikawa¹, Yasuaki Hashimoto¹, Hiroshi Mori¹, Masafumi Sugitani¹, Yutaka Shichino¹, Kazuhito Kawabata¹. ¹Ono Pharmaceutical Co., Ltd., Japan, ²ONO PHARMA UK LTD., United Kingdom

Malignancy-associated hypercalcemia is mainly caused by enhanced bone resorption associated with over-production of the parathyroid hormone-related protein (PTHrP) by tumor. ONO-5334 is a small molecule and an orally-active inhibitor of cathepsin K, which plays an important role in osteoclast-mediated bone resorption. In this study, we evaluated the effect of ONO-5334 on plasma calcium concentration (Ca) in the rabbit hypercalcemia model induced by PTHrP.

Thirty micrograms/day of PTHrP (human 1-34) or vehicle-1 (2% L-cysteine solution) was subcutaneously infused via an ALZET osmotic pump (Model 2ML1) on the back of New Zealand White rabbits (female, 11 weeks of age). On the next day, rabbits infused PTHrP were assigned to one of the following 3 groups (4-5 animals/group): PTHrP-control treated with vehicle-2 (0.5% methylcellulose solution), ONO-5334 3 or 30 mg/kg, based on plasma Ca concentration. ONO-5334 or vehicle-2 was orally administered once daily from the day following PTHrP infusion for 3 days. In separate experiments, alendronate (0.17 or 0.85 mg/kg) or zoledronic acid (0.06, 0.2 or 0.6 mg/kg) was administered intravenously in a single dose on the day following PTHrP infusion. Blood was collected over time until 4 days after beginning the PTHrP infusion, and plasma free Ca concentration was measured.

Plasma Ca concentration, at 24 hours after osmotic pump implantation, significantly increased by 4.3 mg/dL in the PTHrP-control group ($p<0.01$ vs vehicle-1-infused group), and this elevation was sustained during the study period. ONO-5334 at 3 and 30 mg/kg dose-dependently decreased plasma Ca concentration from 3 hours after first dosing and this effect was maintained by repeated dose (2.0 - 3.3 mg/dL reduction in 30 mg/kg group, $p<0.05$ vs PTHrP-control). Significant decreases in plasma Ca concentration were observed with alendronate at 0.85 mg/kg and zoledronic acid at all doses from 54 hours ($p<0.05$ vs PTHrP-control) and 24 hours ($p<0.01$ vs PTHrP-control) after dosing, respectively. The maximum reduction in Ca concentration appeared to be comparable to that of ONO-5334.

These results suggest that ONO-5334 may decrease plasma Ca concentrations much earlier than bisphosphonates in hypercalcemia patients. Rapid onset of the effect of ONO-5334 is considered to be due to direct inhibition of cathepsin K, while, for bisphosphonates, their accumulation in bone is necessary to inhibit bone resorption.

Genome Wide DNA Methylation Array in Genetic Hypercalciuric Stone-forming (GHS) Rats Reveals that Vitamin D Receptor (VDR) Regulates Crystallin Zeta (CryZ) Gene Expression through DNA Methylation. Hongwei Wang¹, Baisheng Fu¹, Jinhua wang¹, David Bushinsky², Murray Favus¹. ¹University of Chicago, Chicago, USA, ²University of Rochester, USA

Hypercalciuria is an important contributing factor in the formation of calcium oxalate kidney stones in idiopathic hypercalciuria (IH). Genetic Hypercalciuric Stone-Forming (GHS) rats are an excellent model for studies of human IH, as both form calcium-containing nephrolithiasis and have hypercalciuria and normal serum calcium. In GHS rats, hypercalciuria arises from increased intestinal Ca absorption and bone resorption, and decreased renal tubule Ca reabsorption due to elevated VDR in Ca-transporting tissues. In the present study, we investigated the role epigenetic regulation of renal Ca transport in the hypercalciuria of GHS rats. Genome wide DNA methylation array and gene microarray performed on kidneys from GHS and SD rats identified 132 gene promoter regions with hyper- or hypo- methylation in GHS rats and about 600 genes that are either enhanced or decreased. After combining the two arrays, five genes were hyper- or hypo-methylated in the GHS rats with either lower or higher gene expression respectively. In proximal and distal tubules, BSC1 transport function requires stabilization by CryZ. Loss of CryZ interrupts BSC1 mediated transport and alters pH-induced changes in ion transport including Ca. ? In GHS rats, CryZ expression is lower and the promoter region is hypermethylated. In vitro and in vivo 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃) downregulated CryZ gene expression through binding to the same specific promoter regions. Immunocytochemistry

staining performed show VDR is mainly located the proximal and distal tubules with higher expression in GHS rats. CryZ is extensively expressed in cortex, medulla and medullary papillae. Conclusion: VDR suppresses CryZ gene expression through specific sites of hyper-methylation in GHS rat kidney. Loss of CryZ may destabilize the BSC1 transporter and thereby contribute to the hypercalciuria

Increased Sost Expression in Hyp-mouse Bone: A Primary Factor Underlying Abnormal Mineralization and Osteomalacia. Baozhi Yuan¹, Stephen Bowman¹, Ying Liu², Robert Blank¹, Min Liu³, Hua Zhu Ke³, Jian Feng², Marc Drezner¹. ¹University of Wisconsin, USA, ²Texas A&M Health Science Center, USA, ³Amgen Inc., USA

A loss of function *PHEX* mutation in patients with X-linked hypophosphatemia (XLH) and in *hyp*-mice underlies the disease phenotype. Thus, targeted *PheX* deletion in osteocytes (*DMPI-Cre-PheX^{Alox/ly}*-mice) results in the *HYP* biochemical phenotype. However, Table 1 shows that *DMPI-Cre-PheX^{Alox/ly}*-mice not only manifest a mild osteomalacia compared to *hyp*-mice, but upon Pi loading restore normal bone histology, while osteomalacia persists in mutant mice. The disparate mineralization suggests osteomalacia in *hyp*-mice is due to a *PHEX* dependent variable, other than hypophosphatemia. Subsequent studies revealed bone *Sost* mRNA is increased in *hyp*-mice compared to wild type mice (11.9 ± 4.6 vs 1.1 ± 0.2 relative expression; $p<0.001$), but not in *DMPI-Cre-PheX^{Alox/ly}*-mice (1.1 ± 0.9). To determine if the suppressive effects of *Sost* mRNA/Sclerostin on mineralization contribute to the bone phenotype in *hyp*-mice, we crossed mutant and *Sost* knockout mice (*Sost^{-/-}*). The offspring *hyp^{Sost^{-/-}}*-mice had decreased serum Pi (4.61 ± 0.67 vs 10.3 ± 1.3 mg/dl; $p<0.01$) like *hyp*-mice (5.18 ± 0.14 mg/dl). The decrement is due to serum FGF23 in *hyp*- (1637 ± 781 pg/ml) and *hyp^{Sost^{-/-}}*-mice (1317 ± 522 pg/ml), which is significantly increased ($p<0.01$) above that in wild type mice (81 ± 21 pg/ml). Subsequently, we examined the effects of diminished *Sost* mRNA on bone in mice treated with a high Pi diet to eliminate any effects of hypophosphatemia. Studies in Table 2 indicate that bone from *hyp^{Sost^{-/-}}*-mice displays increased ($p<0.05$) cortical bone volume (BV/TV), but the increment fails to normalize this variable. However, the bone mineral apposition rate (MAR) increases ($p<0.01$) to a normal level. In accord, bone sections from *hyp^{Sost^{-/-}}*-mice have reduced ($p<0.01$) osteoid volume (OV), but the unmineralized matrix remains greater ($p<0.01$) than in wild type mice, reflecting inordinate stimulation of matrix formation compared to MAR. Our data demonstrate that decreased *Sost* expression normalizes the bone MAR in *hyp*-mice. However, while a reduction of *Sost* mRNA to normal in *DMPI-Cre-PheX^{Alox/ly}*-mice increases matrix formation commensurately with the MAR, rescuing the bone phenotype, an inordinate decreased *Sost* expression in *hyp^{Sost^{-/-}}*-mice excessively enhances matrix formation, resulting in increased osteoid. These observations indicate that osteomalacia in *hyp*-mice results from the cumulative effects of increased *Sost* expression and hypophosphatemia.

The Effect of Antenatal Vitamin D Supplementation on Early Neonatal Calcium Homeostasis. Jennifer Harrington¹, Abdullah Al Mahmud², Rubhana Raqib², Abdullah Baqui³, Daniel Roth¹. ¹The Hospital for Sick Children, Department of Pediatrics, University of Toronto, Canada, ²ICDDR B, Bangladesh, ³The John Hopkins Bloomberg School of Public Health, USA

Antenatal vitamin D supplementation may modulate fetal and neonatal calcium homeostasis. However, the effects of high-dose maternal vitamin D supplementation on early neonatal calcium handling are not well-described. A randomized, double-blinded, placebo-controlled prenatal vitamin D trial in Bangladesh provided an opportunity to study the relationship between antenatal vitamin D status and fetal-neonatal calcium homeostasis.

Objective: In this sub-analysis we aimed to determine the effect of antenatal 3rd-trimester high-dose vitamin D supplementation on early neonatal calcium handling.

Methods: 160 women from Dhaka, Bangladesh were randomized to receive either a weekly dose of 35,000IU of oral vitamin D₃ or placebo from 26 weeks gestation. Blood and urine at time of delivery, cord blood and infant blood and urine from day 3 and 5 of life were collected. For safety monitoring, infants with calcium levels

<1.9mmol/L or >2.82mmol/L or urine calcium:creatinine ratios >2mmol/mmol had further clinical assessment, blood work and renal ultrasound.

Results: Analyses included 132 cord and maternal delivery specimen pairs as well as 74 infants. Vitamin D supplementation significantly increased cord 25(OH)D versus placebo (102.8(±28.6) vs 39.0(±18.7) nmol/L, $p<0.0001$). Maternal and cord 25(OH)D levels strongly correlated ($r=0.87$, $p<0.001$). Total serum calcium was higher in cord blood with supplementation (2.7(±0.1) vs 2.6(±0.2) mmol/L, $p=0.04$). Although hypocalcemia was not observed in either group, the infants whose mothers received vitamin D supplementation had a significant attenuation in the calcium nadir at day 3 (change in calcium from cord to day 3 -0.10(±0.17) vs -0.22(±0.18) mmol/L). Significant associations with change in calcium at day 3 included higher cord 25(OH)D ($r=0.4$, $p=0.01$) and lower cord calcium ($r=-0.57$, $p<0.001$). On multiple regression, the significant predictor for day 3 calcium level was cord 25(OH)D ($p=0.01$, $R^2=0.15$).

6 infants in both the supplemented and placebo group had evidence of transient asymptomatic hypercalcemia which spontaneously resolved, with no ultrasound evidence of nephrocalcinosis.

Conclusions: Antenatal high-dose vitamin D supplementation attenuated the early postnatal calcium nadir. While reassuring that supplementation did not result in higher rates of hypercalcemia, the clinical benefits of the observed effects on neonatal calcium handling need further exploration.

FR0133

Vitamin D2 and D3 Replacement Effectiveness in Patients with Chronic Liver Disease. Dorota Krajewski, Julia (Julianna) Barsony*. Georgetown University Hospital, USA

Patients with chronic liver disease (CLD) have high incidence of vitamin D deficiency and osteoporotic fractures, but vitamin D treatment guidelines have not been established in this population. We have collected data from medical records to determine the D2 and D3 doses required to normalize serum 25OHD levels (above 32 ng/ml) in vitamin D deficient patients with chronic liver disease. We selected CLD patients responding to D2 (CLD-D2, n=53) or D3 treatments (CLD-D3, n=45) and controls (C) without liver disease responding to D2 (C-D2, n=53) or D3 (C-D3, n=45) treatments. To select controls, CLD patients were matched for age, race, gender, body mass index (BMI) and baseline serum 25OHD levels. Exclusion criteria included renal insufficiency, pregnancy, hypercalcemia, recent (past year) or concurrent use of medications known to alter calcium metabolism (i.e. steroids, calcitriol, anti-seizure medications), and history of organ transplant or bariatric surgery. Liver disease severity, defined by MELD scores and serum albumin levels, were comparable between the D2- and D3-treated groups. Subgroup analysis included liver cirrhosis (LC), primary biliary cirrhosis (PBC) and non-alcoholic fatty liver disease (FLD). In responders, treatment effectiveness was characterized by calculating the daily D2 and D3 doses required to raise serum 25OHD concentration by 1 ng/ml. The results showed that effective D2 and D3 doses were both doubled in CLD compared to C ($p<0.001$). In patients with LC, effective doses correlated positively with MELD scores (D3: $r=0.705$, $p<0.005$; D2: $r=0.476$, $p<0.05$) and negatively with serum albumin (D3: $r=0.468$, $p<0.05$; D2: $r=0.464$, $p<0.05$). Effective doses of D2 were higher than D3 doses ($p<0.01$) in every group. Obesity (BMI>35) in controls increased the effective D3 doses by 42±15% ($p<0.05$) and D2 by 33±15% (NS), but FLD increased it even more: effective D3 doses increased by 135±43% and D2 doses by 83±17%. Many CLD patients (LC, n=33; PBC, n=6; FLD, n=60) were nonresponsive to weekly 50,000 IU D2 given for more than 3 months. Our findings demonstrate that patients with chronic liver disease require significantly higher vitamin D replacement doses than controls, proportionally to the severity of the liver disease, and suggest that CLD patients should be preferentially treated with D3 rather than D2.

FR0136

Familial Hypocalcemic Hypercalcemia Type 2 (FHH2) Is Caused by a Mutation of G Protein Alpha 11 ($G\alpha_{11}$). Fadil Hannan^{1*}, M. Andrew Nesbit¹, Sarah Howles¹, Nigel Rust², Maurine Hobbs³, Hunter Heath⁴, Rajesh Thakker¹. ¹Nuffield Department of Clinical Medicine, University of Oxford, United Kingdom, ²Sir William Dunn School of Pathology, University of Oxford, United Kingdom, ³Core Research Facilities, University of Utah, USA, ⁴Indiana University School of Medicine, USA

The calcium-sensing receptor (CaSR), which has a central role in extracellular calcium homeostasis, is a G protein-coupled receptor that acts via the G proteins, G_q and G_{11} , that effect intracellular signalling and alterations in intracellular calcium ($[Ca^{2+}]_i$). CaSR mutations, resulting in a loss-of-function, are associated with familial hypocalcemic hypercalcemia type 1 (FHH1). However, such mutations cause FHH in ~65% of patients and two other loci for FHH have been reported on chromosome 19p and 19q13.3, and these are termed FHH2 and FHH3, respectively. The gene encoding the alpha subunit of G_{11} ($G\alpha_{11}$), referred to as *GNA11*, is located on 19p and we hypothesized that a mutation in $G\alpha_{11}$, which is abundantly expressed in the

parathyroids may cause FHH2. DNA sequence analysis of the 7 exons and 12 intron-exon boundaries of *GNA11* in a patient from the FHH2 kindred revealed a heterozygous 3-bp (CAT) deletion that led to an in-frame deletion of Ile199 (199delIle). This mutation was associated with a gain of an *XmnI* restriction enzyme site, which was used to demonstrate that the 199delIle mutation co-segregated with FHH in the kindred (10 affected and 11 unaffected family members) and not to be present in 120 alleles from 60 unrelated normocalcemic individuals, thereby indicating that it was not a common polymorphism. To investigate the functional consequences of this mutation, wild-type and mutant 199delIle $G\alpha_{11}$ proteins were expressed by transient transfection in HEK293 cells stably transfected with CaSR and assessed by measuring their $[Ca^{2+}]_i$ responses to changes in extracellular calcium ($[Ca^{2+}]_o$). The mutant 199delIle $G\alpha_{11}$ protein resulted in a rightward shift of the $[Ca^{2+}]_i$ dose-response curve with significantly higher $EC_{50} = 2.70mM$ (95% confidence interval (CI) = 2.64-2.77mM) compared to wild-type $G\alpha_{11}$ $EC_{50} = 2.33mM$ (95% CI = 2.29-2.38mM) ($p<0.0001$), consistent with this being a loss-of-function mutation. An examination of the crystal structure of $G\alpha_q$, which has 90% amino acid identity to $G\alpha_{11}$, revealed that Ile199 is located within a 13 amino acid peptide that links two functionally important domains that undergo conformational changes during activation of the $G\alpha_{11}$ protein. Thus, our study has identified the genetic abnormality causing FHH2, and this will further increase our understanding of extracellular calcium homeostasis, and the structure-function relationships of G protein alpha subunits.

Modifications of Bone Material Properties Early Detected after One Year of Menopause in Women. Delphine Farlay^{1*}, Yohann Bala², Susan Bare³, Joan Lappe⁴, Robert Recker⁴, Georges Boivin⁵. ¹INSERM, UMR1033; Université De Lyon, France, ²University of Melbourne, Dept. of Medicine, Australia, ³Osteoporosis Research Center, Creighton University, USA, ⁴Creighton University Osteoporosis Research Center, USA, ⁵INSERM, UMR1033 ; Université De Lyon, France

At menopause, bone remodelling increases and becomes unbalanced leading to bone loss and fragility. However, whether modifications in bone tissue material properties (mineral and organic components) occur across menopause is still unclear. Twenty pairs of iliac bone biopsies, taken from healthy women before and after menopause [12 months after the final menses (mean interval between the two biopsies 60 ± 24 months)], were used. Impaired micromechanical properties have been previously observed at the tissue level (microhardness) in those bone biopsies. The present study thus aims to assess sub-tissue bone mineral and organic matrix composition. Sections two μm -thick were cut and analyzed by infrared microspectroscopy with a Perkin-Elmer microscope in transmission mode. Ten areas of bone matrix in each cortex (150 μm x150 μm) and 20 areas (150x50 μm) in trabecular bone were scanned, in order to observe a large area of the bone biopsy sections. After curve-fitting of infrared spectra, 5 variables were measured: mineral maturity, crystallinity index, mineralization index, carbonation and collagen maturity. Statistical analysis was performed using non parametric Wilcoxon tests. Among the 5 variables, only the mineralization index was significantly decreased after menopause in paired biopsies in trabecular bone ($p=0.0239$), and tended to decrease in cortical bone ($p=0.09$). No significant changes were observed in crystallinity index, mineral maturity, carbonation or collagen maturity, either in trabecular or in cortical bone while the activation frequency had almost doubled. This suggests that, early after menopause, trabecular bone is first affected by modification in material properties, especially by a decrease in the proportionate amounts of mineral and organic components. However, this does not yet affect the bone crystal characteristics (as crystal size, perfection, mineral and collagen maturities). The impact of the duration of menopause on the bone mineral characteristics will be further evaluated on bone biopsies taken after 14 years.

Aortic Calcification, Arterial Stiffness, and Vascular Wnt mRNAs Are Increased In Atherosclerotic LDLR-/- Mice Lacking Smooth Muscle Cell LRP6. Jian Su Shao^{1*}, Abraham Behrmann², Karen Krehma², Su-Li Cheng¹, Linda Halstead³, Attila Kovacs², Bart Williams⁴, Dwight Towler³. ¹Washington University in St. Louis School of Medicine, USA, ²Washington University, USA, ³Washington University in St. Louis, USA, ⁴Van Andel Research Institute, USA

When male LDLR-null mice are fed high fat diabetogenic diets (HFD), osteogenic transcription factors of the Runx, Msx and Sox gene families are upregulated in the aorta with progressive calcification. Msx2 enhances mesenchymal cell mineralization in part via paracrine Wnt signals, ligands for LRP5 and LRP6. Previous studies by others indicate that global LRP5 deficiency reduces valve calcification. We wished to understand the vascular smooth muscle cell (VSMC)-autonomous roles of the related Wnt receptor, LRP6, in diabetic arteriosclerosis. Therefore, we generated and characterized SM22-Cre:LRP6(fl/fl);LDLR-/- (LRP6-CKO) mice as a model for

study, using the SM22 promoter to direct Cre expression in VSMCs. LRP6-CKO and LRP6(fl/fl);LDLR-/- control mice developed equivalent obesity (34% of body weight as fat following HFD for 3 months). No differences in bone or lean body mass – or in fasting hyperglycemia, hypertriglyceridemia, and hypercholesterolemia – were observed. However, LRP6-CKO mice exhibited increased aortic calcium accumulation (2.15 +/-0.15 ug calcium / mg aortic wet weight vs. 1.50 +/-0.12 ug/mg; p = 0.002, n =14-15 per group). Moreover, by histomorphometry, aortic valve leaflet area (1.39-fold; p = 0.03) and wall thickness (48.4 +/- 3.0 vs 41.3+/-0.4 microns; p = 0.04) were increased in LRP6-CKO mice vs. controls. Echocardiography demonstrated increased aortic pulse wave velocity in LRP6-CKO (3.40+/- 0.3 m/s) vs. controls (2.96 +/- 0.14 m/s; p = 0.035, n = 5 per genotype) , confirming the predicted increase in vascular stiffness arising from calcification and wall thickening. To begin to address mechanism, we evaluated the aortic gene expression. LRP6-CKO mice exhibited reduced aortic LRP6, with concomitant reductions in markers of VSMC differentiation (SM22, Myh11,myocardin). Aortic Sox2, a signature of proliferating multipotent mesenchymal progenitors, was increased 18-fold, but no changes were noted in aortic LRP5, Runx2, Sox9, Sox5, Sox6 or Msx2. However, aortic Wnt7b (92-fold), Wnt4 (44-fold), Wnt10a (10-fold), and Wnt3a (170-fold; all p < 0.002) were markedly and selectively upregulated in LRP6-CKO mice, mimicking the expression profile with aortic calcification arising from Mx2 transgenesis. Thus, VSMC LRP6 modulates aortic calcification in LDLR-/- mice, serving to restrain arteriosclerosis with HFD-induced disease. Secondary increases in vascular Wnt ligands with VSMC LRP6 deficiency may drive procalcific responses, presumably via LRP5.

Calcium Supplementation and Cardiovascular Events. Vaishali Patel¹, James Vacek², Rajib Bhattacharya³. ¹The University of Kansas Medical Center, USA, ²KUMC, USA, ³KU Medical Center, USA

Purpose Recent reports have suggested an association between calcium supplementation and increased rate of cardiovascular events. The goal of this retrospective study was to examine the association of calcium supplements with cardiovascular disease states and survival in a large cardiovascular practice.

Methods Data was collected for 5.7 years (1/1/2004 to 10/8/2009) from the electronic medical record of Mid America Cardiology, a large cardiovascular practice at the University of Kansas Medical Center. Patients > age 50 were included in our analysis. Diagnoses were derived from the patient problem list in the patients' electronic medical record based on International Classification of Diseases, 9th Revision (ICD-9) codes. Death was determined from the Social Security Death Index.

Results The data set included 8060 subjects categorized as calcium supplement user vs. non-users. On multivariate logistic regression analysis, calcium supplementation was not an independent predictor of all-cause death. When adjusted for clinical variables and medications, calcium supplementation was not independently associated with the diagnosis of coronary artery disease. There were no significant survival differences for patients on calcium supplements vs. those who were not by product-limit survival estimate. Hazard function analysis indicated that calcium supplementation was not an independent predictor of survival when adjusted for clinical variables. (p=NS).

Conclusion Our data showed no association between calcium supplementation and coronary artery disease as well as overall survival in a large retrospective cohort of patients greater than 50 with high rates of significant cardiovascular risk factors.

Tissue-nonspecific Alkaline Phosphatase Upregulation in Vascular Smooth Muscle Cells Is Sufficient to Cause Medial Vascular Calcification. Campbell Sheen*¹, Wei Wang², Manisha Yadav³, Jose Luis Millan⁴. ¹Sanford Burnham Medical Research Institute, USA, ²Sanford Burnham Medical Research Institute, USA, ³Burnham Institute for Medical Research, USA, ⁴Sanford-Burnham Medical Research Institute, USA

Medial vascular calcification (MVC) is a pathological condition common to variety of diseases, including chronic kidney disease, diabetes, obesity, generalised arterial calcification of infancy, arterial calcification due to deficiency of CD73, Kawasaki Disease and Keutel Syndrome. While the genetic and physiological causes of MVC differ between these diseases, several of them share the common feature of tissue-nonspecific alkaline phosphatase (TNAP) upregulation. To investigate whether TNAP expression is sufficient to cause MVC, we developed a conditional knockin mouse model that overexpresses human TNAP under the control of the vascular smooth muscle cell specific *Tagln* promoter. As early as seven days of age, male mice showed strong alkaline phosphatase activity in the aorta and, by 14 days, distinct aortic calcification was visible by X-ray. Further X-rays and micro-computed tomography at 30 days showed extensive calcification of the aorta and renal, carotid and coronary arteries. Heart weight measurements showed cardiac hypertrophy at 14 days that became progressively worse at 30 days. Survival curves showed that most male mice died between 25 and 60 days of age. Serum alkaline phosphatase activity was approximately five and 22 times normal at days 14 and 30, respectively. No change in serum phosphate was detected at either age, and while serum calcium was normal at 14 days, it was slightly lower than controls at 30 days of age. No difference in serum pyrophosphate levels were detected at either age, implying that it is the local rather than systemic levels of pyrophosphate that are important for inhibition of calcification. Gene expression analysis showed upregulation of classical markers of MVC (*Bmp2* and *Opn*) and osteoblast markers, (*Runx2*, *Alpl*, *Phospho1*, *Pit-1*, *Enpp1*, *Ank* and *Col1a1*) and a decrease in expression of the smooth muscle marker *Tagln*. This data indicates that altering the local Pi/PPi balance is sufficient to initiate the transdifferentiation of smooth muscle cells, a hallmark of MVC. The expression levels of a variety of genes related to phosphate and pyrophosphate metabolism and/or transport were also altered. Overall, the data from this mouse model indicate that TNAP overexpression is sufficient to cause calcification and suggest that TNAP may be a critical mediator in a variety of ectopic calcification disorders.

Genotype-Phenotype Correlations and Pharmacogenetic Studies in 140 Swedish Families with Osteogenesis Imperfecta. Katarina Lindahl*¹, Carl-Johan Rubin², Eva Åström³, Barbro Malmgren⁴, Andreas Kindmark⁵, Osten Ljunggren⁵. ¹Endocrinology, Sweden, ²Uppsala University, Sweden, ³Department of Woman & Child Health, Division of Pediatric Neurology, Karolinska Institutet, Sweden, ⁴Karolinska Institutet, Department of Dental Medicine, Division of Pediatric Dentistry, POB 4064 SE-14104, Sweden, ⁵Uppsala University Hospital, Sweden

Objective: Osteogenesis imperfecta (OI) is a rare heterogeneous disease of connective tissue leading to varying degrees of bone fragility. The worst form (type II) is peri-natal lethal whereas the mildest form (type I) is compatible with a normal life span and may even be diagnosed as osteoporosis in adulthood. Over 1000 mutations causing OI have been described in the genes encoding collagen type I. As *COL1A1* and *COL1A2* are large genes, there are still many codon positions where no mutations have been reported and only a fraction of theoretically possible glycine substitutions have been described. In this study the spectrum of mutations causing OI in Sweden will be investigated and genotype-phenotype correlations as well as pharmacogenetics will be studied.

Method: All patients with OI cared for at the Uppsala Osteoporosis Unit (Uppsala University Hospital) or Astrid Lindgren Childrens Hospital (Karolinska Institutet, Stockholm) were offered to enter the study. 140 families with OI accepted participation; 77 type I, 34 type IV, 20 type III, 5 without previous diagnosis and 4 with unclear OI type. Extensive clinical data is currently being collected on enrolled patients.

Exons and flanking intron sequences of *COL1A1* and *COL1A2* are being sequenced in these families.

Results: So far 133/140 families have been completely analyzed and in 27 no mutation was found. A total of 120 mutations have been detected, of which 104 are of a typical OI-type. In *COL1A1* 73 mutations were found and in *COL1A2* 31 mutations were noted. In 7 families 2 mutations were present, but only one of these was a typical OI-causing mutation. To date 16 amino acid changing mutations that were not of a typical OI-causing type have been noted, and the majority of these have an unclear significance.

Calculations of delta BMD Z-score response to bisphosphonate treatment did not show a difference in treatment response between groups with different types of OI or between patients with OI type I due to a qualitative vs. quantitative collagen defect.

Conclusion: The spectrum of mutations causing OI described in this Swedish cohort is of the expected type, with the exception of the amino acid changing mutations. It is notable that in seven patients two separate mutations were identified.

Preliminary data does not support a mutation dependent response to bisphosphonate treatment.

FR0157

Osteoblast-targeted Expression of an Activating Mutation of Gsa in Mice Mimics van Buchem's Disease/Sclerosteosis rather than Fibrous Dysplasia (FD), and does not alter the Hematopoietic Microenvironment/Niche. Stefano Michienzi*¹, Isabella Saggio², Stefania Cerosimo¹, Cristina Remoli¹, Rossella Costa¹, Graham R Davis³, Alberto Di Consiglio¹, Emanuela Spica¹, Benedetto Sacchetti¹, Ana Cumano⁴, Pamela Gehron Robey⁵, Kenn Holmbeck⁶, Alan Boyde³, Mara Riminucci¹, Paolo Bianco⁷. ¹University La Sapienza, Italy, ²Sapienza University of Rome, Italy, ³Queen Mary University of London, United Kingdom, ⁴Pasteur Institute, France, ⁵NIH/NIDCR, USA, ⁶NIDCR, USA, ⁷Universita La Sapienza, Italy

To understand the role of Gsα mutations in FD, we generated lines of transgenic mice expressing GsαR201C constitutively or targeted to specific cell types. Osteoblast-targeted expression of GsαR201C (2.3COL1A1-GsαR201C) resulted in an overt high bone mass phenotype, without marrow changes and distinct from FD. Comparison of the phenotype of COL1A1-GsαR201C mice (excess Gsα signaling driven by overactivity of Gsα) and COL1A1-caPPR mice (excess Gsα signaling driven by constitutive activity of PTHR1) demonstrated that COL1A1-GsαR201C mice, but not COL1A1-caPPR, developed a deforming cortical bone excess (in addition to excess trabecular bone found in both models), suggesting Gsα-mediated effects in cortical bone not dependent on PTH. Excessive cortical bone developed by expansion of periosteal/cortical osteoblasts (Ox+/ALP+) between 2wk and 3mo of age; bone remodeling was increased, but resorption was not, relative to bone surfaces. Osteoprogenitors did not express the transgene, which was turned on in culture concurrent with mineralization and osteoblastic markers. Compared to WT, SOST expression in mature osteoblastic cells was potentially downregulated in COL1A1-GsαR201C mice, resulting in markedly enhanced Wnt signaling (increased Lef1/Axin 2 mRNAs), explaining the high bone mass phenotype. Thus, mice with osteoblast-targeted GsαR201C phenocopy human diseases caused by loss of function SOST mutations (van Buchem's disease/Sclerosteosis) rather than FD. Red and yellow marrow (femur vs. tail vertebrae, respectively) were normally distributed in COL1A1-GsαR201C mice. After 6 mo, remodeling of the massive cortices established intracortical marrow spaces populated by red or yellow marrow at respective sites. No marrow fibrosis was noted and adipocyte development was normal. Although Gsα signaling in osteoblasts is thought to affect the HSC niche and lymphopoiesis, the HSC fraction (Lin-/Sca-1+/c-kit+, LSK) was unchanged in frequency and absolute numbers. LSK/CD34- cells were also similar to WT. Numbers of CLP (Lin-/IL-7Ra+/Sca-1+/-/c-kit+/-), Pro-B (CD19+/CD43+/IgM-), Pre-B (CD19+/IgM-/CD43-) and B (CD19+/IgM+) cells were not significantly different from WT. We conclude that activating mutations of Gsα in osteoblasts do not impact on hematopoiesis, consistent with lack of expression of the transgene in bone marrow osteoprogenitors, and with preservation of a normal marrow in spite of an excess of osteoblasts and bone.

FR0160

The Prostaglandin Transporter Encoding Gene *SLCO2A1* Is Mutated in Primary Hypertrophic Osteoarthropathy and Isolated Digital Clubbing. Jirko Kühnisch*¹, Wenke Seifert², Beyhan Tüysüz Tüysüz³, Christof Specker⁴, Ad Brouwers⁵, Denise Horn¹. ¹Institute of Medical & Human Genetics, Charité - University Medicine of Berlin, Germany, ²Institute for Vegetative Anatomy, Charité - University Medicine of Berlin, Germany, ³Cerrahpasa Medical Faculty, Department of Pediatric Genetics, Istanbul University, Turkey, ⁴Dept. of Rheumatology & Clinical Immunology, Centre for Internal Medicine, Kliniken Essen Süd, Germany, ⁵Department of Internal Medicine, Gelderse Vallei Hospital, Ede, Netherlands

Prostaglandin metabolism is a critical determinant of bone and cartilage function. Although the functional interaction of prostaglandin E2 (PGE2) within these tissues has been well explored its association with human monogenic disorders is still incomplete. So far, homozygous mutations within the *HPGD* gene encoding the PGE2 catabolizing enzyme 15-hydroxy-prostaglandin dehydrogenase have been identified causing primary hypertrophic osteoarthropathy (PHO). In this study we performed a mutational screen of PHO patients and individuals with isolated digital clubbing. We systematically analyzed genes encoding key proteins of the entire PGE2 pathway namely: *PTGS1*, *PTGS2*, *PTGES*, *PTGES2*, *PTGES3*, *PTGER1*, *PTGER2*, *PTGER3*, *PTGER4*, *SLCO2A1*, *SLCO3A1*, *SLCO4A1*, *PTGRI*, and *PTGR2*. We identified in three unrelated families mutations within the gene solute carrier organic anion transporter family 2A1 (*SLCO2A1*) (MIM ID *601460, chromosome 3q21). The *SLCO2A1* transcript comprises 14 exons and encodes for the 643 amino acid polytopic transmembrane protein prostaglandin transporter (PGT, *SLCO2A1*). PGT localizes to the plasma membrane and is required for internalization of extracellular

PGE2. Within the *SLCO2A1* gene we found a homozygous insertion c.830_831insT, resulting in a premature stopcodon at p.Phe276fsX18; a homozygous missense mutation c.1670T>C introducing an amino acid substitution p.Phe557Ser and a heterozygous nonsense mutation c.754C>T resulting in p.Arg252X. Homozygous mutations in PGT (Phe276fsX18 and Phe557Ser) were found to result in a PHO phenotype comprising clubbing of fingers and toes, periostosis, diaphyseal cortex expansion, swollen joints, hyperhidrosis, and seborrhic hyperplasia. In contrast, the heterozygous mutation p.Arg252X causes isolated digital clubbing, demonstrating a threshold effect by which absence of one *SLCO2A1* allele leads to isolated digital clubbing. Functionally, both stop mutations Phe276fsX18 and Arg252X result in an early translational stop which highly likely result in a loss-of-function of PGT. In summary, we identified mutations within the *SLCO2A1* gene as further molecular cause of isolated digital clubbing and PHO. Our findings suggest that apart from PGE2 degradation by 15-hydroxy-prostaglandin dehydrogenase internalization of PGE2 at the plasma membrane is critical for normal bone, joint and skin function.

Bone Healing Enhancement through Inhibition of Sclerostin by Monoclonal Antibody in Rat Osteotomy Model. Pui Kit Suen^{*1}, Yixin HE², Dick Ho Kiu Chow¹, Le Huang¹, Zhong Liu¹, Chi Wai Man¹, Lizhen Zheng³, Tao Tang¹, Chaoyang Li⁴, Hua Zhu Ke⁴, Ge Zhang⁵, Ling Qin⁶. ¹The Chinese University of Hong Kong, Hong Kong, ²The Cuinese University of Hong Kong, Hong Kong, ³Prince of Wales Hospital, Hong Kong, ⁴Amgen Inc., USA, ⁵Price of Wales Hospital, Hong Kong, ⁶Chinese University of Hong Kong, Hong Kong

Introduction: Sclerostin is a negative regulator of bone formation. Previous studies demonstrated treatment with a sclerostin monoclonal antibody (Scl-Ab) significantly increased bone formation, bone mass and strength in rat closed fracture model. The objective of this study is to investigate the effects of systemic administration of Scl-Ab on fracture repair in rat femur open fracture, a more difficult-to-heal model.

Method: Ninety 6-month-old male SD rats were randomly divided into Scl-Ab group and vehicle group after a transverse osteotomy performed at the mid-shaft of right femur. One day post-surgery, rats were treated with Scl-Ab III (s.c. injection, 25 mg/kg, 2 times per week) or vehicle for 3, 6 or 9 weeks. Femora were collected and subjected to the following analyses: micro-CT, micro-CT-based angiography, four-point mechanical testing and histology. Two-way ANOVA with Bonferroni posttest was used to analyze the data.

Results: Scl-Ab treatment groups had significantly higher callus volume fraction and bone mineral density (BMD) in all 3, 6 and 9 weeks post-fracture compared to their vehicle groups (P<0.01; Figure 1). Micro-CT based angiography demonstrated increased callus vascularization in Scl-Ab group at week 3 and at week 6 (Figure 2). Hematoxylin and eosin (H&E) staining and safranin O staining showed more bony tissue in calluses at week 3 in Scl-Ab group. Four-point bending test showed significantly higher ultimate load in Scl-Ab group than vehicle group at weeks 6 (+98%, P<0.01) and 9 (+45%, P<0.05) post fracture. In addition, ultimate load at week 6 of Scl-Ab group was at the similar level as seen at week 9 of the vehicle group, indicating the increased healing by Scl-Ab in this model. Stiffness and energy to failure were also tended higher in Scl-Ab group (Figure 3).

Conclusions: This study demonstrated that Scl-Ab enhanced bone healing in rat osteotomy model, with increased bone formation, bone mass and bone strength. We observed a trend of increasing callus vascularization in the Scl-Ab group at week 3 and at week 6, based on small sample size, implying Scl-Ab induced coupling of osteogenesis and angiogenesis. Collectively, our results supported that the systemic administration of Scl-Ab enhanced open fracture healing.

Duffy Antigen Receptor for Chemokines (Darc) Regulates Chondrogenesis and Bone Formation During Fracture Repair. Charles Rundle*, Subburaman Mohan, Bouchra Edderkaoui, Jerry L. Pettis Memorial VA Medical Center, USA

There is now considerable experimental data to suggest that hematopoietic bone marrow cells (HBMCs) derived from both local and circulating sources participate in the healing of bone fractures. Recently, chemokine and chemokine receptor functions in the recruitment of HBMCs to the fracture site have received considerable attention. The Duffy antigen receptor for chemokines (*Darc*) is a non-classical chemokine receptor that does not signal but rather acts as a scavenger of chemokines. Based on the findings that *Darc* is expressed by inflammatory and endothelial cells and our findings that *Darc* is a negative regulator of peak bone density in mice, we hypothesized that the disruption of *Darc* would increase the bioavailability of chemokines to attract HBMCs and promote fracture healing. To test this hypothesis, we compared fracture healing in mice with a targeted disruption of *Darc* with the corresponding wild-type (WT) littermate control mice. Micro-CT examination of the fracture calluses revealed significant increases in the cross-sectional area (43%, $P=0.04$, $n=5$) and cancellous bone (30%, $P=0.03$) at the fracture site in *Darc*-knockout (KO) mice as compared to WT mice at 21 days post fracture. We then performed histomorphometric analysis of the fracture callus cartilage in *Darc*-KO mice, and determined that the area of callus cartilage at 7 days post-fracture was significantly augmented (50%, $n=5$, $P=0.02$, $n=5$) in *Darc*-KO mice as compared to WT mice. However, the ratio of cartilage area to total callus area was not different between the two strains of mice. These data suggest an early cartilage formation and more rapid conversion of cartilage to bone in the *Darc*-KO mice compared to WT mice. We determined that mRNA levels of collagen X were increased by 50% in the fracture calluses of *Darc*-KO mice as compared to WT mice at 7 days post-fracture ($P=0.05$, $n=5-6$). Taken together, these observations suggest that *Darc* gene deficiency promoted chondrocyte differentiation and cartilage maturation in the fracture callus, which subsequently resulted in increased bone formation. Based on the present findings, we conclude that the disruption of *Darc* gene expression increased the bioavailability of chemokines that then recruited HBMCs to the fracture site; these HBMCs promoted the early maturation of callus cartilage and its remodeling to bony callus.

Hyperactive WNT Signaling Causes Preaxial Polydactyly in *Sclerostin Sostdc1* Double Knockouts. Nicole Collette*¹, Cristal Yee², Deepa Muruges¹, Richard Harland³, Gabriela Loots⁴. ¹Lawrence Livermore National Laboratory, USA, ²University of California, Merced, USA, ³University of California, Berkeley, USA, ⁴Lawrence Livermore National Laboratory, UC Merced, USA

Sclerostin (*Sost*) is secreted by osteocytes and negatively regulates bone formation. This gene is linked to two rare skeletal dysplasias characterized by generalized increased bone density, sclerosteosis and van Buchem disease. *Sostdc1* (aka *Sostl*, *USAG-1*, *Wise*, *ectodin*) is a paralog of *Sost*, and loss of *Sostdc1* has been shown to cause supernumerary incisor development and fused molars. Both proteins function as extracellular antagonists of both BMP and WNT signaling *in vitro* and *in vivo*. However, these tissues in which gene expression was first characterized are not the sole locations of *Sost* and *Sostdc1* activity. We have shown that human *SOST* overexpression in mice causes dosage-dependent loss of distal posterior skeletal elements, resulting from altered anterior-posterior patterning of the limb bud and preferential antagonism of *Lrp5* WNT co-receptor. *Sostdc1* was shown by others to similarly affect FGF and SHH signaling in the developing tooth bud, and it binds to *Lrp4* receptors to inhibit WNT signaling, suggesting that *Sost* and *Sostdc1* may antagonize similar pathways *in vivo*. *Sost* and *Sostdc1* are expressed in complementary yet non-overlapping domains; their combined expression covers most of the ectoderm and mesenchyme of the developing limb bud prior to cartilage condensation. *Sost* knockout mice occasionally display limb defects consistent with the frequency of soft-tissue syndactyly, nail dysplasia, and radial deviation that occurs in sclerosteosis patients, while *Sostdc1* knockouts show no limb defects. Here we show that *Sost*; *Sostdc1* double mutant mice exhibit preaxial polydactyly, a common limb-associated birth defect characterized by extra digit(s) in the anterior autopod, which is often caused by ectopic sonic hedgehog (*Shh*) expression. Through a combination of skeletal stains, LacZ reporter analysis, and *in situ* hybridization, we show that *Sost* and *Sostdc1* function upstream of *Shh* to restrict *Shh* expression in the posterior limb. We find perturbed BMP signaling in the patterning limb as well. The *Sost* and *Sostdc1* null alleles release *Lrp4/5/6* receptor inhibition in the ectoderm and mesenchyme, and hyperactive BMP and WNT signaling ectopically activate *Shh* in the anterior limb bud to transform the morphology of the first digit.

Novel Link Between CSF-1 and Lung Cancer Bone Metastasis. Sherry Abboud Werner*¹, Fermin Tio², Thomas Prihoda³, Diane Horn³, Jaclyn Hung³. ¹University of Texas Health Science Center at San Antonio, USA, ²South Texas Veterans Health Care System, USA, ³University of Texas Health Science Center, USA

CSF-1 is essential for osteoclastogenesis that, in turn, mediates osteolysis in metastatic tumors to bone. Patients with lung cancer show increased CSF-1 in serum and CSF-1 is a predictor of progression and poor survival. Adenocarcinomas metastasize rapidly and 60% of patients suffer from bone metastasis. Lung cancer stem cells sustain tumor growth and potentiate metastasis. Work in lung cancer metastasis has been hampered by the lack of animal models. The purpose of this study was to determine the role of CSF-1 in lung cancer bone metastasis and whether inhibition of CSF-1 ameliorates the disease. Human lung adenocarcinoma A549 cells were examined *in vitro* for CSF-1/CSF-1R. To establish a model of bone metastasis, A549-luc cells were injected intracardiac in SCID mice and a time course for onset and progression of metastasis was determined using x-ray, *in vivo* bioluminescent imaging and histomorphometry. To determine the effect of CSF-1 knockdown in A549 cells on bone metastasis, cells were stably transfected with a retroviral vector containing either short-hairpin CSF-1 (KD) or empty vector (CT). Mice injected with CT or KD cells were examined for incidence of tumor, tumor burden and tumor size. Results showed that A549 cells express CSF-1 and CSF-1R; CSF-1 also increased A549 proliferation and invasion, whereas soluble CSF-1R inhibited invasion. Mice injected with A549-luc cells showed osteolytic bone lesions in hindlimbs and spine after 3.5 wks, and lesions increased over 5 wks. Tumors recapitulated adenocarcinoma morphology, expressed CSF-1 and showed numerous osteoclasts along tumor/bone interface, trabecular and cortical bone loss. Analyses of KD cells showed decreased CSF-1 protein levels, reduced colony formation in agar assay and decreased fraction of stem-like cells. In mice injected with KD cells, the incidence of tumor metastasis was similar to controls, although fewer mice with KD cells had metastasis in both hindlimbs. KD tumors showed reduced CSF-1 expression, Ki-67+ cells and osteoclasts. Importantly, there was a low incidence of large tumors >0.1 cm in mice with KD cells compared to mice with CT cells (10% vs 62.5%). This study established for the first time a lung osteolytic bone metastasis model that mimics human disease and suggests that CSF-1 is a key determinant of cancer stem cell survival and tumor growth. Results may lead to novel strategies to inhibit CSF-1 in lung cancer and improve therapeutic management of bone metastasis.

Transgenic Overexpression of Ephrin B1 in Osteoblasts Promotes a Skeletal Anabolic Response to Mechanical Loading in Mice. Weirong Xing*¹, Chandrasekhar Kesavan², Shaohong Cheng³, Subburaman Mohan². ¹Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, ²Jerry L. Pettis Memorial VA Medical Center, USA, ³VA Loma Linda Health Care Systems, USA

Mutation of the ephrin B1 gene in humans caused craniofrontonasal syndrome while deletion of the ephrin B1 gene in mice resulted in perinatal lethality and skull defects. Our recent findings that mice with conditional knockout (KO) of ephrin B1 in type I collagen producing osteoblasts resulted in severe calvarial defects, decreased bone size and BMD suggested that locally produced ephrin B1 is an important determinant of bone formation. To test the hypothesis that ephrin B1 overexpression promotes acquisition of peak bone mass, we generated transgenic (Tg) mice overexpressing ephrin B1 in bone cells and evaluated the consequence of ephrin B1 overexpression on the skeletal phenotype. The expression of transgene was controlled by the rat collagen 1A1 promoter/chicken beta-actin/rabbit beta-globin chimeric intron. One of the Tg mouse lines has been confirmed to express 6-fold greater levels of full-length ephrin B1 protein in calvarial osteoblasts and bone marrow stromal cells. The functionality and specificity of overexpressed ephrin B1 was confirmed by rescue of a calvarial defect in ephrin B1 conditional KO mice by crossing ephrin B1 Tg with conditional KO lines. Neither body weight nor body length was significantly different in ephrin B1 Tg vs WT mice at 8 wks of age. Surprisingly, total body BMD as measured by PIXImus was not different in the Tg mice although vertebra BMD was increased by 20% in the Tg mice at 8 wks of age. Since mechanical strain increased the expression of ephrin B receptor 2 (EphB2) in bone cells, and ephrin B1 binding to EphB2 can induce bidirectional signaling, we next evaluated if overexpression of ephrin B1 influenced the skeletal anabolic response to mechanical loading (ML). The right tibiae of Tg and WT mice (10 wks of age (N=8/group)) were loaded at 9N, 2Hz for 36 cycles per day for 2 weeks, and the left tibiae of the same mice were used as unloaded controls. A ML-induced increase in both total volume (72% vs 52%, $P<0.05$) as well as relative cortical bone volume to total volume (11% vs 5%, $P<0.01$) were significantly greater in the Tg mice compared to WT mice. In conclusion, our findings that overexpression of ephrin B1 in bone cells promotes a skeletal anabolic response to ML, thus suggesting that manipulation of ephrin B1 actions in bone may provide a means to sensitize the skeleton to mechanical strain to stimulate new bone formation.

Alternative Splicing, Polyadenylation, and MicroRNAs Targeting Insulin-like Growth Factor-1 in Osteoblasts. Spenser Smith¹, Catherine Kessler¹, Clifford Rosen², Anne Delany^{*1}. ¹University of Connecticut Health Center, USA, ²Maine Medical Center, USA

Insulin-like growth factor I (IGF-1) plays a critical role in skeletal growth. It is an autocrine, paracrine and endocrine regulator of bone mass. Animals and humans with deficits in IGF-1 display decreased peak bone mass and impaired linear growth. We sought to determine the post-transcriptional mechanisms regulating IGF-1 in murine osteoblasts.

IGF-1 splice variants give rise to a common mature IGF-1 peptide, but different E peptides (Ea or Eb) are encoded by inclusion or exclusion of exon 5. We identified expression of exon 4+6 (Ea) and exon 4+5+6 (Eb, mechano-growth factor) splice products, and found that the relative abundance of these variants did not change during osteoblastic differentiation *in vitro*. The IGF-1 3' untranslated region (UTR) encoded by exon 6 contains 2 alternative polyadenylation sites. Use of the proximal site gives rise to a short 3' UTR of ~195 bases, whereas use of the distal site results in a ~6300 base long UTR. The absolute level of IGF-1 mRNA did not change during osteoblastic differentiation. However, use of the distal polyadenylation site was significantly increased during this process; and the abundance of the long IGF-1 RNA increased in concert with that of osteocalcin mRNA. The long IGF-1 RNA isoform is ~50% less stable than the short isoform.

miRNAs are small non-coding RNAs that inhibit gene expression by decreasing transcript stability and/or translation. Using Luciferase-IGF-1 3' UTR reporter constructs and specific miRNA inhibitors, we found that the IGF-1 3' UTR is targeted by miR-29 and miR-365. There are 2 potential binding sites each for miR-29 and miR-365 in the long IGF-1 isoform, whereas the short isoform contains only 1 potential binding site for miR-365. Transfection of osteoblasts with inhibitors for these miRNAs caused a significant increase in IGF-1 protein levels. Further, the expression of miR-29 and miR-365 increased during osteoblast differentiation *in vitro*. The increase in miRNAs that negatively regulate IGF-1, in combination with the increased proportion of IGF-1 mRNAs containing the long 3' UTR, likely results in the down regulation of IGF-1 protein during osteoblastic differentiation. An understanding of how miR-29 and miR-365 regulate osteoblasts and the mechanisms regulating polyadenylation site usage will provide important information about the control of osteoblastic differentiation. This will allow for the identification of novel therapeutic targets.

Conditional Deletion of IGF-I Receptor by Osterix Driven Cre-Recombinase Impairs Both Cartilage and Bone Formation. Yongmei Wang^{*1}, Hashem ElAlieh², Cha K Fong², Daniel Bikle³. ¹Endocrine Unit, University of California, San Francisco/VA Medical Center, USA, ²Endocrine Unit University of California, San Francisco/San Francisco VA Medical Center, USA, ³Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, USA

Osterix (Ox) is expressed in osteoprogenitors, prehypertrophic chondrocytes (PHCs) and perichondrium in the skeleton, and is a key transcription factor for osteoblast (OB) differentiation. Ox driven cre-recombinase is widely used in manipulating genes in osteoprogenitors, but whether it also affects genes in other Ox-expressing skeletal cells remains uncertain. To investigate the role of IGF-I signaling in Ox-expressing cells in the skeleton, we generated IGF-I receptor (IGF-IR) knockout mice (^{Ox}IGF-IRKO) by crossing floxed-IGF-IR mice with mice carrying the Cre recombinase transgene controlled by a GFP labeled Ox promoter (^{Ox}GFP-cre, gift from Dr. Andrew McMahon), and monitored bone development and remodeling from 2 to 7 weeks. Compared with the control mice (floxed IGF-IR, no cre) from the same litters, the ^{Ox}IGF-IRKO mice showed significant growth retardation with smaller body size and shorter bones. At 2-7 weeks, as detected by GFP in the ^{Ox}IGF-IRKO mice, ^{Ox}GFP-cre was highly expressed in the PHCs and the inner layer of perichondral cells which give rise to trabecular OBs, but was sparsely expressed in the OBs lining the trabecular bone surface. At 3 and 7 weeks, immunohistochemistry (IHC) confirmed a marked reduction of IGF-IR expression in the cells of the prehypertrophic zone and perichondrium, but not in OBs lining the trabecular bone surface of the ^{Ox}IGF-IRKO mice. From 2 to 7 weeks, histology revealed a delayed formation of the secondary ossification center (epiphysis), irregular morphology of the growth plate (expanded hypertrophic zone) and less trabecular bone in the tibia and femur of the ^{Ox}IGF-IRKO mice when compared with the controls. Cell proliferation as assessed by the number of PCNA positive cells was reduced by 40% and 45%, respectively, in the perichondrium and in the proliferation zone of the growth plate of the ^{Ox}IGF-IRKO mice. The expression of type II collagen was not altered significantly in the chondrocytes (by IHC), whereas the mRNA level of alkaline phosphatase of the trabecular bone was decreased by 46% (by qPCR) in the ^{Ox}IGF-IRKO mice compared with the controls. Our data indicate that during postnatal bone development and remodeling, IGF-I signaling in the Ox-expressing PHC is required for chondrocyte growth and secondary ossification of the epiphysis, whereas IGF-I signaling in the Ox-expressing inner layer perichondral cells is critical for OB differentiation and maintenance of bone mass.

Disclosures: Yongmei Wang, None.

E-selectin ligand 1 Regulates Bone Homeostasis via Modulating TGF-β Bioavailability in Bone Microenvironment. Tao Yang^{*1}, Ingo Grafe², Yangjin Bae¹, Shan Chen¹, Ming-ming Jiang¹, Terry Bertin¹, Yuqing Chen¹, Brendan Lee³. ¹Baylor College of Medicine, USA, ²Department of Molecular & Human Genetics, Baylor College of Medicine, USA, ³Baylor College of Medicine & Howard Hughes Medical Institute, USA

TGF-β is one of the most abundant growth factors in the skeletal system and plays a crucial role in skeletal homeostasis. Before TGF-β ligand can access its receptors, it must become bioavailable, a process composed of multiple steps e.g. TGF-β expression, maturation, secretion and activation from latency, etc. Although the importance of TGF-β maturation has been revealed in blood pressure homeostasis as well as in cartilage development, to date, how TGF-β maturation is involved in bone remodeling has not been fully appreciated. We previously reported that E-selectin ligand-1 (ESL-1), a Golgi apparatus localized protein, acts as a negative regulator of TGF-β bioavailability by attenuating maturation of proTGF-β during cartilage homeostasis. Our current study shows that *Esl-1*^{-/-} mice exhibit a severe and early-onset osteoporosis, suggesting that ESL-1 also plays a critical role in bone homeostasis. By bone histomorphometry, we found that OC.S/BS is markedly increased in the *Esl-1*^{-/-} bone, while the OB.S/BS is unchanged. *In vitro*, *Esl-1*^{-/-} osteoblasts show a delayed late differentiation, and an increased potency in promoting osteoclastogenesis of co-cultured osteoclast progenitors. However, the osteoclast progenitors from *Esl-1*^{-/-} mice show no difference in osteoclastogenesis under the treatment of mCSF and RANKL, implicating that ESL-1 primarily acts in osteoblasts to regulate osteoblast-osteoclast coupling in a non-cell-autonomous fashion. In addition, the molecular phenotyping of *Esl-1*^{-/-} calvarial tissue exhibits an elevated mature TGF-β/proTGF-β ratio, with a dramatic increase in TGF-β downstream targets (PAI-1, PTHrP, CTGF, etc) as well as osteoclastogenesis stimulus (RANKL). Further *in vitro* co-culture experiments demonstrate that inhibitors of TGF-β or PTHrP can effectively attenuate the osteoclastogenesis of osteoclast progenitors co-cultured with *Esl-1*^{-/-} osteoblasts, suggesting that the TGF-β/PTHrP/RANKL axis is a major mechanism acting downstream of ESL-1 and responsible for the overactive bone resorption in the *Esl-1*^{-/-} mice. In summary, our study identified ESL-1 as an important regulator of bone remodeling, and that the modulation of TGF-β maturation is pivotal in the maintenance of a homeostatic bone microenvironment and for proper osteoblast-osteoclast coupling.

Disclosures: Tao Yang, None.

Modulation of Osteoclast Formation by Cyclically-Strained Myotubes Is Mediated by IL-6. Petra Juffer^{*1}, Richard T. Jaspers², Jenneke Klein-Nulend³, Astrid D. Bakker¹. ¹Department of Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, Research Institute MOVE, Amsterdam, Netherlands, ²Research Institute MOVE, Faculty of Human Movement Sciences, VU University Amsterdam, Amsterdam, The Netherlands, Netherlands, ³ACTA-VU University Amsterdam Dept Oral Cell Biology (Rm # 11N-63), The Netherlands

Skeletal muscle is an endocrine organ that produces numerous growth factors and cytokines, such as IL-6, in response to mechanical loading. In bone, these factors can affect osteoblastic bone formation, but it is unknown whether osteoclasts are also affected, and whether mechanical loading modulates the release of these factors by muscle cells. Therefore we aimed to investigate whether mechanically-loaded myotubes produce soluble factors that affect osteoclast formation, and whether IL-6 is one of these factors.

C2C12 myoblasts were seeded on laminin-coated Bioflex® 6-wells plates, and differentiated into C2C12 myotubes. C2C12 myotubes were mechanically stimulated for 1 h by applying an uni-axial cyclic strain (0-15% deformation, 1 Hz), or kept under static control conditions, and post-incubated without cyclic strain up to 24 h. Conditioned medium (CM) was collected directly after 1 h cyclic strain/static culture, and after 24 h post-cyclic strain/static culture. RNA was isolated directly after 1 h cyclic strain. IL-6 mRNA levels were measured by RT-PCR. Mouse bone marrow cells were cultured in the presence of M-CSF and RANKL, with/without myotube-CM, and with/without mouse IL-6 antibody (10 ng/mL). After 6 days of culture, osteoclast formation was quantified by counting tartrate-resistant acid phosphatase (TRAP) positive multinucleated (≥3 nuclei) cells.

CM harvested from C2C12 myotubes after 1 h static culture and 24 h post-static culture decreased the formation of TRAP⁺-multinucleated cells by 3.5-fold (1 h static) and 7.0-fold (24 h post-static) compared to non-CM. CM harvested from C2C12 myotubes after 1 h cyclic strain increased the formation of TRAP⁺-multinucleated cells by 1.7-fold compared to CM harvested after 1 h static culture. CM harvested from C2C12 myotubes after 24 h post-cyclic strain did not affect the formation of TRAP⁺-multinucleated cells. Cyclic strain increased IL-6 mRNA levels in C2C12 myotubes by 3.0-fold. Addition of IL-6 antibody to the myotube-CM nullified the effect of soluble factors produced by cyclically-strained myotubes on osteoclast formation.

Our data indicate that C2C12 myotubes secrete soluble factors that inhibit osteoclast formation, and that mechanical loading of C2C12 myotubes by cyclic strain stimulates osteoclast formation via IL-6. Since it is known that IL-6 plasma

concentrations increase substantially during muscular activity, our data suggest that muscle cells *in vivo* might affect osteoclasts via IL-6.

Muscle-derived Humoral Factor, Osteoglycin (OGN), Links Muscle to Bone. Ken-ichiro Tanaka*¹, Toshitsugu Sugimoto¹, Susumu Seino², Hiroshi Kajii³. ¹Shimane University School of Medicine, Japan, ²Kobe University Graduate School of Medicine, Japan, ³Kinki University Faculty of Medicine, Japan

Muscle mass is closely related to high bone mass and a decrease in fracture risk in postmenopausal women. These findings suggest that there are interactions between muscle tissues and bone metabolism. We therefore hypothesized that there might be some humoral bone anabolic factors that are produced from muscle tissues. Fibrodysplasia ossificans progressive (FOP) is a rare autosomal dominant disorder characterized by progressive heterotopic ossification in skeletal muscle. ALK2(R206H), the constitutive activating mutation of the BMP type 1 receptor is found in patients with the classic form of FOP. We performed comparative DNA microarray analysis between stable empty vector- and ALK2(R206H)-transfected mouse myoblastic C2C12 cells, since FOP and its molecular pathogenesis could be a clue to help identify some muscle-derived humoral bone anabolic factors. We hypothesized that the expression of muscle-derived bone anabolic factors might be suppressed by the conversion of muscle tissues into bone, because those factors could be predominantly expressed in muscle tissues, compared with their expressions in bone, and their systemic effects could be more important than their local effects in bone tissues. OGN was identified as one of 25 genes whose expressions were decreased <1/4 by ALK2(R206H) expression in these cells. Recombinant OGN as well as stable overexpression of OGN significantly enhanced the levels of alkaline phosphatase (ALP), type 1 collagen (Col1), β -catenin and osteocalcin (OCN) as well as mineralization in mouse osteoblastic cells (MC3T3-E1 and mouse primary osteoblasts). A reduction in endogenous OGN level by siRNA showed the opposite effects in these cells. On the other hand, OGN suppressed the levels of ALP and OCN mRNA induced by BMP-2 in C2C12 cells. OGN was detected in human serum or culture supernatant from mouse myoblasts and myotubes. Conditioned medium from OGN-overexpressed and OGN-suppressed myoblastic cells enhanced and decreased the levels of ALP and OCN in osteoblastic cells, respectively. Moreover, OGN enhanced the levels of phosphorylated ERK1/2, TGF- β -induced transcriptional activity and Col1 mRNA in MC3T3-E1 cells. ERK1/2 inhibitor antagonized the levels of Col1 mRNA enhanced by OGN, although an inhibitor of endogenous TGF- β did not affect it. These findings indicate that OGN enhances the levels of Col1 mRNA partly through ERK1/2 in osteoblasts. In conclusion, our present data suggest that OGN may be crucial factors produced by muscle-derived cells and secreted into blood that exhibits bone anabolic effects.

Physical Activity in Relation to Serum Sclerostin, Insulin-like Growth Factor-1 and Bone Turnover Markers in Healthy Young Men : A Cross-sectional and a Longitudinal Study. Mohammed-Salleh Ardawi*¹, Abdulrahman Al-Sibiany², Talal Bakhsh³, Mohammed Qari⁴. ¹Center of Excellence for Osteoporosis Research & Faculty of Medicine, Saudi Arabia, ²Center of Excellence for Osteoporosis Research & Department of General Surgery, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, ³Center of Excellence for Osteoporosis Research, & Department of General Surgery, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, ⁴Center of Excellence for Osteoporosis Research, and Department of Hematology, Faculty of Medicine, & KAU Hospital, King Abdulaziz University, Saudi Arabia

Background: There is no information on the interaction between sclerostin, insulin-like growth factor (IGF-1) and bone turnover markers (BTMs), in response to mechanical loading by physical activity (PA). The main objective of the present study was to study the relationships between serum sclerostin, serum IGF-1 (s-IGF-1) and BTMs and PA level in young men (age 23-34 years) and to discern how 8 weeks of PA training (PAT) affects the serum levels of sclerostin, IGF-1, and BTMs. This was a cross-sectional study with a sub-group followed longitudinally.

Subjects & Methods: A total of 816 randomly selected young men were cross-sectionally studied. Also, we followed 92 men longitudinally following the 8-week PAT (4 days/week) as compared with 88 controls. All men were medically examined and serum sclerostin, s-IGF-1, BTMs, and bone mineral density (BMD) were determined.

Results: Men with PA > 240 min per week showed significantly (vs sedentary controls) lower serum sclerostin (by 29.5 %, P<0.001) and higher s-IGF-1 (by 88.7%, P<0.001) levels, respectively. Bone formation markers were higher with increasing PA in men with PA > 240 min/week vs sedentary group. Serum sclerostin was lower (by 41.2%, P<0.0001) and s-IGF-1 rose (by 66.3%, P<0.0001) and s-OC, s-PINP, and

s-bone ALP rose by 23.5% (P<0.001), 18.6% (P<0.006) and 47.2% (P<0.001), respectively in response to 8-week PAT as compared with controls.

Conclusions: The present studies demonstrate that, in young men, even minor changes in PA are associated with clear effects on serum sclerostin, s-IGF-1 and BTMs and suggest that sclerostin could be a link between mechanical loading and disuse osteoporosis in humans.

The PPP6R3/LRP5 Locus Influences Lean Mass in Children of Different Ethnic Background and Highlights Pleiotropic Effects and Muscle-bone Interactions. Carolina Medina-Gomez*¹, Denise Hepppe², Karol Estrada³, Joyce Van Meurs³, Albert Hofman⁴, Yi-Hsiang Hsu⁵, David Karasik⁶, Vincent Jaddoe⁷, Maria Zillikens⁸, Andre Uitterlinden⁹, Fernando Rivadeneira³. ¹Erasmus Medical Center, The Netherlands, ²The Generation R Study Group, Erasmus Medical Center, Rotterdam, The Netherlands, Netherlands, ³Erasmus University Medical Center, The Netherlands, ⁴Department of Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands, Netherlands, ⁵Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, ⁶Hebrew SeniorLife, USA, ⁷The Generation R Study, Erasmus Medical Center, Rotterdam, The Netherlands, Netherlands, ⁸Erasmus Mc, The Netherlands, ⁹Rm Ee 575, Genetic Laboratory, The Netherlands

Aim: Lean and bone mass have considerably high phenotypic and genetic correlations with a shared heritability estimate ranging between 30-40% in adults. A genome-wide association study (GWAS) on total body lean mass and a bivariate GWAS on lean mass & BMD was run in a cohort of children to identify genes with pleiotropic effects on peak bone mass attainment and muscle mass. **Methods:** Subjects are part of the Generation R study, a multiethnic birth cohort in Rotterdam, The Netherlands; we included 4,096 children (mean age=6.2, SD=0.50 years) with total body DXA measurements (GE-Lunar iDXA) and genomewide genotyping (Illumina 660K). The univariate and bivariate GWAS were adjusted for age, sex, height, fat percent and 20 genomic principal components using (bivariate) PLINK. A P<5x10⁻⁸ was considered genome-wide significant (GWS). **Results:** Genomic inflation factors were close to unity indicating adequate correction for stratification. In the univariate analysis we identified a GWS association with lean mass ($\beta=0.13$, P=2.9x10⁻⁸) for a SNP mapping to 11q13.2, in the PPP6R3/LRP5 locus. The SNP explains 0.8% of the variation in lean mass and is nominally significantly associated with BMD ($\beta=0.10$, P=7.6x10⁻⁵) explaining 0.4% of BMD variation. The association with lean mass was reduced after additional correction for bone mineral content ($\beta=0.08$, P=0.001), explaining 0.2% of the phenotypic variance. In the bivariate GWAS this SNP was also associated at GWS level (P=4.8x10⁻⁸) showing positive correlations of the bivariate trait with both lean mass ($\rho=0.96$) and BMD ($\rho=0.68$). **Conclusion:** Genetic variation in the PPP6R3/LRP5 locus exerts pleiotropic effects on muscle mass and peak bone mass acquisition of children. Given the high linkage disequilibrium in the region it is difficult to establish from which gene the GWAS signal is arising. PPP6R3 is a 155 Kb gene with 23 exons of unknown function, expressed among other tissues in bone and muscle. LRP5 is ubiquitously expressed, member of the Wnt signaling pathway and shown to play a key role in skeletal homeostasis and mechanosensing. Replication in additional children cohorts is underway; while the same SNP has been found associated at genome significant level in a bivariate GWAS of bone strength and lean mass in two large consortia of adult individuals (ASBMR 2012). These pleiotropic effects on muscle mass and BMD observed in children are likely to be evident later in life.

Disclosures: Carolina Medina-Gomez, None.

Bone Formation is Compromised by Disruption of Runx2-WW-domain Protein Interaction. Yang Lou*¹, Weibing Zhang², Marcio Beloti³, Dana Frederick⁴, Andre Van Wijnen⁴, Gary Stein⁴, Janet L. Stein⁴, Jane Lian⁴. ¹University of Massachusetts, USA, ²Univ of Massachusetts Medical School, USA, ³School of Dentistry of Ribeirao Preto, University of Sao Paulo, Brazil, ⁴University of Massachusetts Medical School, USA

The WW-domain protein (WWDP) family consists of members with one or more WW (Tryptophan-Tryptophan)-repeated motifs that are expressed in many tissues and act as co-regulatory partners of transcription factors through binding to PPxY motifs. Several WW-domain proteins, including WWP1, WWOX, YAP and TAZ, can bind to the transcription factor RUNX2 and either stimulate or suppress RUNX2 activity, dependent on the gene context, for control of skeletal development. Our earlier *in vitro* studies showed that mutation of Y433 to A433 (in the PPxY motif) in the essential NMTS domain of RUNX2 can totally or partially disrupt its interaction with these WW-domain proteins. To understand the *in vivo* significance of the cooperation of RUNX2 and WWDPs during skeletogenesis, we generated a mutant mouse model with a single amino acid substitution (Y433 to A433) integrated into the endogenous Runx2 locus. Homozygous Runx2^{Y433A/Y433A} mice exhibit developmental defects in calvaria and epiphysis of long bones at birth. The frontal calvarial sutures in

Runx2 mutant mice are not completely closed and the defect persists into adulthood. By histology the calvarial defects appear similar to RUNX2 deficient mouse models. Micro-CT bone density (BMD) and bone volume (BV) are decreased in frontal calvaria of *Runx2*^{Y433A/Y433A} mice that include the unmineralized suture area. No change in BV or BMD occurs in the parietal calvaria, suggesting commitment to osteogenesis is impaired, but mineralization is not compromised in *Runx2* mutant mice. *Ex vivo* cultures from calvaria or bone marrow of homozygous mice display delayed osteogenic differentiation at early stages. *Runx2*, *Osx*, *Col 1* and *Alk Phos* expression are reduced. Mineral deposition is moderately reduced in mutant mouse osteoblasts with delayed osteocalcin expression. Long bones of *Runx2*^{Y433A/Y433A} mice exhibit a striking disorganization of the growth plate at birth, and a thin diaphysis with weak *Alk Phos* staining on the periosteal surface. Molecular markers for chondrogenic and osteogenic differentiation are reduced. Together, the findings in calvaria and long bones indicate impairment of both intramembranous and endochondral bone formation from cell autonomous defects in the *Runx2*^{Y433A/Y433A}. We propose the mechanism for these defects is related to a critical interaction of *Runx2* with one or more positive and negative WW-domain proteins during osteogenesis.

Characterization of the Skeletal Phenotype in Osteoactivin Transgenic Mice. Nagat Frara^{*1}, Fabiola Delcarpio-Cano¹, Robin Pixley¹, Roshanak Razmpour¹, Christina Mundy², Fouad Moussa³, Samir Abdelmagid³, Steven Popoff², Favez Safadi³. ¹Temple University, USA, ²Temple University School of Medicine, USA, ³Northeast Ohio Medical University, USA

Osteoactivin (OA), a transmembrane protein, has recently emerged as a vital glycoprotein for the differentiation and function of bone forming osteoblasts. OA expression has been shown to increase during osteoblast development with maximal expression during the final stages of differentiation. Recent studies showed that OA is also expressed by osteoclasts and plays a role in their differentiation and function. In this study, we used a transgenic mouse model over-expressing OA under the control of CMV promoter (OATg) to determine the mechanisms by which OA contributes to bone formation and remodeling *in vivo*. Western blot analysis showed a three-fold increase in OA expression in OATg compared to wild-type (WT) osteoblasts. Micro-CT analysis of femurs from 12 week-old OATg showed increased trabecular bone volume (BV/TV) in OATg mice compared to WT mice. Given that OA is also over-expressed in osteoclasts in OATg mice, we evaluated bone resorption by histomorphometry and ELISA. Serum RANK-L and CTX-1 levels were significantly decreased in OATg compared to WT mice indicative of defective osteoclast-mediated bone resorption in OATg mice. Histomorphometric analysis showed that osteoblast numbers are increased but that osteoclast numbers are dramatically reduced in OATg compared to WT mice. Next, we examined whether osteoblast differentiation is altered in OATg mice. Osteoblasts were derived from bone marrow mesenchymal stem cells of 8 week-old OATg and WT mice and from calvaria of newborn OATg and WT mice. Although proliferation was increased in OATg osteoblasts, differentiation was reduced in OATg osteoblast cultures associated with decreased alkaline phosphatase activity/staining as well as matrix mineralization compared to WT control cultures. Moreover, qPCR analysis showed that OA over-expression down-regulated mRNA expression of osteoblast markers in OATg osteoblasts compared to controls. Taken together, these data indicate that over-expression of OA *in vivo* increases bone mass by decreasing osteoclast-mediated bone resorption and enhancing osteoblast-mediated bone formation. However, OA over-expression has a negative effect on osteoblast differentiation and maturation *ex vivo*, an effect that may be dose-dependent. Additional studies are warranted to better understand the effects of OA over-expression on bone formation and remodeling *in vivo*.

Dlx3 Inactivation in Osteoblasts Results in Defective Endochondral Bone Formation. Juliane Isaac^{*1}, Olivier Duverger², Hong-Wei Sun³, Stacey Russell⁴, Gary Stein⁵, Jane Lian⁵, Maria I Morasso². ¹Developmental Skin Biology Section, NIAMS/NIH, USA, ²Developmental Skin Biology Section, NIAMS, National Institutes of Health, USA, ³Biodata Mining & Discovery Section, NIAMS, National Institutes of Health, USA, ⁴Departments of Cell Biology & Orthopedic Surgery, University of Massachusetts Medical School, USA, ⁵University of Massachusetts Medical School, USA

Human mutations in the homeodomain transcription factor *DLX3* gene are etiologic to Tricho-dento-osseous (TDO), an ectodermal dysplasia characterized by defects in hair, teeth and bone development. Although clinical observations and *in vitro* studies suggest that *Dlx3* plays a crucial role in bone development, the *in vivo* role of *Dlx3* in regulation of endochondral bone formation of the post natal mouse has not been elucidated. To address the mechanisms by which *Dlx3* functions during osteogenesis, we conditionally inactivated *Dlx3* in osteoblasts by crossing *osteocalcin (Oc)-Cre* mice with *Dlx3*^{fllox/LacZ} mice to generate conditional

Dlx3-deficient (*Dlx3*^{Oc-cKO}) mice. *Dlx3* is expressed in hypertrophic chondrocytes (at low levels) and continues to increase in osteoblasts and osteocytes. Micro-architectural analyses of femurs were performed on *Dlx3*^{Oc-cKO} and *Dlx3*^{+/+} males from 5 weeks to 6 months. While the bone volume and the length of the whole femur were not affected, bone mineral density (BMD) was significantly decreased in the *Dlx3*^{Oc-cKO} males in comparison to *Dlx3*^{+/+} males. Cortical bone showed a decrease in bone density and increased porosity at all ages for *Dlx3*^{Oc-cKO} males, while cortical thickness remained unchanged. In contrast, trabecular bone of the distal femur showed increases of the relative bone volume, trabeculae number and connectivity density, associated with decreased trabecular spacing and an unchanged trabecular thickness, revealing an increased bone mass density of trabeculae in the *Dlx3*^{Oc-cKO} males. These changes suggest increased bone resorptive activity in the cortical bone; however in the metaphysis, stimulated osteoprogenitor differentiation forming new trabeculae is indicated. Analysis of RNA seq obtained from mRNAs extracted from femurs of 5-week-old males identified transcripts differentially expressed in *Dlx3*^{Oc-cKO} versus *Dlx3*^{+/+} mice. Using *Ingenuity Pathways Analysis (IPA)*, we showed that differentially expressed genes were enriched in molecules involved in the differentiation of osteoblasts and in the development and function of connective tissue. These data support that conditional deletion of *Dlx3* in osteoblasts may affect bone formation through a network of Wnt, hedgehog and BMP signaling pathways contributing to an increase in trabecular bone. Overall, these data indicated a key role for *Dlx3* in endochondral bone formation of adult mice and selective functional activity of *Dlx3* between cortical and trabecular bone.

Modulating Osteogenic Differentiation of Induced Pluripotent Stem (iPS) Cells Through Direct Inhibition of SOX9 by MicroRNA-335-5p and MicroRNA-342-3p. Mengqi Huang^{*}, Yuhua Hu, Qisheng Tu, Jake Jinkun Chen. Tufts University School of Dental Medicine, USA

To selectively induce the osteogenic differentiation of induced pluripotent stem (iPS) cells, it is imperative to understand the regulatory molecular mechanisms underlying the process of how these cells switch between osteogenic and chondrogenic differentiation paths. Recent studies have successfully identified SOX9, the master gene of chondrogenesis, was downregulated during osteogenic differentiation while the important factor, Osterix(OSX) was upregulated. Here we found two specific microRNAs, miR-335-5p and miR-342-3p, were upregulated after ascorbic acid treatment of iPS cells, which indicated that they may be involved in the regulation of osteogenic differentiation. To verify the pivotal roles of miR-335-5p and miR-342-3p as direct posttranscriptional regulators of SOX9 in mouse iPS cells to osteogenic lineage, we performed a series of studies including micro-RNA microarray, luciferase reporter assays, site-specific mutations, and gain- and loss-of-function analyses. Micro-RNA microarray chips showed that miR-335-5p and miR-342-3p directly repressed SOX9 expression in iPS cells through respectively unique binding sites in its 3'UTR (Fig.1,2). To investigate effects of miR-335-5p and miR-342-3p specifically targeting SOX9, we cotransfected these miRNAs into iPS cells with the cloned luciferase-SOX9/3'UTR plasmids and pMIR-REPORT beta-gal control plasmids. Luciferase activity in iPS cells stably transfected with luciferase-SOX9/3'UTR construct decreased after transfection with miR-335-5p and miR-342-3p precursor hairpins when compared with cells transfected with negative control pre-miRNAs. The effects of miR-335-5p and miR-342-3p were reversed by anti-miR-335-5p and anti-miR-342-3p treatments, which downregulated endogenous miR-335-5p and miR-342-3p (Fig.3). As a result of decreased SOX9 protein level by miRNA control, we observed that in miR-335-5p- and miR-342-3p-overexpressing iPS cells there were increased mineral nodule formation and elevated mRNA and protein levels of OSX, a key osteogenic gene (Fig.4,5). In conclusion, miR-335-5p and miR-342-3p promoted osteogenic differentiation by down regulating the expression of SOX9 in mouse iPS cells. We propose miR-335-5p and miR-342-3p to target molecules for promoting bone regeneration and wound healing. Moreover, *in vivo* experiments are ongoing to further determine the effects of iPS cells regulated by miR-335-5p and miR-342-3p in critical-size calvarial bone defects in a mouse model.

Ubiquitin E3 Ligase Itch Negatively Regulates Osteoblast Differentiation from Mesenchymal Stem Cells. Hengwei Zhang¹, Lei Shu², Brendan Boyce², Lianping Xing³. ¹Univeristy of Rochester, USA, ²University of Rochester Medical Center, USA, ³University of Rochester, USA

Itch, a HECT family E3 ligase, affects numerous cell functions by regulating ubiquitination and degradation of target proteins. The role of Itch in osteoblasts(OBs) has not been investigated. Using 1-month-old Itch^{-/-} mice and WT littermates, we report Itch^{-/-} mice have significantly increased 1) bone volume(%BV/TV:42 ± 4vs25 ± 3.5); 2) OB numbers(#/mm:558 ± 28vs405 ± 35), and 3) bone formation rate(BFR:0.9 ± 0.1vs0.5 ± 0.04 μm³/μm²/day;MAR:1.2 ± 0.1vs0.8 ± 0.1 μm/day;MS/BS:0.75 ± 0.02vs0.63 ± 0.06% in WT mice). Compared to WT mice, bone marrow stromal cells(BMSCs) from Itch^{-/-} mice have increased OB differentiation(CFU-F colony#/well:79 ± 4vs52 ± 3; CFU-ALP+ colony#/well:63 ± 5vs38 ± 2; mineralized nodule#/well: 105 ± 7vs68 ± 8) and decreased adipogenesis (Oil red O+ cells#/well:390 ± 83vs1005 ± 71). To investigate if increased OB differentiation in Itch^{-/-} mice is due to enhanced mesenchymal stem cell (MSC) functions, we isolated CD45-enriched MSCs from BMSCs of Itch^{-/-} and WT mice and found that Itch^{-/-} CD45- cells had 1) normal MSC numbers (Sca1+/CD105+/CD11b-/CD31- cells), proliferation

and apoptosis; 2) increased OB marker gene expression (*alp*: $160 \pm 20\%$; *oc*: $180 \pm 15\%$; *runx2*: $170 \pm 15\%$ of WT cells); and 3) decreased expression of adipocyte master genes (*pparg*: $45 \pm 10\%$; *clebpa*: $55 \pm 4\%$; *clebpb*: $57 \pm 4\%$; and *clebpd*: $48 \pm 10\%$ of WT). To directly test the OB differentiation potential of *Itch*^{-/-} MSCs in vivo, we implanted *Itch*^{-/-} or WT CFU cells and decalcified bone matrix in a scaffold into tibial defects of SCID mice. *Itch*^{-/-} cells formed significantly more new bone in defects of recipient mice compared with WT cells (% BV/TV: 5.8 ± 1.9 vs 2.4 ± 0.7 ; % new bone area: 0.4 ± 0.08 vs 0.2 ± 0.05). Furthermore, over-expression of WT *Itch*, but not an *Itch* ligase-dead mutant, rescued OB differentiation defects of *Itch*^{-/-} BMSCs (%ALP+ area: 6.5 ± 1 in GFP vs 0.5 ± 0.1 in WT *itc* vs 6 ± 0.8 % in *itc* mutant). Consistent with E3 ligase function of *Itch*, the expression of known *Itch* targeting proteins, such as JunB, Runx2 and active β -catenin, was increased in *Itch*^{-/-} BMSCs. Our findings show that *Itch* negatively regulates OB differentiation from MSCs through degradation of multiple positive regulators of OBs. Thus *Itch* is a potential new target for bone anabolic drug development to treat patients with osteoporosis.

Collagen 10-Expressing Chondrocytes Have the Capacity to Become Osteoblasts In Vivo. Xin Zhou^{*1}, Klaus von der Mark², Stephen Henry³, Takako Hattori⁴, Benoit de Crombrughe¹. ¹MD Anderson Cancer Center, USA, ²Department of Experimental Medicine I, Nikolaus-Fiebiger-Center of Molecular Medicine, University of Erlangen-Nuremberg, Germany, ³University of Texas MD Anderson, USA, ⁴Department of Biochemistry & Molecular Dentistry, Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Science, Japan

To examine whether cells derived from hypertrophic chondrocytes might contribute to the osteoblast pool in endochondral bones, we conditionally deleted an *Osx/EGFP* allele either in hypertrophic chondrocytes by *Coll10a1-Cre* or in chondrocytes by tamoxifen-induced *Agcl-CreERT2*. This *Osx* allele expresses *EGFP* only after Cre recombination and only in cells in which *Osx* is actively transcribed, namely, hypertrophic chondrocytes, osteoblast precursors, mature osteoblasts and osteocytes. Surprisingly, in addition to *EGFP*-positive (*EGFP*⁺) hypertrophic chondrocytes, abundant non-chondrocytic *EGFP*⁺ (*Osx*^{+/+}) cells were seen in the primary ossification centers. These cells were tightly associated with type I collagen, and their appearance coincided with the onset of ossification at the primary spongiosa from E15.5 until after birth. Subsequently, they were distributed throughout trabeculae surfaces, present in the endosteum, and embedded within the bone matrix. Similar results were obtained when the *Osx/EGFP* allele was inactivated in chondrocytes by tamoxifen-induced *Agcl-CreERT2*. Inactivation of the two alleles of *Osx* in hypertrophic chondrocytes by *Coll10a1-Cre* led to severely decreased bone formation selectively in the primary ossification centers due to lack of *Osx*-expressing osteoblasts, despite the presence of *Runx2*-expressing preosteoblasts in this area. Our results thus indicate that *Coll10a1*-expressing chondrocytes have the capacity to undergo transdifferentiation to become osteoblasts. In addition to cells in the periosteum, *Coll10a1*-expressing chondrocytes represent a second significant source of osteoblasts contributing to endochondral bone formation in vivo. We hypothesize that this finding represents a unique case of naturally occurring transdifferentiation in mammalian development.

Epigenetic Control of Osx-target Genes during Osteoblast Differentiation through NO66 Histone Demethylase. Krishna Sinha^{*1}, Hideyo Yasuda², Xin Zhou³, Benoit DeCrombrughe¹. ¹UT MD Anderson Cancer Center, USA, ²U.T.M.D. Anderson Cancer Center, USA, ³MD Anderson Cancer Center, USA

The osteoblast-specific transcription factor Osterix (*Osx*) is needed for differentiation of *Runx2*-expressing precursors into mature osteoblasts through activating a large repertoire of osteoblast genes including *Coll1a1*, *Bsp* and *Oc*. In *Osx*-null embryos, *Runx2*-positive *Osx*-null cells are arrested in their differentiation because expression of these osteoblast genes is absent. The mechanisms underlying the activation of these *Osx*-target genes in transition of preosteoblasts to osteoblasts is not very clear. We present several lines of evidence to support the hypothesis that *Osx* is indispensable for the formation of an active chromatin state of its target genes. Indeed, our results indicate that activation of the *Osx*-target genes is likely to include DNA demethylation, removal of repressor-complex from chromatin, recruitment of activators and chromatin modifying activities. With chromatin immunoprecipitation assays in *Osx*-wt and *Osx*-null calvarial cells, we demonstrate that the functional interactions of *Runx2* and *Osx* with chromatin of these genes are essential for expression of these genes in osteoblasts. Based on our findings, we conclude that in absence of *Osx*, chromatin of the *Osx*-target genes is inaccessible for the transcriptional activators including *Runx2*, *c-Myc* as well as histone modifying enzymes. We have earlier reported that NO66 is a JmjC histone demethylase specific for lysine 4 and 36 of histone H3, interacts with *Osx* and inhibits *Osx*-dependent promoter activity. Consistent with previous report, the interaction of NO66 with the chromatin of the *Bsp* and *Oc* genes is associated during repression of these genes in

Osx-null cells, indicating that NO66 might regulate histone methylation levels at the chromatin through its demethylase activity. Taken together, our results provide novel mechanistic insights in activation of *Osx*-target osteoblast genes through NO66 histone demethylase as well as DNA and histone methylation, thus adding another layer of control in chromatin architecture during transition of preosteoblasts to osteoblasts.

Preconditioning Mouse Periosteal Cells to Hypoxia by Inactivation of the Phd2 Oxygen Sensor Improves In Vivo Ectopic Bone Formation. Steve Stegen^{*1}, Nick Van Gastel², Riet Van Looveren², Peter Carmeliet³, Frank Luyten⁴, Geert Carmeliet⁵. ¹Universiteit Leuven, Belgium, ²Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, ³Laboratory of Angiogenesis & Neurovascular Link, Vesalius Research Center, VIB & Laboratory of Angiogenesis & Neurovascular Link, Vesalius Research Center, KU Leuven, Belgium, ⁴University Hospitals KU Leuven, Belgium, ⁵Katholieke Universiteit Leuven, Belgium

Tissue engineered constructs composed of a scaffold seeded with osteogenic cells are a promising strategy to heal osseous defects. However, the hypoxic conditions that cells encounter upon implantation can seriously impair the successful outcome and hinder bone formation. To anticipate to this detrimental environment and circumvent its negative effects, we aim at preconditioning osteogenic cells by switching on the hypoxia-inducible factor (HIF) pathway before implantation. We hypothesize that activation of this transcriptional program will not only promote angiogenesis, but will also facilitate a metabolic reprogramming which will favor cell survival in the hypoxic environment.

The HIF prolyl hydroxylase (PHD) oxygen sensors hydroxylate HIF-1 α and target it for proteasomal degradation in normoxia. In this study we genetically inactivated PHD2, the major isoform, in order to stimulate the hypoxia pathway. Murine periosteum derived cells (mPDC) obtained from *Phd2*^{lox} mice were transduced with adenovirus-Cre (Ad-Cre) or adenovirus-GFP (Ad-GFP). Within 3 days after Ad-Cre transduction, PHD2 protein levels significantly decreased (*Phd2*^{low}), leading to stabilization of HIF-1 α in normoxic conditions. As a consequence, the HIF-regulated transcriptional program was activated in the *Phd2*^{low} mPDC, which was reflected by an increased production of the angiogenic factor VEGF. In addition, mRNA levels of glucose transporters (*Glut1*) and glycolytic enzymes (*Ldh-a*, *Pdk1*) were increased, indicative of a glycolytic switch.

To investigate whether PHD2 inactivation influenced their bone forming capacity, the mPDC were seeded on a calcium phosphate-collagen scaffold and implanted ectopically in nude mice. Compared to Ad-GFP mPDC, the *Phd2*^{low} mPDCs formed significantly more new bone with osteocytes embedded in the mineralized bone, abundant osteoblasts lining the bone spicules, which surrounded islands of bone marrow. Intriguingly, the Ad-GFP mPDCs formed bone only at the periphery of the scaffold, whereas *Phd2*^{low} mPDCs formed also bone in the center, a site considered to be more hypoxic. In addition, the number and size of the blood vessels was increased in the *Phd2*^{low} condition, and these were closely associated with the sites of bone formation.

In conclusion, we show that genetic inactivation of *Phd2* activates the hypoxia signaling pathway in periosteal cells, improving their potential to form bone and attract blood vessels *in vivo*.

Runx2 and Osterix Molecular Complex Synergistically Regulate Osteogenic Genes. Harunur Rashid^{*1}, Haiyan Chen², Changyan Ma¹, Krishna Sinha³, Benoit DeCrombrughe³, Amjad Javed². ¹Department of Oral & Maxillofacial Surgery, University of Alabama at Birmingham, USA, ²University of Alabama at Birmingham, USA, ³UT MD Anderson Cancer Center, USA

Commitment and maturation of mesenchymal cells into osteoblast require *Runx2* and specificity protein 7 (Sp7) transcription factors. Deletion of either gene results in failed osteoblast development and bone formation. Similar skeletal phenotype by structurally unrelated proteins suggests their functional interdependence. However, molecular cross-talk between *Runx2* and Sp7 is not known. Here we investigated molecular and functional interaction between Sp7 and *Runx2* proteins. Co-IP assays revealed a physical interaction between endogenous Sp7 and *Runx2* proteins in human osteoblasts. Sp7 interacts with both isoform of *Runx2* in multiple cell types. Successful reciprocal Co-IP suggested a stable association between Sp7 and *Runx2*. Consistent with their physical interaction, a high degree of *Runx2* and Sp7 nuclear foci co-localized *in situ*. We next defined region responsible for this interaction by serial deletion mutants of both proteins. We find that DNA binding runt homology domain but not the transcriptional activation region of *Runx2* is required for this interaction. In contrast, the transactivation domain of Sp7 (89-192) but not the DNA binding Zinc fingers is necessary for *Runx2* interaction. We next tested if *Runx2*-Sp7 molecular complex differentially regulates target gene expression. Gene promoter considered markers of mature osteoblast (OC), chondrocyte (ColX), and FGF3 were

tested. Sp7 or Runx2, stimulate OC-promoter by 5 and 8 fold respectively. However, co-expression of Runx2 and Sp7 results in synergistic activation of ~70 fold. Similarly, ColX-promoter was activated by Sp7 (3 fold) and Runx2 (4 fold) but a synergistic activation of >17 fold was evident when both proteins were co-expressed. FGF3-promoter was induced ~30 fold by Sp7 or Runx2. However, a synergistic induction of 130 fold was manifested upon their co-expression. Thus Runx2 and Sp7 functionally cooperate for maximal induction of cell phenotype-restricted gene. Requirement of Runx2-Sp7 interaction for functional synergism was established by Runx2 mutant that lack activation domain but preserve Sp7 interaction. Runx2-Δ230 poorly activated (2 fold) OC-promoter but in presence of Sp7 showed synergistic response of 43 fold. Finally site-directed mutagenesis identified that functional synergism is primarily mediated through Runx responsive motif in the OC-promoter. Together, our data demonstrate that, Sp7 regulate Runx2 transcriptional activity and function through physical association.

PPR-Dependent Signaling in Osteoprogenitors Regulates Bone Marrow Hematopoietic Stem Cell and Leukocyte Niches. Cristina Panaroni^{*1}, Rhiannon Chubb², Joy Wu². ¹Endocrine Unit, Massachusetts General Hospital, USA, ²Massachusetts General Hospital, USA

The signaling pathways mediating the interactions between osteoblasts and hematopoietic cells are crucial for the maintenance of hematopoietic niches. One important pathway in osteoblasts involves the PTH/PTHrP receptor (PPR). The targeted expression of constitutively active PPR to osteoblasts in mice leads to increased trabecular bone and increased numbers of hematopoietic stem cells (HSCs). Beyond support of HSCs, osteoblasts are also necessary to sustain B lymphopoiesis in bone marrow (BM). The PPR is a G protein-coupled receptor (GPCR) that signals through multiple G proteins including Gsz. We have previously demonstrated that deletion of Gsz in osteoprogenitors in mice results in reduced bone mass with fewer osteoblasts and impaired differentiation of B cell precursors blocked at the pre-pro B to pro-B transition *in vivo*. Since PTH regulates HSCs *in vivo* and enhances support of B lymphocyte differentiation by osteoblastic cells *in vitro*, we hypothesized that ablation of PPR in osteoprogenitors would negatively affect BM hematopoiesis. Osterix-Cre:PPR(fluo) conditional knockout (KO) mice were generated using the Cre recombinase under the control of the Osterix promoter to ablate PPR in osteoblast precursors. The BM cellularity is not altered in the mutant mice despite a significant reduction in body weight. As previously reported, and similar to Gsz KO mice, PPR KO mice exhibit a specific reduction in B cell precursors in the bone marrow. However, we also found higher levels of myeloid cells and a significant increase in T lymphocytes in the BM of PPR KO mice. On the contrary, in the periphery PPR KO mice exhibit severe myeloid and lymphoid deficiency, with dramatic reductions in spleen and thymus cellularity. In order to better understand the splenic and thymic failure we investigated the HSC compartment in PPR KO mice. BM and spleens of 3 week-old PPR mice showed a dramatic decrease in short term-HSCs and multipotent progenitors but not in long term-HSCs. Our results demonstrate that PPR signaling upstream of Gsz in osteoprogenitors is very important for the maintenance of specific stem cell subsets in the BM niche and plays a direct role in BM HSC and leukocyte differentiation.

The Inositol Polyphosphate/Protein Kinase Cδ Signaling Cascade is Required for the Connexin43-dependent Amplification of Runx2 Activity. Corinne Niger¹, Maria Luciotti², Atum Buo³, Carla Hebert², Vv Ma², Joseph Stains^{*1}. ¹University of Maryland School of Medicine, USA, ²University of Maryland, USA, ³University of Maryland, School of Medicine, USA

Connexin43 (Cx43) plays an important role in bone biology by enabling the cell-to-cell communication of small molecules. Yet, the identity of the second messengers shared by Cx43 and the molecular targets of these second messengers are largely unknown. In order to identify the biologically relevant second messengers being communicated by Cx43, we characterized a system in which Cx43 expression levels impact the responsiveness to FGF2 by modulating the transcriptional activity of Runx2. Here, we show the requirement of the PLCγ1/inositol polyphosphate/ PKCδ signaling cascade to the Cx43-dependent regulation of Runx2 in MC3T3 osteoblasts. Cx43 overexpression potentially enhanced the response of a Runx2-binding OSE2-luciferase reporter to FGF2. Inhibition of phospholipase C activity by U73122, ET-18-OCH3, a dominant negative PLCγ1 construct or PLCγ1-siRNA reduced this response by > 3-fold. Because PLCγ1 is classically associated with the production of DAG and InsP3, we examined the effect of a DAG lipase inhibitor (RHC-80267) and InsP3R antagonist (2-APB) on Runx2. Surprisingly, neither inhibitor had the expected effect on Runx2 activity, suggesting that an alternate pathway downstream of PLCγ1 generates the second messenger that is communicated by Cx43. Indeed, siRNA- knockdown of inositol polyphosphate multikinase (IPMK), which generates InsP4 and InsP5, and inositol hexakisphosphate kinase 1 (IP6K1), which generates inositol pyrophosphates (InsPP), prevented the Cx43-dependent potentiation of FGF2-induced signaling through Runx2, reducing transcriptional activity by ~50%. Likewise, the IP6K inhibitor TNP abolished basal and Cx43-dependent Runx2

activity, and blocked the interaction of Runx2 and PKCδ as determined by co-immunoprecipitation. This is likely due to the observation that IP6K1 but not IP6K2 siRNA prevented the nuclear accumulation of PKCδ following FGF2 treatment. To validate a role for InsPP in osteoblast function and Runx2 activity, we examined the effect of TNP on osteogenesis by real time PCR. Treatment with TNP reduced the expression of the Runx2-regulated genes, Col1a1, Osteocalcin and Osterix more than 2-fold, while Runx2 expression was unaffected. These data implicate the InsPP as mediators of the Cx43-dependent amplification of the osteoblast response to FGF2 and suggest that these low molecular weight second messengers may be biologically relevant mediators of osteoblast function that converge on Runx2 and are communicated by Cx43.

A FoxO1-Independent Action of Canonical Wnt signaling in Osteoblasts Regulates Bone Resorption. Aruna Kode^{*}, Ioanna Mosialou, John S Manavalan, Stavroula Kousteni. Columbia University Medical Center, USA

FoxO1 has evolved as a regulator of bone physiology that acts on osteoblasts to control their function at two levels, bone formation and whole body glucose metabolism. However, the role of osteoblast-expressed *FoxO1* in bone resorption has not been explored. We found that *FoxO1* deletion in osteoblasts increased bone resorption by increasing osteoclast numbers. Another molecule known to affect osteoclast formation through its action in osteoblasts is *b-catenin*, the canonical Wnt signaling target. In fact, *FoxO1* and *b-catenin* physically associate in osteoblasts. Therefore, we examined whether *FoxO1* affects bone resorption in association with *b-catenin*. Initial studies using a combination of cell culture assays and mouse models of *FoxO1* lack-of-function (*FoxO1^{osb/-}*) and *b-catenin* gain-of-function (*bcat(ex3)^{osb}*) mutations in osteoblasts supported this hypothesis at the transcriptional level. They showed that *FoxO1* regulates the expression of the *b-catenin* transcriptional targets, *Axin2*, *Tcf1*, *Tcf3* and *Lef1*. In contrast, expression of the *FoxO1* targets *cyclin D1*, *p27Kip1*, *Superoxide Dismutase 2*, *catalase* and *Gadd45* were not affected by *b-catenin*. A potential impact of such interaction on the skeleton was tested *in vivo*. However, genetic experiments did not support a synergism in bone mass regulation. Indeed, constitutive activation of *b-catenin* in osteoblasts (*bcat(ex3)^{osb}* mice) increased bone mass by suppressing osteoclast formation and led to osteopetrosis. This effect is mediated through upregulation of *osteoprotegerin* (*Opg*) expression. Inactivation of a single allele or both alleles of *FoxO1* in osteoblasts in compound *FoxO1^{osb/+};**bcat(ex3)^{osb}* or *FoxO1^{osb/-};**bcat(ex3)^{osb}* mice did not affect early onset osteopetrosis caused by constitutive activation of *b-catenin*. Osteoclast formation and bone volume were not reinstated in *FoxO1^{osb/+};**bcat(ex3)^{osb}* or *FoxO1^{osb/-};**bcat(ex3)^{osb}* mice. Similarly, thickening of the ribs and the formation of osteomata, benign bone tumors of the ribs, as well as the lack of tooth eruption observed in *bcat(ex3)^{osb}* mice were not affected by either *FoxO1* haploinsufficiency or by complete deletion of *FoxO1* in osteoblasts. Similar to *bcat(ex3)^{osb}* mice, normal osteoblast numbers were observed in *FoxO1^{osb/+};**bcat(ex3)^{osb}* animals. These observations identify *FoxO1* as a transcriptional potentiator for some of the TCF binding properties of *b-catenin*. However, the anti-osteoclastogenic effects of *b-catenin* occur independent of *FoxO1* activity.

Activated G_s Signaling in Immature Osteoblasts Alters the Hematopoietic Stem Cell Niche in Mice. Edward Hsiao^{*1}, Koen Schepers¹, Mark Scott², Trit Garg¹, Emmanuelle Passegue¹. ¹University of California, San Francisco, USA, ²Gladstone Institute for Cardiovascular Disease, USA

Adult hematopoiesis occurs primarily in the bone marrow space where blood cells closely interact with stromal niche cells, including osteoblastic lineage cells. Despite this close association, little is known about the specific roles of osteoblasts in supporting hematopoietic stem cell (HSC) function, and how conditions affecting bone formation influence hematopoiesis. Here, we use a constitutively-active engineered G_s-coupled G-protein coupled receptor (GPCR) to activate G_s-GPCR signaling in osteoblasts and assess how the concomitant increase in bone formation impacts HSC function and blood homeostasis. The Col1(2.3)^{+/Rsl1+} transgenic mouse model showed a 5-15 fold increase in trabecular bone mass with near complete loss of the normal bone marrow cavity, with histological features similar to fibrous dysplasia of the bone. The mice showed BM aplasia with progressive loss of up to 85% of HSC numbers and impaired megakaryocyte and erythrocyte development with defective recovery after myeloablation with 5FU. These blood phenotypes developed without compensatory extramedullary hematopoiesis. Surprisingly, the loss of HSCs occurs despite a large expansion of HSC-supportive niche cells, including osteoblasts, mesenchymal stem cells, and endothelial cells. Expression analysis showed that the Col(2.3)^{+/Rsl1+} osteoblasts had decreased expression of key HSC-maintenance genes, including *SDF1*, *VCAM1*, and *Angpt1*, accounting for the impaired ability to support HSC function. In addition, we observed significantly impaired HSC function in competitive transplantation experiments when naive HSCs were initially co-cultured with Col1(2.3)^{+/Rsl1+} OBCs. These findings indicate that long-term activation of G_s-GPCR signaling in osteoblasts of the HSC niche decreases HSC-supportive activity and leads to lineage-specific hematopoietic defects. Our results also suggest that long-term activation of G_s-GPCR signaling, such as in medical conditions of excess

parathyroid hormone, may lead to adverse effects on endogenous HSCs and contribute to hematopoietic disorders such as anemia and thrombocytopenia.

Diet Induced Obesity Enhances Bone Marrow Myeloproliferation by Down-regulating Runx1 and Crebbp Expression. Benjamin Adler^{*1}, Danielle Green¹, M. Ete Chan¹, Clinton Rubin². ¹Stony Brook University, USA, ²State University of New York at Stony Brook, USA

Bone marrow hematopoiesis is a process which is tightly regulated by the bone marrow microenvironment to ensure lifelong hematopoietic production. Obesity increases lifetime susceptibility to a host of chronic diseases, implicating a suppressed immune system. Further, obesity biases bone marrow stromal cells (BMSCs) towards the formation of adipose tissue, compromising the bone marrow niche. Considering the consequences of obesity on immunity and the niche, we hypothesize that a high fat diet (HFD: 60% Kcal from fat) will impair bone marrow hematopoiesis. Seven week old male C57Bl/6J mice were fed either a high fat (HF) or regular chow (RD) diet. Bone marrow was analyzed using flow cytometry after 1 and 6 weeks to characterize hematopoietic cell populations. Within one week, B-cell proportions were reduced by -10% in HF compared to RD ($p < 0.05$). By 6w of HFD B-cells had collapsed by -25% and T-cells were reduced by -33%, while the myeloid cell fraction increased by +16% as compared to RD ($p < 0.01$). In RNA extracted from bone marrow at 6w, the expression of Ebf1 and Pax5, representing commitment to the B-cell lineage, were reduced by -29% and -34% in HF animals ($p < 0.01$). This response is reminiscent of hematopoietic defects in other conditions, such as aging, where excessive myeloproliferation and impairments to lymphopoiesis are seen. Interestingly the expression of hematopoietic transcription factors Runx1 and Crebbp was also decreased in HF animals by -17% and -24% ($p < 0.01$) at 6w. Hematopoietic stem cell quiescence and differentiation are balanced by several transcription factors which were first identified, in cases of extreme dysfunction, as oncogenes. Partial or complete loss of these particular transcription factors has been previously implicated in hematopoietic disorders characterized by the increased myelopoiesis and limited lymphopoiesis described here. This however is the first time that obesity has been observed to impact their expression. These data demonstrate that hematopoiesis is vulnerable to even short-term exposure to HFD, which disrupts leukocyte allocations. The data also indicate that obesity acts through a previously unrecognized mechanism in the bone marrow, down regulation of Runx1 and Crebbp, intimating therapeutic targets. These data emphasize the importance of taking a systems approach to diseases, such as obesity and osteoporosis, whose spatial co-location (bone marrow) may elucidate key pathways and interactions.

Disruption of Hematopoietic Stem Cell Lineage Determination and Increased Rate of Leukemia Cell Engraftment in Mice Lacking Osteoblasts. Maria Krevvata^{*1}, Barbara Silva¹, John S Manavalan¹, Aris Economides², Ellin Berman³, Stavroula Kousteni¹. ¹Columbia University Medical Center, USA, ²Regeneron Pharmaceuticals, Inc., USA, ³Memorial Sloan-Kettering Cancer Center, USA

The fate of hematopoietic stem cells (HSCs) depends on the bone marrow niche. The osteoblast in particular, as a component of the niche, is involved in establishing homing, survival, and differentiation of HSCs. Here we examined the effect of osteoblasts on HSC function. For this purpose, we ablated osteoblasts and examined the effect on the bone marrow compartment and on extramedullary hematopoiesis. Activation of diphtheria toxin A chain (DTA) in collagen type IA1- expressing osteoblast precursors ($DTA_{osb}^{+/-}$ mice) in mice led to 50% reduction in osteoblast numbers while osteoclast surface was not affected. At 10 weeks of age $DTA_{osb}^{+/-}$ mice showed a decrease in bone marrow cellularity. In the bone marrow the hematopoietic stem and progenitor cell (HSPC) pool size, defined by Lin-Sca+c-Kit+ (LSK) cells, increased in $DTA_{osb}^{+/-}$ mice as compared to wild type littermates. The LSK+/CD150+/CD48- subset, a population with a myeloid commitment bias, was increased. The number of myeloid (CD11b+/Gr1+) cells increased in both the bone marrow and the spleen of $DTA_{osb}^{+/-}$ mice. Spleen size was not altered in 10-week old mice but increased with increasing age suggesting an age-dependent increase in extramedullary hematopoiesis in $DTA_{osb}^{+/-}$ mice. Increased myeloid activity was coupled with a reduction in B-lymphopoiesis in the bone marrow and spleen suggesting that the hematopoietic lineage progression was altered. Erythropoiesis was not affected as both the number of Ter119+ erythroid progenitors in the bone marrow and spleen as well as the number of red blood cells was not altered by osteoblast depletion. The functionality of the altered hematopoietic compartment was tested in a model of lymphoma/lymphoblastic leukemia. $DTA_{osb}^{+/-}$ mice injected with leukemic cells showed earlier tumor engraftment in the blood, bone marrow, spleen and liver as compared to wild type littermates. Total tumor burden was increased and overall survival was significantly shorter following osteoblast ablation. A 50% increase in hind-limb paralysis supported the finding of increased tumor burden at bone sites of $DTA_{osb}^{+/-}$ mice. These results indicate that osteoblast ablation alters lineage determination of HSCs by affecting the myeloid and lymphocytic compartments. Moreover, it allows for a greater engraftment of leukemia cells within the marrow

cavity. The increase in myeloid populations coupled with a decrease in B-lymphopoiesis may predispose to and increase the burden of leukemia.

FGF-2 Maintains a Niche-dependent Population of Self-renewing Highly Potent non-adherent Mesenchymal Progenitors through FGFR2c. Nunzia Di Maggio^{*}, Arne Mehrkens, Adam Papadimitropoulos, Andrea Banfi, Ivan Martin. Basel University Hospital, Switzerland

Bone marrow-derived mesenchymal stem/stromal cells (MSC) are a heterogeneous population of multipotent progenitors capable of generating bone, cartilage and fat tissues and represent a fundamental tool in regenerative medicine. However, MSC are rare and require significant in vitro expansion, which is accompanied by rapid loss of differentiation capacity, limiting their potential for clinical application.

We found that primary human bone marrow (BM) cultures contain a population of intrinsically non-adherent mesenchymal progenitors (NAMP), which are distinct from the initially adhering Colony Forming Units-fibroblast (CFU-f) and are normally discarded in current culture procedures. NAMP could generate an adherent progeny with significantly greater proliferation and multilineage differentiation potential in vitro and 3-fold greater bone formation in vivo, suggesting that they represent a more primitive population. Furthermore, NAMP progeny was enriched with cells expressing CD146, SSEA-4 and SSEA-1, which have been found to mark populations of early multipotent mesenchymal progenitors. Upon serial replating, NAMP were able to regenerate and expand in suspension as non-adherent clonogenic progenitors, while also giving rise to an adherent progeny. This took place at the cost of a gradual loss of proliferative potential, shown by a reduction in colony size. However, when NAMP were expanded on the initial adherent BM fraction, they underwent significantly greater expansion than during serial replating without any loss of proliferative potential. Although not excluding cell-to-cell interactions, conditioned medium experiments showed that the adherent BM fraction positively regulates NAMP survival and proliferative potential at least in part through secreted signals. The presence of FGF-2 was critical for NAMP maintenance, but it could not induce them from the adherent fraction at any time during culture. Mechanistically, we found that NAMP function specifically depends on signaling through FGFR2c, which is expressed during osteogenesis and alterations of which have been described to affect the balance between self-renewal and differentiation of osteoprogenitors in vivo.

In conclusion, our data show that the adherent BM fraction can provide a niche function for the in vitro self-renewal of highly potent non-adherent mesenchymal progenitors and suggest potential strategies to overcome a crucial limitation in the use of MSC for regenerative medicine.

Generation and Characterization of Osterix-Cherry Reporter Mice. Sara Strecker^{*1}, Yu Fu¹, Peter Mave². ¹University of Connecticut, USA, ²University of Connecticut Health Center, USA

Objectives: Osterix is a zinc finger transcription factor which functions as a master regulator of osteoblast differentiation. We report here on the generation of Osterix-mCherry reporter mice. Methods: We subcloned a 40 kb region encompassing the Osterix gene from BAC clone RP24-362M3. An mCherry fluorescent reporter was then inserted into this subcloned genomic DNA region. Pronuclear injection was carried out with this construct and two founder lines were generated. Results: Preliminary characterization of reporter gene expression at early postnatal ages indicates Osterix expression is largely restricted to cells of the osteoblast lineage. Robust mCherry expression can be detected in cells of the osteoblast lineage in the skull, long bones, and axial skeleton. Reporter expression can also be detected in the kidney. At adult ages, Osterix expression is not exclusive to the osteoblast lineage and is moderately expressed in hypertrophic chondrocytes and weakly expressed in cells present within the bone marrow. Osterix expressing cells in the bone marrow appear close to, but are not on the bone surface. These cells appear similar to reticular cells with regards to their cell morphology. To validate the expression pattern of Osterix-mCherry reporter expression, we carried out immunostaining studies for endogenous Osterix protein on tissue sections. Also, qRT-PCR analysis for Osterix on FACS isolated cells from day 5 stromal cultures revealed that the mCherry positive cell fraction was approximately 35 fold higher in endogenous Osterix gene expression relative to the negative cell fraction. Conclusions: These studies substantiate that our reporter accurately represents endogenous Osterix expression in the cortical bone and cells of the bone marrow. The identity and significance of these mCherry positive cell types is currently under investigation. Future studies will further validate and characterize the mCherry + reporter expression relative to endogenous Osterix gene expression.

Legumain: A Novel Regulator of Human Skeletal (Mesenchymal) Stem Cell Differentiation. Diyako Qanie*¹, Abbas Jafari², Kenneth Hauberg¹, Li Chen³, Moustapha Kassem⁴. ¹University of Southern Denmark, Denmark, ²University of Southern Denmark, Denmark, ³Medical Biotechnology Center (MBC), Denmark, ⁴Odense University Hospital, Denmark

Secreted proteins of human skeletal (mesenchymal) stem cells (hMSC) may play an important role in controlling hMSC biological function via autocrine or paracrine effects. Thus, we employed quantitative proteomic analysis by Stable Isotope Labelling in Cell Culture (SILAC) and identified 315 proteins that exhibit significant (≥ 2 fold) changes during osteoblast (OB) differentiation of hMSC. Among the 14 up-regulated secreted proteins with unknown function in hMSC biology, we identified Legumain (LGMN), also called asparaginyl endopeptidase (AEP) which is a cysteine protease enzyme hydrolyzing asparaginyl bonds. Previous studies showed that LGMN exerted inhibitory effects on osteoclast differentiation via its C terminal fragment. We confirmed the production and regulation of LGMN during OB differentiation of hMSC by RT-PCR and Western blot analysis. Stable silencing of LGMN in hMSC using shRNA significantly promoted osteoblast differentiation while inhibited adipocyte differentiation. On the other hand, stable over-expression of LGMN using lentivirus vector in hMSC showed the reverse effects: significantly reduced osteoblast differentiation and enhanced adipocyte differentiation. Furthermore, conditioned medium obtained from LGMN over-expressing hMSC reduced osteoblast differentiation. In conclusion, our data demonstrated a novel autocrine/paracrine role of LGMN regulating the balance between osteoblast and adipocyte differentiation of hMSC by inhibiting osteogenesis and promoting adipogenesis of hMSC in bone marrow. Thus targeting LGMN expression could be a therapeutic drug for enhancing bone formation in bone-loss related diseases.

NF- κ B RelB Null Mice Develop Erosive Arthritis by Increasing Inflammatory Monocyte/Macrophages. Zhenqiang Yao*¹, Yanyun Li², Lianping Xing¹, Brendan Boyce². ¹University of Rochester, USA, ²University of Rochester Medical Center, USA

RelB, a NF- κ B family member, typically forms heterodimers with p52 to activate alternative NF- κ B signaling. RelB^{-/-} mice have normal basal, but impaired RANKL-induced osteoclast (OC) formation in vitro and metastasis-mediated resorption. We have found that RelB^{-/-} mice develop age-related trabecular bone gain, which we attribute to increased osteoblast (OB) functions. We generated RelB/p52 double KO (dKO) mice in a B6/129 background (BG) and found that these and RelB^{-/-} mice in this BG are more healthy than RelB^{-/-} mice in the original BG but still have impaired RANKL-induced OC formation in vitro. However, ~50% of the mice in the mixed BG develop erosive arthritis, with marked synovial inflammation (area 1.2 ± 0.4 and 1.4 ± 1 mm²/knee joint in ^{-/-} and dKO mice, respectively) accompanied by activated OCs (12.3 ± 8.3 and 16.3 ± 2.1 per knee joint) eroding bone. In contrast to the impaired RANKL-induced OC formation in vitro, the ^{-/-} mice have enhanced TNF-induced OC formation and resorption (pit area 1.1 ± 0.2 vs. 0.23 ± 0.02 mm²/slice) when we used fewer OC precursors (OCPs) because ^{-/-} mice have 5-10 fold more inflammatory monocyte/macrophages (Mon/Macs) which are mainly CD11b+Gr-1+F4/80+(M1). M-CSF, GM-CSF and TNF independently drive myeloid precursor differentiation to Mon/Macs which include 3 populations: CD11b+Gr-1+F4/80+(M1), CD11b+Gr-1-F4/80+ (M2) and CD11b-Gr-1-F4/80+ (M3) Mon/Macs. Comparing bone marrow (BM) cells cultured from WT and ^{-/-} mice, we found that M-CSF induced 86% vs 51% M2; GM-CSF induced 46% vs. 49% M1 and 14% vs. 32% of M3; TNF induced 21% vs. 61% M1 and 10% vs. 16% of M3. Notably, ^{-/-} mice have age-dependent increased TNF but not M-CSF or GM-CSF levels in serum and BM, reflecting TNF inducing its own transcription by activating RelA, and RelB forming an inhibitory complex with RelA to inhibit TNF transcription. RANKL plus either GM-CSF or TNF did not induce OC formation, consistent with RelB^{-/-} mice having more M1 Mon/Macs which form fewer OCs in vitro. However, RANKL induced significant numbers of OCs in ^{-/-} mice, suggesting that ^{-/-} myeloid precursors respond normally to RANKL in vivo. We conclude that RelB negatively regulates TNF production and the increased TNF in RelB^{-/-} mice drives myeloid precursor differentiation into inflammatory Mon/Macs (M1) which mediate joint inflammation and enhance OC function to erode bone. Development of small molecular analogs of RelB could provide a novel approach for the treatment of inflammatory arthritis.

Disclosures: Zhenqiang Yao, None.

FR0244

Osteocyte-derived RANKL in Bone Remodeling. Tomoki Nakashima*¹, Mikihito Hayashi¹, Hiroshi Takayanagi². ¹Tokyo Medical & Dental University, Japan, ²The University of Tokyo Department of Immunology, Japan

RANKL and its receptor RANK are key regulators of osteoclastogenesis. Aberrant expression of RANKL explains why autoimmune diseases, cancers, and periodontal disease are associated with systemic and local bone loss. In particular, RANKL is the pathogenic factor that causes bone and cartilage destruction in arthritis. Inhibition of RANKL function by the decoy receptor osteoprotegerin or anti-RANKL antibody prevents bone loss in postmenopausal osteoporosis, cancer metastasis and arthritis. RANKL has been postulated to be mainly expressed by osteoblasts, BMSCs and T cells, but there has been no genetic evidence regarding the major cellular source of RANKL in the bone microenvironment. We show that osteocytes embedded within the bone matrix are the critical source of RANKL in bone remodeling. Osteocytes, the most abundant cell type in bone tissue, are thought to orchestrate bone homeostasis by regulating both bone resorption and formation, but in vivo evidence and the molecular basis for the regulation has not been sufficiently demonstrated. To unambiguously isolate high purity osteocytes from bone tissue, we generated osteocyte-specific EGFP reporter mice in which osteocytes could be identified by the expression of EGFP driven by the Dmpl promoter. Using fluorescence activated cell sorting, we established a method for the isolation of high purity osteocytes from the fractions obtained by enzymatic digestion of bone. The isolated osteocytes morphologically exhibited dendritic processes and exclusively expressed Dmpl, Sost, Reln and Npy, which are well-known osteocyte-specific genes. In contrast, osteoblast-specific genes such as Kera and Fmod were strongly expressed in isolated osteoblasts. Notably, osteocytes express a much higher amount of RANKL and have a much greater capacity to support osteoclastogenesis than either osteoblasts or BMSCs. The crucial role of RANKL expressed by osteocytes was validated by the severe osteopetrotic phenotype observed in adult mice lacking RANKL specifically in osteocytes. In addition, we generated T cell-specific Tnfsf11-deficient mice, which did not exhibit any discernible osteopetrotic phenotype, indicating that the RANKL expressed on T cells does not significantly contribute to the physiological regulation of osteoclastogenesis. Thus, we provide in vivo evidence for the key role of osteocyte-derived RANKL in bone remodeling, establishing a molecular basis for osteocyte regulation of bone resorption.

RANKL Employs Distinct Binding Modes to Engage RANK and OPG. Christopher Nelson¹, Julia Warren*², Steven Teitelbaum², Daved Fremont¹. ¹Washington University in St. Louis, USA, ²Washington University in St. Louis School of Medicine, USA

The soluble decoy receptor osteoprotegerin (OPG) plays a pivotal role in bone biology by moderating the processes that control bone mineral density. OPG binds to, and sequesters, all known forms of the TNF-related cytokine RANKL (receptor activator of NF- κ B ligand), and by doing so interferes with activation of the cell-surface receptor RANK. Here we report the crystal structures of the cytokine-binding regions of murine OPG and RANK in complex with murine RANKL. Although OPG and RANK are related members of the tumor necrosis factor receptor superfamily, the contradictory biological functions of the two receptors (soluble-decoy versus cell-surface signaling) impose different structural constraints on their binding domains. Although similar in domain organization and structure - the cytokine-binding regions of both receptors consist of four cysteine-rich domains (CRDs) linked in tandem - monomeric OPG binds RANKL with roughly 24-fold higher affinity than RANK, and inhibits RANKL-stimulated osteoclastogenesis approximately 50-times more effectively. The difference in affinity is largely attributable to a much longer off-rate of OPG compared to RANK. Several RANKL residues shift their orientation leading to rearrangement of the C-D and D-E loops. These shifts result in a much more hydrophobic binding groove for OPG than for RANK. Indeed, a tight fit of OPG with RANKL does not appear possible without significant shifts in the positions of side chains within the receptor-binding cleft. High affinity binding requires OPG^{F127}, a residue mutated in juvenile Paget's disease. These results suggest that cytokine plasticity may modulate the interactions of specific TNF-family cytokine/receptor pairs in order to fine tune receptor selectivity.

RANKL Induces TRAF3 Lysosomal Degradation Through NF- κ B RelB, an Effect Prevented by the Lysosome Inhibitor Chloroquine. Yan Xiu*¹, Yoshikazu Morita², Chen Zhao¹, Zhenqiang Yao³, Lianping Xing³, Brendan Boyce¹. ¹University of Rochester Medical Center, USA, ²Megmilk Snow Brand Co., Ltd., Japan, ³University of Rochester, USA

TRAF3 inhibits RANKL-induced osteoclast (OC) formation through proteasomal degradation of NF- κ B-inducing kinase (NIK) and thus could limit resorption in

inflammatory bone diseases, such as rheumatoid arthritis (RA). However, RANKL also promotes TRAF3 degradation to activate NIK-induced NF- κ B canonical and non-canonical signaling, but how TRAF3 is degraded (lysosomal vs proteasomal) or how it inhibits OC formation is unclear. Hydroxychloroquine is a lysosome inhibitor, used to reduce inflammation in RA, but its effects on OCs are unknown. We report that chloroquine (CQ) reduced OC #s by 3-fold and resorption by >90% *in vitro* associated with increased TRAF3 protein levels. We generated OC-specific TRAF3^{-/-} mice and observed 2-fold more OCs in their calvarial bones vs WT mice. CQ reduced OC #s by 50% in WT mice *in vivo* but had no effect in TRAF3^{-/-} mice. CQ significantly reduced PTH-induced marrow fibrosis in WT (11 ± 1 vs 29 ± 3% with PBS), but not in TRAF3^{-/-} mice (30 ± 4 vs 28 ± 3%). Retroviral expression of TRAF3 in OC precursors (OCPs) significantly reduced RANKL-induced OC #s, associated with reduced NF- κ B RelA, RelB, and NIK protein levels and decreased p100 processing to p52, suggesting that TRAF3 suppresses canonical and non-canonical signaling to inhibit OC formation. We treated WT OCPs with RANKL and the proteasome inhibitor, MG132, the lysosome inhibitors, NH₄Cl or CQ, or the autophagy inhibitors, Bafilomycin or 3-Methyladenine, and found that only the lysosome and autophagy inhibitors prevented RANKL-induced TRAF3 degradation. We over-expressed a TRAF3-GFP fusion protein in OCPs and found that TRAF3 colocalized with the lysosomal protein LAMP2. RANKL increased co-localization of TRAF3 and LAMP2, which was prevented by CQ. Finally, we found that RANKL induced 2.5-fold more TRAF3 expression in RelB^{-/-} OCPs. Furthermore, over-expression of RelB in RelB^{-/-} OCPs reversed this reduced ability of RANKL to degrade TRAF3, indicating RelB is involved in RANKL-induced TRAF3 lysosomal degradation. Our findings indicate that RANKL induces TRAF3 lysosomal/autophagic degradation, an effect mediated by RelB, and that CQ inhibits OC formation *in vitro* and *in vivo* by preventing TRAF3 lysosomal degradation. They suggest that strategies to increase TRAF3 levels in OCPs, such as treatment with CQ or CQ derivatives, will inhibit bone resorption in conditions where RANKL is increased, such as RA.

Activation of the NLRP3 Inflammasome in Myeloid Cells Causes Massive Bone Resorption. Sheri Bonar¹, Cynthia Brecks², Matthew McGeough³, Susannah Brydges³, Chang Yang⁴, Deborah Novack⁵, Hal Hoffman³, Roberto Civitelli⁵, Gabriel Mbalaviele^{*5}. ¹Washington University in St. Louis, USA, ²Washington University In St. Louis, USA, ³University of California, San Diego, La Jolla, CA, USA, ⁴Washington University in St. Louis School of Medicine, USA, ⁵Washington University in St. Louis School of Medicine, USA

Nod Leucine rich Repeat with a Pyrin domain 3 (NLRP3) is a member of the NOD-like receptor family of proteins involved in innate immune responses. NLRP3 forms an inflammasome, intracellular protein complex that converts pro-IL-1 β into mature IL-1 β . We recently reported that mice globally expressing constitutively activated NLRP3 exhibit severe osteopenia stemming from abnormally accelerated bone resorption, attended by increased osteoclastogenesis. To gain insights into the cell context dependent function of NLRP3, we generated knockin mice expressing a constitutively active NLRP3 mutant in myeloid cells driven by the LysM promoter (NLRP3^{LysM}). At 2 weeks of age, NLRP3^{LysM} mice are significantly smaller and osteopenic relative to WT mice based on whole body DXA, histomorphometric and μ CT (50% lower BV/TV) analyses. FACS analysis revealed 3-fold higher number of CD11b^{low}Gr1^{low}CD117⁺ osteoclast (OC) precursors in unfractionated bone marrow cells of NLRP3^{LysM} mice relative to WT mice. Consistent with these results, the number of OC developing from unfractionated bone marrow cells or cultured bone marrow macrophages (BMMs) in the presence of M-CSF and RANKL was higher in NLRP3^{LysM} cells than in WT cells. In addition, degradation of poly(ADP-ribose) polymerase 1, a negative regulator of OC formation and substrate of the inflammasome, increased during osteoclastogenesis of NLRP3^{LysM} BMMs to a larger extent than in WT cells. Conversely, BMMs from ASC (another component of the inflammasome) or NLRP3 knockout mice formed fewer OC than WT BMMs. Thus, NLRP3 activation increases both the number of OC precursors and their sensitivity to osteoclastogenic factors. Consistent with the notion that bone degradation products might serve as endogenous activators of NLRP3, hydroxyapatite crystals (HA) induced IL-1 β production by 300-fold in BMMs, an effect that required the presence of NLRP3 and ASC. Moreover, treatment of co-cultures of WT BMMs and bone marrow stromal cells with HA led to increased OC formation. In summary, NLRP3^{LysM} mice phenocopy the severe osteopenia of mice globally expressing constitutively activate NLRP3, demonstrating that NLRP3 drives osteoclastogenesis acting directly in the myeloid lineage. Since NLRP3 activation by HA stimulates IL-1 β production and osteoclastogenesis, bone degradation products activation of the NLRP3 inflammasome in bone-resident myeloid cells may result in a positive feedback that amplifies bone resorption.

Calcium/calmodulin-signaling Regulates TRPV4 Action by the Process Supporting Myosin IIA Association in Osteoclasts. Ritsuko Masuyama^{*1}, Atsuko Mizuno², Hiroshi Kaijiya³, Hideki Kitaura⁴, Koji Okabe³, Toshihisa Komori¹. ¹Nagasaki University Graduate School of Biomedical Sciences, Japan, ²Jichi Medical University, Japan, ³Fukuoka Dental College, Japan, ⁴Tohoku University, Japan

Osteoclast differentiation is critically dependent on Ca²⁺ signaling. A Ca²⁺ permeable channel, transient receptor potential vanilloid 4 (TRPV4), mediates Ca²⁺ influx in the late stage of osteoclast differentiation and thereby regulates Ca²⁺ signaling. We previously reported that *Trpv4*-null mice had increased bone mass resulting from impaired osteoclast maturation, and found that the system supplying cellular Ca²⁺ switched from Ca²⁺ oscillations to Ca²⁺ influx during osteoclast differentiation. However, the system-modifying effect of TRPV4 activity remains to be determined. To elucidate the mechanisms underlying TRPV4 activation based on osteoclast differentiation, TRPV4 gain-of-function mutants were generated by the amino acid substitutions R616Q and V620I in TRPV4 and were restrictedly introduced into osteoclast lineage in *Trpv4* null mice to generate osteoclasts *Trpv4*^{R616Q/V620I} rescue mice.

As expected, TRPV4 activation increased osteoclasts surface in tibia section (+260% vs *Trpv4*-null, +80% vs WT; $P < 0.01$), thereby resulting in bone loss (-24% vs *Trpv4*-null, -12% vs WT mice; $P < 0.05$). During *in vitro* analysis, *Trpv4*^{R616Q/V620I} osteoclasts showed activated Ca²⁺/calmodulin signaling compared with osteoclasts lacking *Trpv4* as shown by the increased *NFATc1* expression. Although the regulatory system involved with TRPV4 activation in osteoclasts remains unknown, the Ca²⁺/CaM complex has been suggested as one possible regulator because osteoclasts differentiation is accompanied by dramatic induction of calmodulin. We therefore investigated *Trpv4*^{R616Q/V620I} mice that lacked the calmodulin-binding domain (*Trpv4*^{R616Q/V620I- Δ CaM). Bone loss due to TRPV4 activation was abrogated by loss of interactions between Ca²⁺/calmodulin signaling and TRPV4 that observed in *Trpv4*^{R616Q/V620I- Δ CaM mice. Finally, modulators of TRPV4 interactions with the calmodulin-binding domain were investigated by proteomic analysis. Interestingly, non-muscle myosin IIA was identified by LC-MS/MS analysis, which was confirmed by immunoblotting following coimmunoprecipitation with TRPV4. Furthermore, myosin IIA gene silencing significantly reduced TRPV4 activation concomitant with impaired osteoclast migration examined by wound healing assay.}}

These results indicate that TRPV4 activation reciprocally regulates Ca²⁺/calmodulin signaling, which involves an association of TRPV4 with myosin IIA, and supports sufficient osteoclast function.

Foxp3, the Master Transcriptional Regulator in Regulatory T Cells, Controls Osteoclastogenesis and Bone Mass. Tim Hung-Po Chen^{*1}, Yousef Abu-Amer². ¹Washington University School of Medicine, USA, ²Washington University in St. Louis School of Medicine, USA

Regulatory T cells (Tregs) play an essential role in prevention of autoimmune response. Scurfy mice, which present spontaneous null mutation of the forkhead gene *foxp3*, lack Tregs and immune self-tolerance and mimic the human disease IPEX (immunodysregulation polyendocrinopathy enteropathy X-linked syndrome) which is associated with bone deformities. Despite recent research in Tregs, the mechanism of Foxp3 in bone remains unclear. In this study, we first evaluated parameters of bone in scurfy mice and found that lack of Foxp3 led to osteoporotic phenotype in mice. Histological and μ CT analyses revealed increased osteoclasts, thinner cortical bone, and reduced trabecular regions in the Foxp3 deficient scurfy mice than in wildtype controls. Taken together, Foxp3 deficient mice exhibited increased erosion and poor bone quality. We next examined gene expression of inflammatory cytokines of magnetic beads sorted CD4⁺ T cells in these mice by qRT-PCR. RANKL, TNF α and IL-17, were up-regulated. *NFATc1* mRNA and NEMO/IKK γ protein were also increased in CD4⁺ T cells. Co-immunoprecipitation assays revealed physical interaction between NEMO and Foxp3 in both primary CD4⁺ T cells and transiently transfected 293T cells, suggesting a post-translational regulatory mechanism of NEMO protein via Foxp3. The notion that expression of Foxp3 is T cell-exclusive has been recently challenged. Therefore, we tested whether in addition to extrinsic cues from Tregs, Foxp3 is also required in osteoclastogenesis in a cell intrinsic manner. We found that macrophages derived from scurfy mice generated more osteoclasts compared with wild type controls. Interestingly, flow cytometry analysis revealed that the protein expression of Foxp3 was down-regulated 7-fold in the wildtype culture during this course of RANKL treatment, suggestive of an inhibitory role of Foxp3 in RANKL induced osteoclastogenesis. These cells also showed higher proliferative activity (S-phase cells) in cultures as assessed by BrdU flow cell cycle analysis. Phenotypic analysis by flow cytometry revealed a proportion of CD11b⁺ monocyte/osteoclast precursors was markedly increased in Foxp3 deficient bone marrow, whereas a proportion of gr1⁺ granulocyte/myeloid derived suppressor cells (MDSCs) and CD11c dendritic cells were decreased. In summary, our findings suggest that Foxp3 may play a critical role in bone metabolism, not merely by its conventional function in Tregs but by directly affecting osteoclast development

Impairment of Osteoclastic Bone Resorption in Rapidly Growing Female p47^{phox} Knockout Mice. Jin-Ran Chen^{*1}, Kelly Mercer², Oxana P. Lazarenko³, Thomas M. Badger⁴, Martin J. J. Ronis⁵. ¹Arkansas Children's Nutrition Center, & Department of Pediatrics, University of Arkansas for Medical Sciences, USA, ²Arkansas Children's Nutrition Center, USA, ³Arkansas Children's Nutrition Center, & Department of Physiology & Biophysics, University of Arkansas for Medical Sciences, USA, ⁴Arkansas Children's Nutrition Center. The Departments of Pediatrics, Physiology & Biophysics, University of Arkansas for Medical Sciences, USA, ⁵Arkansas Children's Nutrition Center, & Department of Pediatrics, Pharmacology & Toxicology, University of Arkansas for Medical Sciences, USA

Bone formation is dependent on the activity and differentiation of osteoblasts; whereas resorption of preexisting mineralized bone matrix by osteoclasts is necessary not only for bone development but also for regeneration and remodeling. Bone remodeling is a process in which osteoblasts and osteoclasts are coupled. It changes dramatically during the course of development as it undergoes age-dependent regulation. Accumulation of reactive oxygen species (ROS) has been suggested to inhibit bone remodeling at each life stage. Tightly controlled and cell-specific NADPH-oxidase (Nox) activities represent one of the major sources of ROS in many cell types. Here, we have utilized a p47^{phox} knockout mouse model in which the majority of Nox activity is lost as the result of loss of an essential cytosolic co-activator, and characterized bone phenotype in these mice compared to their wild type controls. We found that, in female p47^{phox} -/- mice at 6 weeks of age, bone mineral density and bone mineral content were higher in comparison to wild type controls (P < 0.05). Consistent with this, bone strength was found to be higher in femur from p47^{phox} -/- mice, compared with those from wild type controls, in three point bending tests (P < 0.05). Flow cytometric analysis showed that osteoblastic calvarial cells isolated from female p47^{phox} -/- mice had significantly lower levels of ROS. Furthermore, bone histomorphometric analysis revealed that osteoclast number was lower in p47^{phox} -/- mice compared with their wild type controls (P < 0.05). This is in agreement with reduced gene expression of bone resorption markers RANKL and TRAP in RNA isolated from both femur and bone marrow cells from female p47^{phox} -/- mice compared to their wild type controls (P < 0.05). Moreover, in *ex vivo* primary osteoblast and osteoclast precursor co-culture, TRAPase staining revealed lower numbers of mature osteoclasts (containing 3 or more nuclei) in wild type primary osteoblasts plus p47^{phox} -/- pre-osteoclast cultures compared with wild type primary osteoblasts plus wild type pre-osteoclast cultures. These data indicate that the high bone mass in 6 week old female p47^{phox} -/- mice is due to lower ROS generation leading to decreased osteoclastogenesis. *Supported in part by ARS CRIS #6251-51000-005-03S (JRC) and R01 AA18282 (MJJR).*

Canonical Wnt Signaling Mediates an Osteoprotegerin-independent Inhibitory Effect on Osteoclastogenesis. Johannes Keller^{*1}, Michael Amling¹, Joachim Albers², Anke Baranowsky³, Thorsten Schinke⁴. ¹University Medical Center Hamburg-Eppendorf, Germany, ²Universitätsklinikum Hamburg Eppendorf, Germany, ³Universitätsklinikum Hamburg-Eppendorf, Germany, ⁴Department of Osteology & Biomechanics University Medical Center Hamburg Eppendorf, Germany

Wnt signaling plays a pivotal role in the regulation of bone remodeling, and its inhibition by specific antagonists is one of the causes for excessive bone resorption observed in individuals with multiple myeloma. Since an osteoblast-specific inactivation of β -catenin, the major intracellular mediator of canonical Wnt signaling, causes reduced expression of the osteoclastogenesis-inhibitor Opg, it appeared that this influence is solely mediated indirectly. Here we show that activating canonical Wnt signaling in murine bone marrow cells inhibits their differentiation into multinucleated osteoclasts, independent of Opg. Likewise, specific inactivation of β -catenin in the osteoclast lineage results in osteopenia due to increased osteoclastogenesis, despite normal Opg production. The same phenotypic abnormalities were observed in mice lacking the Wnt receptor Frizzled-8 (Fzd8), which was identified as a candidate regulator of bone resorption by genome-wide expression analyses. Taken together, these findings demonstrate that osteoclastogenesis is directly regulated by canonical Wnt signaling, and that this regulation is mediated, at least in part, through the serpentine receptor Fzd8.

Foxp3⁺ CD8 T-Cells Can Suppress Bone Turnover in Response to RANKL Administration and in Ovariectomized Mice. Reggie Aurora^{*1}, Zachary Buchwald², Jennifer Kiesel², Deborah Novack³, Richard Di Paolo². ¹Saint Louis University University, USA, ²Saint Louis University School of Medicine, USA, ³Washington University in St. Louis School of Medicine, USA

We have been previously shown that osteoclasts can cross-present antigens. Co-culturing CD8⁺ T-cells with osteoclasts induced a FoxP3⁺ regulatory phenotype *in vitro* in the presence of antigen [1]. These osteoclast-induced FoxP3⁺ CD25⁺ CD8 T-cells (OC-iT_{REG}) can suppress osteoclast activity *in vitro* in a cell-contact independent, cytokine dependent manner. To determine if OC-iT_{REG} could suppress bone turnover *in vivo* we adoptively transferred these T-cells into an OT-I transgenic mouse that lacks endogenous T_{REG}. We then injected the recipient mice with RANKL. Suppression of bone turnover (as measured by CTX) was observed in the mice that received T_{REG}. In contrast no suppression was observed in the untreated controls or in mice treated with anti-CD3/CD28 activated CD8 T-cells. We have also shown that the OC-iT_{REG} can suppress bone turnover in ovariectomized (OVX) mice, a model of post-menopausal osteoporosis. A single infusion of OC-iT_{REG} into mice two weeks post-OVX reduced bone turnover for at least 10 days. Next, to investigate whether the endogenous FoxP3⁺ CD8 T-cells could also suppress osteoclast resorption, we used the FoxP3^{GFP} reporter mouse and found that GFP⁺ but not GFP⁻ CD8 T-cells purified from the bone marrow could suppress osteoclast pitting *in vitro*. To determine whether the endogenous CD8⁺ T-cells also have bone regulatory activity *in vivo*, we performed a RANKL dose titration into wt mice and mice lacking CD8⁺ T-cells (TCR α -, b2M-). Mice lacking CD8⁺ T-cells had increased bone turnover relative to wt controls, at doses > 0.5 mg/kg RANKL. To confirm the observed suppression was due to the absence of CD8 T-cells, TCR α - mice were reconstituted with fractionated CD8 or CD4 T-cells. Mice that received CD8 T-cells showed suppression whereas the CD4 did not. Our results show that OC-iT_{REG} and endogenous CD8 T-cells can suppress osteoclast activity *in vitro* and *in vivo*.

Mice with Inactivating Mutations in the RANK PVQEET⁵⁶⁰⁻⁵⁶⁵ and PVQEQG⁶⁰⁴⁻⁶⁰⁹ Motifs Exhibit Increased Bone Mass Due to Impaired Osteoclastogenesis. Zhenqi Shi^{*1}, Joel Jules², Bob Kesterson³, Dongfeng Zhao⁴, Xu Feng⁵. ¹University of Alabama, USA, ²University of Miami Miller School of Medicine, USA, ³Department of Genetics, UAB, USA, ⁴The University of Alabama At Birmingham, USA, ⁵University of Alabama at Birmingham, USA

RANKL plays a crucial role in osteoclastogenesis by activating RANK, which activates various signaling pathways including NF- κ B, JNK, ERK, p38 and Akt in osteoclast precursors by recruiting TNF receptor-associated factors (TRAFs). *In vitro* studies have identified three functional TRAF-binding motifs: PFQEP³⁶⁹⁻³⁷³ (Motif 1), PVQEET⁵⁶⁰⁻⁵⁶⁵ (Motif 2), and PVQEQG⁶⁰⁴⁻⁶⁰⁹ (Motif 3) in the RANK cytoplasmic domain. Notably, Motif 2 and Motif 3 are more potent than Motif 1 in mediating osteoclastogenesis *in vitro*, and mutation of both Motif 2 and Motif 3 dramatically impaired RANK's ability to promote osteoclastogenesis *in vitro*. To validate these findings *in vivo*, we generated knockin (KI) mice bearing inactivating mutations in Motif 2 (PVQEET to LLNDDS) and Motif 3 (PVQEQG to LLNDNA). The introduced mutations were confirmed by sequencing. Western blot and RT-PCR analyses verified that bone marrow macrophages (BMMs) from wild type (WT), heterozygous KI (RANK^{+/mut}) and homozygous KI (RANK^{mut/mut}) mice have similar levels of RANK expression. RANK^{mut/mut} mice are viable, born at the expected Mendelian frequency, and have normal tooth eruption. However, X-ray and micro-computed tomography (μ CT) analysis of femurs of 12-week old mice have revealed dramatic increases in bone mass in RANK^{mut/mut} compared to age and sex matched WT counterparts. Consistently, BMMs from RANK^{mut/mut} mice failed to form osteoclasts in tissue culture dishes and on bone slices *in vitro* in response to M-CSF and RANKL stimulation. Mechanistically, while RANKL-induced activation of the NF- κ B, ERK, p38, JNK and Akt pathways remains normal in RANK^{mut/mut} BMMs, RANKL-stimulated expression of NFATc1 is impaired in these cells. Given that TNF α - and IL-1-mediated osteoclastogenesis requires RANK signaling, we further examined the role of Motifs 2 and 3 in TNF α /IL-1-mediated osteoclastogenesis. We found that the capacity of TNF α and IL-1 to promote osteoclastogenesis from RANK^{mut/mut} BMMs in the presence of RANKL in tissue culture dishes and on bone slices is significantly impaired, indicating that Motifs 2 and 3 are integral signaling components to initiate normal RANK signaling to support TNF α - and IL-1-mediated osteoclastogenesis. These findings indicate that Motifs 2 and 3 are critical for osteoclastogenesis *in vivo* and thus they have the potential to serve as novel therapeutic targets for osteoporosis and bone erosion in rheumatoid arthritis.

Stat5 Suppresses Bone Resorption of Osteoclasts by Upregulating Expression of Dusp Family. Jun Hirose*, Hironari Masuda, Yasunori Omata, Sakae Tanaka. The University of Tokyo, Japan

Signal transducers and activators of transcription (Stats) are family of proteins which transmit the signals of various cytokines through Jak/Stat pathways. Stat5 is a member of Stat family and essential for cytokine-regulated processes such as proliferation, differentiation, and survival in hematopoietic cells. To investigate the role of Stat5 in osteoclasts, we generated mice with osteoclast-specific conditional deletion of Stat5a and Stat5b (Stat5cKO mice) by crossing Stat5a&b floxed mice and Cathepsin K-Cre mice. They grew normally without apparent morphological abnormalities, but they exhibited decreased bone mass as assessed by micro CT and DEXA, which became prominent in the course of aging. The mice exhibited an increased serum level of CTx-I, and histomorphometric analysis of proximal tibia of 8-week-old Stat5 cKO mice revealed a significant increase in the eroded surface/bone surface ratio and the osteoclast surface, but not in the osteoclast number. RANKL and M-CSF-induced osteoclast differentiation was indistinguishable between WT and Stat5 cKO cells and there was no difference in the survival of WT and Stat5cKO osteoclasts. However, bone-resorbing activity of Stat5 cKO osteoclasts was markedly promoted as compared with WT osteoclasts. To examine the mechanisms underlying, we analyzed major intracellular signaling pathways in Stat5 cKO osteoclasts, and found that Erk activity was increased in cKO osteoclasts. The expression of MAPK phosphatases Dusp (dual specific phosphatase) 1 and 2 was significantly decreased in Stat5 cKO osteoclasts as determined by DNA microarray and real-time RT-PCR analyses. Retrovirus vector-mediated overexpression of Stat5 promoted Dusp1 and 2 expression in osteoclasts. Among the known stimulators of Stat5, IL-2, IL-3, IL-5, GH and PRL, only IL-3 induced activation of Stat5 in osteoclasts, and nuclear translocation of Stat5 was observed in response to IL-3 stimulation. Rapid induction of Dusp1 and 2 expression by IL-3 was observed in WT osteoclasts but not in Stat5 cKO osteoclasts. Our results suggest that Stat 5 negatively regulates the bone-resorbing function by promoting Dusp1 and 2 expression, and IL-3 may be one of the stimulators of Stat5 in osteoclasts.

Evaluation of Osteocyte Dedifferentiation in vitro and in vivo. Elena Torreggiani*¹, Slavica Pejda¹, Igor Matic¹, Mark Horowitz², Ivo Kalajzic¹. ¹University of Connecticut health Center, USA, ²Yale University School of Medicine, USA

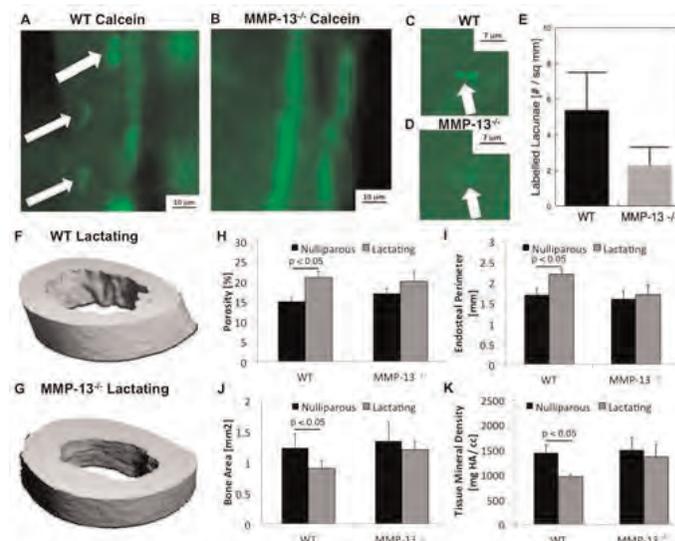

Cellular dedifferentiation has been observed in biological phenomena such as carcinogenesis, but it has been difficult to study due to a lack of experimentally traceable systems. Presently, there is no evidence for the ability of mature osteoblast lineage cells to dedifferentiate. The use of visual transgenes, such as GFP, has been instrumental for identifying cells at different stages of maturation. However, markers expressed under the control of a specific promoter are no longer expressed when promoter activity ceases. A valuable tool for lineage tracing is the Cre/loxP system. In this study we present evidence that DMP-1 expressing cells (preosteocytes/osteocytes) can undergo dedifferentiation in vitro and in vivo, accompanied by changes in gene expression. We have utilized transgenic mice in which the DMP1 promoter drives GFP expression as a visual marker of the current stage of differentiation (DMP-GFP) or drives Cre recombinase in order to activate an historical reporter in osteocytes and their progeny (DMP-Cre). Primary bone chip outgrowth cell (BCOC) cultures were prepared by enzymatic digestion (collagenase/trypsin/EDTA) to remove surface osteoblasts. When we utilized a DMP-GFP transgene, BCOC were GFP negative by epifluorescence and immunofluorescent staining for GFP. Using DMP-Cre mice bred with a Rosa-tomato reporter strain, cells that emerged from bone chips after 48-72 hours expressed Tomato. This result suggests that cells that have previously expressed the DMP promoter have the ability to dedifferentiate. Using FACS sorting we have isolated DMP-Cre/Tomato+ and DMP-Cre/Tomato- cells and shown that the positive population has the ability to redifferentiate into the osteogenic lineage, while the negative population did not mineralize, but showed some evidence of adipogenesis. BCOC cultures from DMP-GFP/DMP-Cre/Tomato mice also showed redifferentiation with the appearance of dual DMP-GFP+/Tomato+ cells. Following subcutaneous transplantation of whole bone chips derived from DMP-Cre/Tomato mice we observed formation of numerous DMP-Cre/Tomato+ osteoblasts on the surface of bone chips. Our results indicate that under certain conditions cells embedded in the matrix can grow out and begin to proliferate, suggesting that mature osteoblast lineage cells could provide an additional source of preosteoblasts capable of proliferation and differentiation. Future studies will aim to evaluate factors that affect osteocyte dedifferentiation in vivo and in vitro.

Disclosures: Elena Torreggiani, None.

Matrix Metalloproteinase-13 is Required for Osteocytic Perilacunar Remodeling. Simon Tang*, Tamara Alliston. University of California, San Francisco, USA

Like bone mass, bone quality is specified in development, actively maintained post-natally, and disrupted by disease. The roles of osteoblasts, osteoclasts, and osteocytes in the regulation of bone mass are increasingly well defined. However, the cellular and molecular mechanisms by which bone quality is regulated remain unclear. Proteins that remodel bone extracellular matrix, such as the collagen-degrading matrix metalloproteinase (MMP)-13, are likely candidates that regulate bone quality. Using MMP-13 deficient male two-month old mice, we examined the role of MMP-13 in the remodeling and maintenance of bone matrix and subsequent fracture resistance. Throughout the diaphysis of MMP-13-deficient tibiae, we observed elevated non-enzymatic crosslinking and concentric regions of hypermineralization, collagen disorganization, and canalicular malformation. These defects localize to the same mid-cortical bone regions where osteocyte lacunae and canaliculi exhibit MMP-13 and tartrate-resistant acid phosphatase expression, as well as the osteocyte marker Sclerostin. Despite otherwise normal measures of osteoclast and osteoblast function, dynamic histomorphometry revealed that the remodeling of osteocyte lacunae is impaired in MMP-13-/- bone. While WT bone showed regular calcein incorporation in the perilacunar spaces (A, C), demonstrating osteocyte perilacunar remodeling, the loss of MMP-13 resulted in the loss of this phenomenon (B, D, E). MicroCT analysis of tibia from nulliparous and lactating WT show that lactation causes significant increases in cortical bone porosity (F; $p < 0.05$; t-test) and endosteal perimeter (I; $p < 0.05$; t-test), and decreases in cortical bone area (J; $p < 0.05$; t-test) and tissue mineral density (K; $p < 0.05$; t-test). In contrast, the cortical bone structural parameters of MMP-13-/- mice, when compared to MMP-13-/- nulliparous controls, were not significantly altered by lactation demonstrating the need for MMP-13 for osteocyte-mediated remodeling of perilacunar matrix. The loss of MMP-13, and the resulting defects in perilacunar remodeling and matrix organization, also significantly reduced MMP-13-/- bone fracture toughness and post-yield behavior. Taken together, these findings demonstrate that osteocyte perilacunar remodeling of mid-cortical bone matrix requires MMP-13 and is essential for the maintenance of bone quality.

MMP-13 is required for osteocyte perilacunar remodeling.

Osteocyte-Produced Microvesicles: a Potential Mechanism for Communication With Osteoblasts and Osteoclasts. Pat Veno, Matt Prideaux, Vladimir Dusevich, Lynda Bonewald, Sarah Dallas*. University of Missouri - Kansas City, USA

Recent findings have highlighted the key role of osteocytes as regulators of osteoblast and osteoclast function that integrate hormonal and mechanical signals to control bone mass. However, the mechanisms by which osteocyte signals reach these bone cells are not well defined. Exosomes (50-100nm) and microvesicles (100-1000nm) are membrane-bound vesicular particles released by cells that deliver "packets" of proteins, mRNAs and microRNAs to target cells and alter their function. We have previously reported microvesicle-like particles that appear to be shed by osteocytes. To further understand their properties and function, live cell imaging and confocal and electron microscopy were used, together with microvesicle purification and analysis of their protein composition. Using transgenic mice expressing a membrane targeted GFP variant in osteocytes (Dmp1-mem-GFP), 3D confocal microscopy showed abundant spherical GFP+ve microvesicles in the bone matrix of neonatal and adult bones. Similar vesicles were seen by immunostaining for the osteocyte

membrane protein E11/gp38. GFP+ve microvesicles were also seen in marrow spaces/vascular channels in bone as well as in marrow cell suspensions from the long bones, suggesting they may be shed into the marrow space and/or circulation. Microvesicles were purified from mineralized, osteocyte-enriched primary cultures of Dmp1-mem-GFP calvarial cells and IDG-SW3 cells (a late osteoblast cell line that differentiates into mature osteocyte-like cells). Western blotting showed that several osteocyte marker proteins were present in the microvesicles, including E11, sclerostin, FGF23 and RANKL in addition to known microvesicle proteins, β -actin, fibronectin and flotillin-2. Of these, fibronectin and sclerostin were enriched in microvesicles compared to cell lysate. PTH treatment for 24h increased RANKL and E11 levels in microvesicles and decreased sclerostin. Live imaging of osteocytes from Dmp1-mem-GFP mice showed extensive membrane ruffling and shedding of vesicles from the cell body and dendrites and suggested increased microvesicle release in response to PTH. These data show that osteocytes shed microvesicles containing bone regulatory proteins which may represent a novel mechanism for cell-cell communication in bone. Release of RANKL containing microvesicles may allow osteocytes to signal to osteoclast precursors in the bone marrow and hormones such as PTH may alter microvesicle content to regulate bone remodeling.

Mice Like it Hot: Housing Mice at Room Temperature Results in Cancellous Bone Loss. Urszula Iwaniec, Russell Turner*, Kenneth Philbrick, Laurence Lindenmaier, Dawn Olson, Gianni Maddalozzo. Oregon State University, USA

In contrast to humans, age-related cancellous bone loss begins in mice even as cortical bone continues to be accrued. This premature osteopenia is characterized architecturally by a pronounced decrease in trabecular number but preservation of trabecular thickness. Unlike humans who are homeotherms, the mouse is a facultative daily heterotherm and experiences cyclic changes in core temperature and bouts of torpor when subjected to cold temperature stress (temperatures below thermoneutral; ~32°C for mice) and/or caloric restriction. Activation of sympathetic signaling is important for mice to successfully adapt to low temperature and suppression of sympathetic tone has been reported to increase cancellous bone mass in mice. We therefore reasoned that premature age-related bone loss commonly seen in mice may be due to temperature stress induced by housing the animals at room temperature (20-24°C). To test this hypothesis, 1-month-old female C57BL/6J (B6) and C3H/HeJ (C3H) mice (n=20/strain) were randomized to 1 of 2 temperatures (22°C or 32°C) and maintained with no bedding for 4 months. Compared to B6 mice housed at 22°C, B6 mice housed at 32°C consumed less food (2.8±0.1 vs. 4.7±0.1 g/day; mean±SE, p<0.01). However, there was no significant effect on total body mass, lean mass, or fat mass. Furthermore, there were minimal temperature-dependent effects on cortical bone mass and architecture. In contrast, mice housed at the warmer temperature had higher cancellous bone volume/tissue volume in the distal femur metaphysis (6.6±0.4 vs. 3.0±0.2%, p<0.01), distal femur epiphysis (26.5±0.6 vs. 22.1±0.4%, p<0.01), and in the 5th lumbar vertebra (16.7±0.4 vs. 14.1±0.4%, p<0.01). The sparing effect of thermoneutral housing on cancellous bone was due to preservation of trabecular thickness. Similar temperature-dependent differences in cancellous bone mass were obtained in C3H mice (data not shown). These results support the conclusion that mild cold stress has a major negative impact on cancellous bone mass and architecture in mice and that early onset cancellous bone loss in this species is due, in part, to cold adaptation. They also suggest that studies using mice as a preclinical model to investigate interactions between energy homeostasis and bone or the etiology of age-related bone loss need to account for confounding species differences in thermo-regulation and energy metabolism.

The Effects of Acute Hyperinsulinemia on Bone Metabolism in Healthy Adults. Kaisa Ivaska*, H. Kalervo Vaananen¹, Maikki Heliövaara², Pertti Ebeling², Heikki Koistinen². ¹University of Turku, Finland, ²Helsinki University Hospital, Finland

Recently, studies in mice have demonstrated that insulin signaling in osteoblasts stimulates bone formation and promotes the release of osteocalcin (OC) from the bone microenvironment, particularly in the uncarboxylated form. As only few studies have assessed the role of insulin signaling as regulator of bone metabolism in humans, we evaluated the effect of acute insulin infusion on markers of bone metabolism in healthy subjects. Eight subjects (51.6±10.3 yrs, BMI 31.6±3.4 kg/m²) participated in a 4-h hyperinsulinemic (40 mU/m²/min) euglycaemic (5 mM) clamp and a control 4-h saline infusion on two separate days. In addition, 12 healthy men (23.5±5.1 yrs, BMI 22.0±2.8 kg/m²) participated in a 4-h hyperinsulinemic euglycaemic clamp with a high insulin infusion rate (72 mU/m²/min). Blood samples to determine the markers of bone formation (PINP), resorption (CTX, TRACP5b) and osteocalcin (total OC, uncarboxylated OC) were collected before and at the end of infusions. During 4-h insulin infusion, the concentration of resorption marker CTX decreased by 11% (p<0.05), whereas CTX remained unchanged during saline control. Fasting CTX correlated positively with insulin sensitivity (r=0.91, p<0.01, n=8). High insulin infusion rate resulted in a more pronounced suppression of bone resorption (median decrease in CTX 32%, p<0.01). Markers of osteoblast activity (PINP, total OC)

remained unchanged during insulin and saline infusions, whereas the ratio of uncarboxylated-to-total OC significantly decreased in response to insulin (p<0.05 and p<0.01 for low and high insulin infusion rate, respectively). In summary, insulin decreases bone resorption and modulates carboxylation of osteocalcin in healthy subjects. Insulin appears to have direct effects on bone metabolism, shifting the overall balance in the favor of bone formation.

The Sympathetic Nervous System Mediates Trabecular Bone Loss Caused by the Second Generation Antipsychotic Risperidone. Katherine Motyl*¹, Deborah Barlow², Karen Houseknecht², Clifford Rosen³. ¹Maine Medical Center Research Institute, USA, ²University of New England, USA, ³Maine Medical Center, USA

Second generation antipsychotics (SGAs) are associated with metabolic complications and reduced bone mass. Previously, we reported that risperidone (RIS) increases bone resorption and reduces bone formation in C57BL/6J (B6) mice. Molecular targets of RIS include dopamine receptor (D2R) and serotonin receptors (5HT_{2A}, 5HT_{2C}), therefore direct and/or indirect mechanisms could affect bone. First, we examined whether there is potential for RIS to act directly on bone by measuring RIS levels in bone marrow after oral gavage with 0.75 mg/kg RIS with mass spectrometry. Both RIS and its active metabolite 9-OH RIS were found in bone marrow at concentrations comparable to published brain values (0.87±0.15 ng/g and 2.29±0.55 ng/g, respectively). Consistent with the notion that RIS could act locally in bone, primary BMSC cultures treated with RIS had significantly accelerated osteoclast differentiation. Second, we hypothesized that RIS could act indirectly through inhibition of the serotonin receptor (5HT_{2C}) in the brain responsible for suppression of sympathetic signaling to bone. Therefore, we treated 8-wk old B6 female mice with 0.75 mg/kg RIS or vehicle (VEH) by daily oral gavage for 4 wks. Serum RIS and its active metabolite 9OH-RIS were within clinically relevant ranges (26±2 nM and 78±7 nM, respectively). A subset of mice from RIS and VEH groups were administered 0.5 g/L propranolol (PR, β 2AR antagonist) in the drinking water for the duration of the study. PR did not reduce the amount of RIS in serum. Neither RIS nor PR altered body composition or total aBMD by DEXA. However, RIS alone significantly lowered distal femur trabecular BV/TV, Conn.D Tb.N and increased Tb.Sp. Importantly, all of these changes were prevented by combined RIS and PR treatment. Furthermore, oral gavage alone (VEH gavage vs untreated) did not affect trabecular mCT parameters. Our findings strongly suggest that trabecular bone changes from RIS are sympathetically mediated, and likely related to its binding to 5HT_{2C}. Patients on SGAs are often prescribed β -blockers in order to combat akathisia (restlessness), thus, the clinical relevance of these findings can be readily tested. In conclusion, we have determined that both indirect (CNS mediated) and direct mechanisms likely account for trabecular bone changes from RIS. Understanding these mechanisms is crucial for developing therapeutic strategies to counteract deleterious side effects. NIH AR061932.

Estrogen Regulates Physiological Bone Turnover by Targeting Mesenchymal Cells in Mice. Alexandra Heyny*¹, Carmen Streicher², Pierre Chambon³, Reinhold Erben⁴. ¹inst. of Physiology, Pathophysiology & Biophysics, Austria, ²University of Veterinary Medicine Vienna, Austria, ³Institut de Génétique et de Biologie Moléculaire et Cellulaire, France, ⁴University of Veterinary Medicine, Austria

It is well known that bone metabolism is regulated by estrogen. Estrogen acts through two receptors, estrogen receptor-alpha (ER α) and -beta (ER β). Previous studies indicated that ER α is more important than ER β for the regulation of bone metabolism. However, it is still a matter of controversy whether hematopoietic or mesenchymal cells are the main effector cells responsible for mediating the effects of estrogen on bone. To answer this question, we established a reconstitution model resulting in selective deletion of ER α in hematopoietic or mesenchymal cells. We lethally irradiated 16-week-old female wild-type (WT) and global ER α knockout mice (α ERKO) on C57BL/6 genetic background, and reconstituted them with sex-matched bone marrow from α ERKO or WT mice, respectively. In irradiated WT mice reconstituted with α ERKO mouse bone marrow, all mesenchymal cells are of recipient origin and express a functional ER α , whereas hematopoietic cells are of donor-origin and lack ER α . Conversely, in irradiated α ERKO mice reconstituted with WT bone marrow, hematopoietic cells express a functional ER α , whereas mesenchymal cells lack ER α . To control for the deleterious effects of irradiation on ovarian function, irradiated mice received physiological doses of 17 β -estradiol (10 μ g/kg) 5 times per week over 4 weeks post-irradiation. Thereafter, all mice were ovariectomized (OVX), and subcutaneously received either vehicle or 10 μ g/kg 17 β -estradiol 5 times per week. Non-irradiated sham-operated, OVX and estradiol-supplemented OVX WT and α ERKO mice served as controls. All mice were killed 4 weeks post-OVX. pQCT analysis revealed femoral metaphyseal bone loss in non-irradiated vehicle-treated WT and α ERKO OVX mice 1 month post-OVX, relative to baseline and to estradiol-supplemented OVX mice of the same genotype. Bone and uterus of OVX α ERKO mice did not respond to physiological doses of estradiol. Similar to non-irradiated

OVX WT mice, estrogen treatment of OVX WT mice reconstituted with α ERKO bone marrow fully prevented OVX-induced bone loss. In contrast, estrogen treatment failed to increase bone mass in OVX α ERKO mice reconstituted with WT mouse bone marrow. Our data indicate that cells of the mesenchymal cell lineage, but not hematopoietic cells, are mediating the effects of estrogen on bone.

A Controlled Intervention of Weight Loss and Bone Mineral Density in Older Men. Claudia Pop¹, Katherine Tomaino¹, Deeptha Sukumar¹, Yvette Schluske¹, Christopher Gordon², Robert Zurfluh¹, Xiangbing Wang³, Sue Shapses¹. ¹Rutgers University, USA, ²McMaster University, Canada, ³Robert Wood Johnson Medical School, USA

Weight loss has been shown to decrease bone mineral density (BMD) in older women and in mixed populations of older women and men (1-2). This is the first prospective controlled trial to examine the response of BMD to intentional weight (wt) loss in men. Thirty-nine overweight and obese (body mass index, 31.9 ± 4.4 kg/m²) men (58 \pm 6 years) were assigned to either weight loss (WL; n=20) or weight maintenance (WM; n=19) for six months. Men in the WL group adhered to caloric restriction (500 kcal deficit/day) and both groups were supplemented individually to meet the recommended intakes of Ca and vitamin D. Bone was measured with dual energy x-ray absorptiometry and peripheral quantitative computed tomography (pQCT) at baseline and six months. Serum was measured at baseline, 1, 3 and 6 mo for serum 25-hydroxyvitamin D, parathyroid hormone, total and free testosterone and estradiol. Steroids and pQCT are reported for a subset. In addition, physical activity levels (PAL) were recorded before and during the intervention. The WL group lost $-7.7 \pm 4.4\%$ weight and $-20.5 \pm 18.0\%$ fat mass versus $-0.2 \pm 1.3\%$ weight and $+2.2 \pm 4.6\%$ fat mass in the WM group (ANOVA). There was a greater BMD decrease in WL than WM group over six months at the femoral neck, FN, ($-0.5 \pm 2.6\%$ vs $+1.1 \pm 2.2\%$; $p < 0.05$) and total body ($-0.9 \pm 2.4\%$ vs $+1.5 \pm 2.7\%$, $p < 0.01$) but not at other bone sites (radius, lumbar spine, total hip). Tibial pQCT measurements showed that the change in cortical bone area and thickness differed between the WL compared to WM group ($p < 0.05$) with trends for other parameters. There were no differences in sex steroids at baseline, but paired t-test showed an increase in serum free testosterone and estradiol in the WM group ($p < 0.05$) and no change in the WL group after 6 months. However, the changes were not significantly different between groups (ANOVA). Additionally, PAL did not differ between groups. Others have found that wt-stable men (50-69 y), show a slight annual increase in FN-BMD (0.5%/y) (3) that appears less than the increase found in the overweight/obese men in this trial. These data show that men who lose 8% wt show a different pattern of FN and total body BMD change vs. controls. Balancing the benefits of wt loss with risk of bone loss may differ depending on age and gender. References: 1. Sukumar, J Bone Miner Res, 2011; 2. Shah K, J Bone Miner Res, 2011; 3. A Critical Role for Caspase-2 in Regulating Osteoclast Numbers in Male Age-Related Osteoporosis. Ramaswamy Sharma¹, Difernando Vanegas², Daniel Victor², Marisa Lopez-Cruzan³, Diane Horn², Kathleen Woodruff², Roberto Fajardo⁴, Stephen Harris⁵, Sherry Abboud Werner⁵, Brian Herman⁶. ¹University of Texas Health Sciences Center At San Antonio, USA, ²The University of Texas Health Science Center at San Antonio, USA, ³UTHSCSA, USA, ⁴UT Health Science Center, San Antonio, USA, ⁵University of Texas Health Science Center at San Antonio, USA, ⁶UT HSC San Antonio, USA

Molecular mechanisms underlying age-dependent bone loss are not fully known. Such knowledge is critical for designing novel and safe therapies for the prevention and treatment of senile osteoporosis. Recent studies suggest that aging-related increases in oxidative stress are a major cause of SO. We have previously shown that the cysteine protease, caspase-2, is required for oxidative stress-induced apoptosis. Here, we show that caspase-2 expression in wild type (WT) mice decreased with age, correlating with a decrease in bone mineral density (BMD). Genetic ablation of caspase-2 resulted in significantly decreased BMD in old male *Casp2*^{-/-} mice, decreased bone volume, trabecular number and cortical thickness, decreased breaking force and increased total indentation distance of old *Casp2*^{-/-} bone. Together, these data suggest that loss of caspase-2 promoted bone loss. We find that lack of caspase-2 results in increased oxidative stress that may enhance differentiation of the bone-resorbing cells, osteoclasts. As expected, we found higher osteoclast numbers in *Casp2*^{-/-} mice *in vivo* and also after *in vitro* differentiation from bone marrow macrophages. Further, TRAP enzyme activity of *in vitro* differentiated *Casp2*^{-/-} osteoclasts was higher. Addition of the caspase-2 inhibitor, zVDVAD-fmk, to mature osteoclast cultures resulted in higher numbers of intact osteoclasts whereas overexpression of normal but not mutant caspase-2 resulted in decreased TRAP activity. Immunohistochemistry indicated constitutive expression of caspase-2 in bone marrow cells, osteoblasts, and lining cells. However, caspase-2 was detected in *in vitro* differentiated osteoclasts only after treatment with high levels of oxidants. Importantly, *Casp2*^{-/-} osteoclasts were less

sensitive to oxidant treatment and exhibited higher TRAP activity. Therefore, caspase-2 regulates osteoclast numbers perhaps via apoptosis. Finally, we found 2-fold higher levels of the osteoclast survival factor, Csf-1, in *Casp2*^{-/-} bone lysates, suggesting a mechanistic explanation for caspase-2-based osteoclast regulation. As proof-of-concept, we generated mice over-expressing caspase-2 selectively in osteoclasts; we observed significantly increased trabecular bone volume, trabecular number and trabecular thickness. In conclusion, our data highlight a novel role for caspase-2 in male age-dependent osteoporosis and suggest the use of caspase-2 as a diagnostic marker for osteoporosis and as a putative target for therapy.

Serum Sclerostin and Bone Microarchitecture – Strong Positive Association in Men from the STRAMBO Cohort. Pawel Szulc¹, Stephanie Boutry², Claudia Goettsch³, Martina Rauner⁴, Nicolas Vilyayphiou⁵, Michael Schoppet⁶, Roland Chapurlat⁷, Lorenz Hofbauer⁸. ¹INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France, ²INSERM UMR 1033, University of Lyon, France, ³Division of Endocrinology, Diabetes, & Bone Diseases, Dresden University, Germany, ⁴Medical Faculty of the TU Dresden, Dresden, Germany, ⁵INSERM UMR1033, Université de Lyon & Hospices Civils de Lyon, France, ⁶Philipps-University, University of Marburg, Germany, ⁷E. Herriot Hospital, France, ⁸Dresden University Medical Center, Germany

Sclerostin is secreted by osteocytes. We assessed the relation of serum sclerostin levels with bone mineral density (BMD) measured by DXA and with bone microarchitecture assessed by high resolution peripheral QCT (XtremeCT Scanco) in 1,154 men aged 20 to 87 years. After the age of 63, the association between serum sclerostin levels and age was weaker ($r=0.17$, $b=0.20 \pm 0.03SD/10$ yrs) than before this age ($r=0.55$, $b=0.43 \pm 0.03SD/10$ yrs). Further analyses are adjusted for age, weight, height, muscle strength, smoking, glomerular filtration rate, and serum levels of estradiol, parathyroid hormone, and osteoprotegerin.

Before the age of 63, men in the highest sclerostin quartile had higher BMD at the spine, hip and whole body (4-7%, $p < 0.001$) compared with the three lower quartiles combined. They had higher trabecular volumetric BMD (Tb.vBMD) at the distal radius and tibia due to higher trabecular number (Tb.N) (6 to 8%, $p < 0.001$) and less heterogeneous trabecular distribution (4 to 6% lower Tb.Sp.SD, $p < 0.001$).

After the age of 63, men in the lowest sclerostin quartile had 4 to 15% lower BMD compared with the highest quartile (0.32-0.94 SD, $p < 0.001$) at all skeletal sites. They had lower cortical thickness and density at the distal radius and tibia compared with the highest quartile (3 to 9%, 0.30-0.55 SD, $p < 0.05-0.001$). Tb.vBMD correlated positively with serum sclerostin levels, also when the central and subendocortical compartments were analyzed separately at both skeletal sites ($r=0.15$ to 0.22 , $p < 0.001$). Men in the lowest sclerostin quartile had 10% lower Tb.N (0.7 SD, $p < 0.001$) and higher Tb.Sp.SD (7 to 9%, 0.8 SD, $p < 0.001$) compared with the highest quartile. After adjustment for BMD, men in the highest sclerostin quartile had higher Tb.N (3 to 5%, 0.25-0.30 SD, $p < 0.001$) and lower Tb.Sp.SD (2 to 4%, 0.32-0.42 SD, $p < 0.001$) compared to the three lower quartiles combined.

Total cross-sectional and trabecular areas did not differ across the quartiles of sclerostin regardless of the skeletal site or age range. The differences in trabecular thickness (Tb.Th) were generally weak or non-significant.

Thus, in men, serum sclerostin levels were strongly positively associated with BMD and quality of bone microarchitecture after adjustment for potential confounders, especially after the age of 63. The association was stronger in the trabecular compartment and dependent mainly on the differences in Tb.N and Tb.Sp.SD, but not Tb.Th.

Low Holotranscobalamin and Cobalamins Predict Incident Fractures in Elderly Men; The MrOS Sweden. Catharina Lewerin^{*1}, Herman Nilsson-Ehle², Stefan Jacobsson³, Valter Sundh⁴, Helena Johansson⁵, Mattias Lorentzon⁶, Magnus Karlsson⁷, Osten Ljunggren⁸, John Kanis⁹, Steven Cummings¹⁰, Claes Ohlsson¹¹, Dan Mellstrom¹². ¹Västra Götaland, Sweden, ²Section of Hematology & Coagulation, Sahlgrenska University Hospital, Sweden, ³Department of Clinical Chemistry & Transfusion Medicine, Sahlgrenska Academy at the University of Gothenburg, Sweden, ⁴Department of Community Medicine & Public Health, Geriatric Medicine, Sahlgrenska Academy at the University of Gothenburg, Sweden, ⁵Center for Bone & Arthritis Research (CBR), Departments of Internal Medicine, at the Institute of Medicine, Sahlgrenska Academy at the University of Gothenburg, Sweden, ⁶Center for Bone Research at the Sahlgrenska Academy, Sweden, ⁷Skåne University Hospital Malmö, Lund University, Sweden, ⁸Uppsala University Hospital, Sweden, ⁹University of Sheffield, Belgium, ¹⁰San Francisco Coordinating Center, USA, ¹¹Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, ¹²Sahlgrenska University Hospital, Sweden

Background: Subclinical cobalamin deficiency is common in the elderly and has been suggested to affect bone metabolism. However the relationship between cobalamin status and incident fractures is not clear. The aim was to determine whether serum cobalamins or holotranscobalamin (the metabolic active cobalamin) are associated with risk of developing fracture among older men.

Methods: Men participating in the Gothenburg part of the population-based MrOS (Osteoporotic Fractures in Men) Sweden cohort and without on-going B vitamin medication were included in the present study (n=790, age range 69-81 years).

Results: During an average follow up of 5.9 years, 110 men sustained one or more X-ray verified fractures including 45 men with clinical vertebral fractures. In age adjusted linear regression analysis, holoTC below the median (<51.8 pmol/L) was associated with lower lumbar spine L1-4 BMD compared to those over the median ($\beta=-0.03$, $p<0.028$), and the lowest quintile of holoTC correlated with lumbar spine L1-4 BMD ($\beta=-0.03$, $p<0.043$) compared to quintile 2-4. The risk of fracture (adjusted for age, smoking, BMI, BMD, falls, prevalent fracture, plasma total homocysteine, cystatin C, 25-OH-vitamin D, intake of calcium and physical activity), increased by 38% and 26% per each SD decrease in cobalamins (HR 1.38; 95% CI 1.11-1.72) and holotranscobalamin (HR 1.26; 95% CI 1.03-1.54), respectively. Men in the lowest quartile of cobalamins and holotranscobalamin, (age, BMI and BMD adjusted), had an increased risk of all fracture (cobalamin, HR=1.67 [95% CI 1.11-2.5]; holotranscobalamin, HR=1.76 [95% CI 1.18-2.61]) and clinical vertebral fractures (cobalamin, HR=2.42 [95% CI 1.31-4.47]; holotranscobalamin, HR=2.47 [95% CI 1.35-4.53]) compared to quartile 2-4. No associations between folate or homocysteine and incident fractures were seen.

Conclusion: We present novel data showing that low holotranscobalamin and cobalamins predict incident fracture in elderly men. This association was unaffected by adjustment for BMI, BMD, plasma total homocysteine and cystatin C.

A Comparison of Bone Turnover Markers in Hip Fracture Patients vs. a Matched Group of Non-Fractured Controls during the 12 Month Recovery Period Post-Hip Fracture. Janet Yu-Yahiro^{*1}, Jay Magaziner², William Hawkes³, Marc Hochberg⁴, Denise Orwig², Rich Hebel⁵, Anne R. Cappola⁶. ¹Union Memorial Hospital, USA, ²University of Maryland, Baltimore, USA, ³University of Maryland School of Medicine, Department of Epidemiology, Division of Gerontology, USA, ⁴University of Maryland School of Medicine, USA, ⁵University of Maryland School of Medicine, Department of Epidemiology & Public Health, Division of Gerontology, USA, ⁶Perelman School of Medicine at the University of Pennsylvania, USA

Objective: To compare levels and trajectories of serum bone turnover markers (BTMs) during the 12 months hip fracture recovery period in a cohort of hip fracture patients and age- and bone mineral density (BMD) matched non-fracture controls.

Methods: Hip fracture patients enrolled in the Baltimore Hip Studies (BHS4) (n=58) were matched by age and total hip BMD to non-fracture controls from the Baltimore cohort of the Study on Osteoporotic Fractures (SOF) (n=58). Blood was drawn from BHS4 at time of fracture and at 2, 6, and 12 months post fracture from 1998 to 2004 and from SOF subjects at Visits 2 (1988-89) and 4 (1993-1994). The mean time between these SOF visits was 42.3 months and comparison bone marker values were estimated for time points 2, 6 and 12 months using linear models. Blood was assayed for bone specific alkaline phosphatase (BSAP), C-terminal propeptide of type 1 collagen (C1CP), carboxyterminal cross-linked telopeptide of type I collagen (CTX), 25-hydroxyvitamin D (25(OH)D), and intact parathyroid hormone (iPTH). Samples from a single individual from all time points were assayed together with SOF and BHS4 samples included in each assay to control for interassay variability. Mixed

model fitting was used for repeated measures analyses with the outcome measures as dependent variables.

Results: Women in SOF and BHS4 were comparable in age 79.0 +5.6 vs. 79.4 +5.4 yrs, and total hip BMD 0.670 +0.087 vs. 0.665 +0.115 gm/cm². Over 12 months, markers of osteoblastic activity (BSAP and C1CP) were lower in hip fracture patients than controls. BHS4 subjects had significantly higher iPTH levels and significantly lower 25(OH)D levels at baseline compared to SOF controls and 25(OH)D levels remained significantly lower in hip fracture subjects compared to controls throughout the 12-mo period (Table 1).

Conclusion: Over the 12 month post fracture period, hip fracture subjects were vitamin D insufficient with secondary hyperparathyroidism and had more osteoclastic activity and less osteoblastic activity when compared to non-fracture controls. Although these results do not enable us to differentiate between the effect of vitamin D deficiency and the impact of hip fracture healing on post fracture bone markers, they demonstrate that there is a distinctly different bone metabolic profile in hip fracture patients compared to controls, which is independent of BMD and age.

Quantification of the Circadian Modulation of the Bone Resorption Marker CTX-I in Serum and Urine under Controlled in-patient Conditions. Maria Small^{*1}, Derk-Jan Dijk², Richard Eastell³, Aldona Greenwood², John Sharpe⁴, Mikihiro Yuba⁴, Stephen Deacon¹. ¹Ono Pharma UK Ltd, United Kingdom, ²Surrey Clinical Research Centre, United Kingdom, ³University of Sheffield, United Kingdom, ⁴ONO Pharma UK, United Kingdom

Bone resorption is higher during the night compared to the daytime and is reflected in serum (s) and urine (u) CTX-I levels. However, there are a number of factors including food intake that may influence this diurnal profile. This study investigated the characteristics of the CTX-I profile over 24h in 25 post-menopausal women (PMW) (mean age +/-SD 65.3+/-6.0) in an environment minimizing confounding influences of irregular sleep, food intake and exercise. Sleep/wake disorders/complaints were excluded and a regular sleep/wake cycle (SWC) (22:30-06:30) was scheduled 7 days prior to and during the 3 day lab study (sampling on last day). Subjective sleep diaries and actigraphy were used to confirm compliance with SWC instructions and exercise restrictions. Serum sampling was obtained ~ every 2h. A longline indwelling cannula was used for overnight sampling to minimise

disturbance. Urine was collected from 08:00 ~ every 2h (4h overnight). While in clinic, meals were served at 07:00, 13:00 and 19:00 with only water at other times. Breakfast had the same nutritional content as dinner since these times were considered to influence resorption the most. Characteristics of the 24h profiles were determined by non-linear regression fitting a cosine model to the data. This gave estimates of mesor (M) (average), amplitude of the 24h variation (Amp) and time of the fitted maximum of CTX-I. Significant ($p < 0.05$) wave fits were obtained in 25 and 14 subjects for sCTX-I and uCTX-I, respectively. Each subject's Amp was > 0 ($p < 0.05$). The Amp between subjects varied and correlated with the M in both serum and urine ($r \geq 0.824$, $p < 0.001$). Mean (+/- SD) peak time and Amp estimates were 03:17 +/- 46mins and 0.187 +/- 0.078 $\mu\text{g/L}$ for sCTX-I, and 04:06 +/- 1h29mins and 33.22 +/- 12.84 $\mu\text{g/h}$ for uCTX-I. The study covered ~4m period (Jul/Aug and Nov). A significantly ($p < 0.01$) earlier peak time in sCTX-I was obtained in Nov compared to Jul/Aug. A similar effect was not observed for Amp or M. Because timing of sleep and meals was identical across the periods, this effect may be related to the change from summer to wintertime. The data show that in PMW, CTX-I has a clear circadian profile with mean peak levels at ~3am in serum and ~4am in urine. The Amp is greater in PMW with higher CTX-I levels. Circadian characteristics can be assessed at the level of the individual. These data have implications for the assessments of bone resorption status based on a single sample.

Serum Sclerostin Levels are Associated with Osteoporotic Fractures in Type 2 Diabetic Patients. Masahiro Yamamoto^{*1}, Toru Yamaguchi¹, Mika Yamauchi¹, Kiyoko Nawata², Toshitsugu Sugimoto³. ¹Shimane University Faculty of Medicine, Japan, ²Department of Health & Nutrition, The University of Shimane, Junior College, Matsue Campus, Japan, ³Shimane University School of Medicine, Japan

Purpose: The patients with type 2 diabetes mellitus (T2DM) have an increased risk for vertebral fractures (VFs) compared to non-T2DM controls independent of bone mineral density (BMD) (JBMR 2009), suggesting that poor bone quality is possible cause of increased bone fragility. Low bone formation, a part of component of bone quality, is associated with VFs in T2DM women (JCEM 2012). Recent reports show that sclerostin, which is one of Wnt signaling inhibitors secreted from osteocyte, are inversely correlated with bone turnover markers. However, it is unclear whether serum sclerostin levels are correlated with osteoporotic fractures. The aim of this study is to clarify this relationship in T2DM men and women patients.

Methods: We compared parameters of bone metabolic markers including sclerostin measured by ELISA, osteocalcin, urinary NTX and spine BMD between 147 Japanese postmenopausal T2DM women (DMw) and 156 T2DM men over 50 years old (DMm), whose creatinine levels were within normal range.

Results: Sclerostin levels were significantly higher in DMw than DMm ($P < 0.01$). Stepwise regression analysis including independent variables of BAP showed that serum sclerostin was positively correlated with spine BMD and creatinine levels in both groups (DMw: $r = 0.39$, $F = 28.7$, $r = 0.30$, $F = 16.6$; DMm: $r = 0.43$, $F = 42.5$, $r = 0.17$, $F = 6.0$, respectively) and positively associated with age and HbA1c in DMm group ($r = 0.21$, $F = 9.6$, $r = 0.21$, $F = 9.4$, respectively). BAP, osteocalcin and uNTX were inversely correlated with sclerostin in DMm group ($r = -0.17$, $F = 6.8$; $r = -0.15$, $F = 4.03$; $r = -0.19$, $F = 7.6$, respectively). Multiple logistic analysis adjusted for age, BMI, HbA1c, creatinine, calcium, phosphate, and spine BMD revealed that sclerostin levels were associated with all osteoporotic fractures [DMw, 1.66 (1.08-2.55), DMm 1.54 (1.04-2.28)] and VFs [DMw, 1.59 (1.02-2.49), DMm, 1.55 (1.04-2.32)].

Conclusion: These results showed that sclerostin levels were correlated with several variables including BMD and associated with osteoporotic fractures independent of BMD. These findings suggested that increase in sclerostin level may cause bone

fragility due to poor bone quality and may explain, in part, why T2DM patients have an increased bone fragility despite their elevated BMD.

Clinical Abdominal CT can Effectively Predict the Risk for Osteoporotic Vertebral Fracture. Akifumi Nishida^{*1}, Masako Ito², Masataka Uetani¹. ¹Nagasaki University School of Medicine, Japan, ²Nagasaki University Hospital, Japan

Purpose: To evaluate the ability of clinical abdominal CT in assessing the risk for osteoporotic vertebral fractures compared with dual-energy X-ray absorptiometry (DXA).

Method and Materials: The subjects were 269 patients (108 men and 161 women, aged 56.8 ± 13.6 , 21-88 years) who underwent BMD measurement by DXA [lumbar spine (L-DXA), total hip (TH-DXA), femoral neck (FN-DXA) and vertebral morphometry] and diagnostic abdominal CT within 6 months from DXA examination. Clinical abdominal CT was performed with a 64-detector row scanner. Unenhanced axial images were obtained with a section thickness of 3 mm. The mean attenuation (in Hounsfield units) of integral, cortical and trabecular region of L2 vertebra (INT-CT, COR-CT and TRA-CT) was measured on a standard workstation (Aquarius NetStation, TeraRecon). The diagnostic ability of clinical abdominal CT and DXA with respect to discriminate prevalent vertebral fracture was assessed using receiver operating characteristic (ROC) analysis.

Results: CT attenuation measurement correlated with BMD measurement by DXA ($r = 0.202-0.687$). Seventy-three patients (27.1%) had vertebral fractures. For predicting vertebral fracture by CT attenuation measurement, ROC analysis provided area under the curve (AUC) values of 0.832 [95% confidence interval (CI) 0.773-0.891] for TRA-CT, 0.818 (95% CI 0.756-0.879) for INT-CT and 0.490 (95% CI 0.397-0.583) for COR-CT. Except for COR-CT, these values were greater than those of BMD measurement, which were 0.693 (95% CI 0.617-0.770) for L-DXA, 0.724 (95% CI 0.650-0.798) for FN-DXA and 0.715 (95% CI 0.641-0.790) for TH-DXA (Figure).

Conclusion: CT attenuation measurements of integral and cortical region of lumbar vertebra had greater discriminatory ability for vertebral fracture than DXA. CT attenuation measurements on clinical abdominal CT provide valuable data for identifying individuals at risk for fracture who would require treatment of osteoporosis, with no additional radiation or costs.

Impact of a Reimbursement Change on Bone Mineral Density Testing in Ontario, Canada. Susan Jaglal^{*1}, Gillian Hawker¹, Ruth Croxford², Cathy Cameron³, Sarah Muncie¹, Sonya Allin⁴. ¹University of Toronto, Canada, ²Institute for Clinical Evaluative Sciences, Canada, ³Women's College Hospital, Canada, ⁴Toronto Rehabilitation Institute-University Health Network, Canada

Background: As of April 1, 2008 the physician reimbursement fee schedule for bone mineral density (BMD) testing using DXA in Ontario, Canada was revised with increased restrictions. BMD tests for patients with low fracture risk were limited to once every 36 months but prior to that, limited to once in any 24-month period. No change was made for high-risk patients who continued to be limited to one test every 12 months and a new fee code for a baseline testing with individuals being limited to

one baseline test in their lifetime. Objective: To examine the impact of the policy change for increased restrictions on BMD testing on trends in BMD testing rates, overall, by sex, risk category, age and following recent fracture. Methods: Data from the Ontario Health Insurance Plan which captures all reimbursement for DXA in the province were used to assess patterns in BMD testing from April 1, 2002 to March 31, 2011. Fractures were determined from administrative databases on physician visits, hospital discharges and emergency department visits. Joinpoint analyses were used to examine significance of trends. Results: Prior to the policy change the number and rate of DXAs were increasing steadily from 433,419 in 2002/03 to 507,658 in 2007/08 and then decreased to 422,915 in 2010 and the decrease was more pronounced for women between the ages of 50 and 79 years. The rates in men continued to increase gradually each year and levelled off after 2008. Following the policy change in 2008, the number and age-adjusted rate of BMD testing dropped particularly in the low risk group from 5.7/100 to 1.8/100 among women. More importantly, the rate of BMD testing decreased in groups at high risk for fracture after 2008. A significant decrease was seen among women who were eligible for BMD testing when they turned 65 years. Among those with fractures, overall rate of BMD testing at 6 or 12 months after fracture decreased after the policy change. Between 2002 and 2007, rates of testing following hip fractures increased by an estimated 1.68 per 100 fractures in both men and women and then fell. Conclusion: The policy change restricting access to BMD testing reduced overall testing particularly in low-risk women but also negatively affected groups at high risk for fracture, where BMD testing is indicated. This suggests that referring physicians are reducing DXA referrals across the board rather than targeting only low risk patients, thereby decreasing appropriate referrals.

Management of Fragility Fractures: Impact of the Optimus Initiative on Family Physicians. Marie-Claude Beaulieu¹, Sophie Roux², Noémie Poirier³, Michèle Beaulieu⁴, François Cabana⁵, Gilles Boire³. ¹Université de Sherbrooke, Canada, ²University of Sherbrooke, Canada, ³Centre hospitalier universitaire de Sherbrooke, Canada, ⁴Merck Canada Inc, Canada, ⁵CHUS, Canada

Background: The OPTIMUS initiative was first implemented in January 2007 to educate patients and inform and empower Family Physicians (FPs) to diagnose and treat OP revealed by a Fragility Fracture (FF). In this prospective initiative, women and men over age 50 were screened for incident FF in orthopaedic clinics, and eligible outpatients were randomized to Standard Care (SC) or to either Minimal (MIN) or Intensive (INT) interventions, consisting in an initial face-to-face and phone follow-up interventions with patients by dedicated personnel and information letters with individualized recommendations to FPs. As of December 2010, 1043 outpatients (including 200 SC controls) with nonvertebral FF and 250 hip FF inpatients have been included. More than 270 of the 360 FPs from our area have been reached at least once by OPTIMUS. A better collaboration between bone health specialists, orthopaedists and FPs has taken place and treatment initiation has been improving. Initiation rates and persistence on treatment at one year after a FF event have increased from less than 20% in the control group to 43% in the MIN and 55% in the INT Intervention groups.

Objectives: To determine the factors influencing FPs' decision to treat OP
Methods: 272 FPs reached by OPTIMUS were sent a questionnaire evaluating their main reasons to start a treatment for osteoporosis, their knowledge and use of fracture risk calculators, and the potential for collaboration with nurses from Family Physician Groups (GMF), a Ministry of Health-supported grouping of FPs. One hundred and three (38%) filled questionnaires were returned.

Results: Previous FFs (100/103; 97%) and BMD results (80/103; 78%) were the two major indicators (Agree and Strongly Agree) mentioned by FPs to initiate a pharmacological treatment of osteoporosis; 10-year fracture risk (67/103; 65%) was less frequently mentioned. The FRAX and/or CAROC (Canadian Association of Radiologists and Osteoporosis Canada) tools were known by the majority (58/103; 56%), but were rarely used (FRAX by 11, CAROC by 26). Twenty-three of 30 (77%) FPs aware of CAROC found it easy to use, compared to only 14 of the 28 (50%) knowledgeable about FRAX; 9 (32%) found FRAX difficult to use. Of those FPs using FRAX and/or CAROC, 25 (68%) felt they were useful to convince patients to get treated. Two thirds (69/103) of the responding FPs already collaborated with GMF nurses to manage patients with chronic diseases, but only 6 were doing so for OP patients.

Conclusions: After 4 years of existence, the OPTIMUS initiative appears to progressively overcome the previously BMD-driven decision of FPs and to prioritize a post-FF intervention to treat osteoporosis. Fracture risk calculators remain infrequently used. There is an opportunity to integrate/systematize management of FF patients in groups of FPs with the help of GMF nurses, as these nurses are already involved in management of other chronic diseases.

Accurate and Fast Strength Predictions of Patient-specific HR-pQCT-based plate-rod Models Distinguish Women with Vertebral Fractures. Ji Wang^{*1}, Bin Zhou¹, Xiaowei Liu², Xiutao Shi¹, Emily Stein³, Elizabeth Shane³, X Guo¹. ¹Columbia University, USA, ²University of Pennsylvania, USA, ³Columbia University College of Physicians & Surgeons, USA

Deteriorating trabecular microstructure associated with aging and menopause predisposes postmenopausal women to vertebral (VB) fractures. While HR-pQCT has advanced clinical assessment of trabecular microstructure, prediction of yield strength by HR-pQCT voxel-based Finite Element Analysis (FEA) is impractical for clinical use due to its prohibitive high computational costs. Recently, a highly efficient plate-rod (PR) modeling technique based on HR-pQCT has been developed to fill the unmet clinical need to estimate bone strength. In this study, the new HR-pQCT PR models were validated against gold standard- μ CT voxel models, as well as HR-pQCT voxel models. Then, patient-specific PR models were evaluated to determine whether they discriminated VB fracture status in postmenopausal women. For validation, 19 registered μ CT (25 μ m) and HR-pQCT (82 μ m) images of trabecular sub-volumes of distal tibiae were obtained from human cadaveric samples (Fig.1A,B). For testing clinical potential of PR models, HR-pQCT images of distal radius were obtained from 20 patients with VB fractures and 30 control subjects (age-matched and no difference in aBMD by DXA except at femoral neck). After segmenting images of the trabecular microstructure into individual trabeculae, PR models were generated by modeling each rod with a 2-node beam element and each plate with multiple 3-node shell elements (Fig.1C). Both the PR models and voxel models were subjected to nonlinear FEA to estimate Young's modulus (E_y) and yield strength (σ_y). Predictions by HR-pQCT PR models strongly correlated with those of μ CT-based and HR-pQCT-based voxel models, for modulus (Fig.1D) and for strength (Fig.1E). Notably, the simplified PR models achieved both major reductions in CPU time for nonlinear FEA (64,000-fold for μ CT and 1,200-fold for HR-pQCT), and a dramatic reduction in element number (Fig.1F). Most importantly, these highly efficient patient-specific HR-pQCT PR models revealed dramatic deficiencies in modulus and strength in VB patients and demonstrated the power to discriminate VB fracture status (Fig.2). In conclusion, we thoroughly validated a novel HR-pQCT PR model of human trabecular bone against μ CT and HR-pQCT voxel models and demonstrated its ability to discriminate fracture status in postmenopausal women. An accurate nonlinear FEA of HR-pQCT PR models that requires only seconds of desktop computer time has tremendous promise as a powerful tool for clinical assessment of bone fracture risk.

In Breastfeeding Women, Trabecular Bone Loss at the Radius, Seen by High Resolution Peripheral Quantitative CT (HRpQCT), Persists at 18 Months Postpartum. Anna Kepley¹, Stephanie Boutroy², Chiyuan Zhang¹, Mariana Bucovsky¹, Mary Beth Vrabel¹, Shannon Kokolus¹, Polly Young¹, Adi Cohen^{*2}. ¹Columbia University, USA, ²Columbia University Medical Center, USA

Lactation is associated with rapid, large decreases in lumbar spine (LS) and femoral neck (FN) BMD followed by recovery. Both human and rodent studies suggest that recovery of bone mass after weaning is site-specific, with full recovery at the spine, but only partial recovery at the femur. To characterize the site-specificity and type of bone loss (cortical versus trabecular) and recovery during lactation and weaning, we studied 15 healthy exclusively breastfeeding (BF; exclusive lactation over 8±3 mo, any lactation, 12±3 mo) and 11 healthy non-breastfeeding (nBF) women. We measured BMD by DXA (LS, FN, and the predominantly cortical 1/3 radius) and cortical (Ct) and trabecular (Tb) volumetric BMD and bone microarchitecture by radial and tibial HRpQCT (Scanco) over 18 months postpartum. At baseline (36±22 days postpartum), BF women were older (BF: 33±4, nBF: 26±4 yrs; p<0.001) and had lower BMI (BF: 24.0±3.1, nBF: 27.6±5.0 kg/m²; p=0.03) than nBF women. Return of menses occurred at 7.0±3.7 mo in BF and 1.7±0.8 mo postpartum in nBF (p<0.001). By both DXA and HRpQCT (Table), nBF women gained bone mass at most sites during the observation period. By DXA in BF women, expected BMD loss with recovery at the LS and partial recovery at the femoral neck were seen, while 1/3 radius BMD increased. In contrast, by HRpQCT, mean decreases in radial Tb vBMD, particularly at the inner Tb compartment, persisted even at 18 mo postpartum, while few changes were seen over time at the tibia (Table). Radial and tibial Ct vBMD did not change in either group. In both groups, changes in HRpQCT measures were highly variable. In BF women, timing of the baseline visit, age, time of return of menses, duration of full lactation, and time of initiation of solid food did not significantly predict DXA BMD or radial Tb vBMD changes over time. In summary, while bone loss and recovery were seen at the LS and FN in BF women, no significant changes were seen at the tibia and radial Tb bone loss persisted even at 18 months postpartum. The pattern of bone loss and recovery in breastfeeding women varies by site and type of bone.

Lower Vertebral Body Bone Strength in Subjects with Prevalent Fracture Assessed by High Resolution Axial Skeleton Quantitative Computerized Tomography. Rene Rizzoli^{*1}, Fanny Merminod¹, Mélanie Hars², Bert Rietbergen³. ¹University Hospital, Switzerland, ²Hôpitaux Universitaires De Genève, Switzerland, ³Eindhoven University of Technology, The Netherlands

Bone microarchitecture is an important determinant of bone strength, hence of fracture risk. It provides additional and complementary information to areal BMD in predicting fracture risk, when assessed by high-resolution (HR) peripheral (p)QCT. Combined with micro-finite element analyses (FEA), bone mechanical properties can be quantified. Recently HR flat-panel QCT imaging devices became available that can reveal microstructural features of the axial skeleton. We investigated if micro-FE analysis based on such HR-QCT measurements of the spine can better identify patients with prevalent fracture than density or peripheral morphology measures.

HR flat panel CT (Allura FD20 XperCT, Philips Healthcare, NL) images with a resolution of 137 microns, were created of the vertebrae T12 in vivo, in 23 patients with prevalent fracture (12 vertebral and 15 upper limb fractures) and in 17 unfractured controls, aged 66.4±1.9 (x±SD) and 66.0±1.2 years, respectively. Micro-FE models were created by converting voxels to elements with a density-dependent stiffness and comprised the vertebrae with cut-off endplates. Microstructural features and the thin cortical shell could be well represented by the models. Compression tests were simulated to determine vertebral stiffness, estimated failure load and stiffness corrected for vertebral height and cross-sectional area (modulus). In

addition, we measured spine and proximal femur areal BMD and distal radius and tibia microstructure by HRpQCT (XtremeCT, Scanco, CH).

Spine and proximal femur aBMD did not differ between fractured patients and controls. Distal radius, but not distal tibia, total density, BV/TV, trabecular number and thickness were lower in the fractured patients (p=0.044 to 0.001). At T12 level, micro-FEA revealed in the fractured group lower estimated failure load (4.5±2.0^{E3} vs 6.1±1.8^{E3} N, p=0.015) and modulus (673±257 vs 958±271 N/mm², p=0.002). When only patients with vertebral fracture were considered, none of the HRpQCT difference remained significant. In contrast, T12 stiffness (4.9±2.4^{E4} vs 7.1±2.6^{E4} N/mm, p=0.033), estimated failure load (3.9±1.9^{E3} vs 6.1±1.8^{E3} N, p=0.004) and modulus (601±268 vs 958±271 N/mm², p=0.002) were lower in the group with vertebral fracture.

These results underline the major interest of high-resolution axial QCT and FE analysis in axial skeleton fracture risk assessment.

Disclosures: Rene Rizzoli, None.

Mechanical Implications of Subtle Changes in Trabecular Bone Estimated by MRI-Based Finite Element Modeling. Wenli Sun^{*1}, Chamith Rajapakse², X Guo³, Felix Werner Wehrli⁴. ¹University of Pennsylvania, USA, ²University of Pennsylvania School of Medicine, USA, ³Columbia University, USA, ⁴University of Pennsylvania Medical Center, USA

Early detection of changes in bone's mechanical competence is critical for the effective management of osteoporosis. Micro magnetic resonance imaging (µMRI) based finite-element (µFE) analysis can non-invasively capture temporal changes in bone strength at peripheral sites. In this study, we examined (1) the sensitivity of µMRI-based µFE analysis in detecting subtle alterations in bone stiffness, (2) the accuracy of the method, and (3) a regression model to improve the accuracy of detected changes in the limited signal-to-noise (SNR) regime of *in-vivo* µMRI.

30 human distal tibiae had previously been imaged with mCT at 25 mm isotropic voxel size. High-resolution 3D reference models were generated by extracting the trabecular bone region. The effect of bone resorption was evaluated with two modes of bone loss: homogeneous thinning (HT) and heterogeneous pitting (HP). Three levels of bone loss were implemented: 0.5%, 1%, and 2%. Micro-MR images were processed by resampling to 150-µm isotropic voxel size and superimposing Gaussian noise to reduce SNR to 20, 15, and 10. Axial stiffness was computed via simulated compressive loading in the axial direction. Paired t-tests were used to determine whether the stiffness derived from degraded and non-degraded *in-vivo* models were different. Further, the accuracy of detected differences in stiffness before and after bone loss under *in-vivo* conditions was compared to the ground truth. Finally, a linear regression model was generated to determine the dependence of mFE-derived stiffness on SNR on the basis of 15 cadavers, while the other 15 were used to test the performance of the correction algorithm based on the derived parameters.

Under *in vivo* µMR imaging conditions, 0.5 % degraded HT (and HP) models yielded 0.87% (0.67%), 0.81% (0.65%), 0.72% (0.60%) lower stiffness values than prior to bone loss at SNR=20, 15, and 10, respectively (p<0.0001). Further, the detected difference in pre- and post-bone loss stiffness under *in-vivo* MRI conditions were correlated to those derived from high-resolution reference models with R²= 0.35 (0.50), 0.26 (0.29), 0.12 (0.11) at SNR=20, 15, and 10, respectively. The error after correction in the SNR=10-20 range reached 8%-16% (12%-47%) of the high resolution reference values, it was considerably smaller than the error prior to correction. The data suggest that mechanical implications caused by subtle changes in TB density are detectable via FE analysis under *in-vivo* µMR imaging conditions. The strength of the correlation between the low and high resolution models decreased with decreasing SNR as expected. The correction model improved the accuracy of detected changes.

FR0314

Rapid Cortical Bone Loss in Patients with Chronic Kidney Disease. Thomas Nickolas^{*1}, Emily Stein², Chiyuan Zhang³, Serge Cremers³, Stephanie Boutroy¹, Xiaowei Liu⁴, Donald McMahon², Mary Leonard⁵, X Guo³, Elizabeth Shane². ¹Columbia University Medical Center, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Columbia University, USA, ⁴University of Pennsylvania, USA, ⁵Children's Hospital of Philadelphia, USA

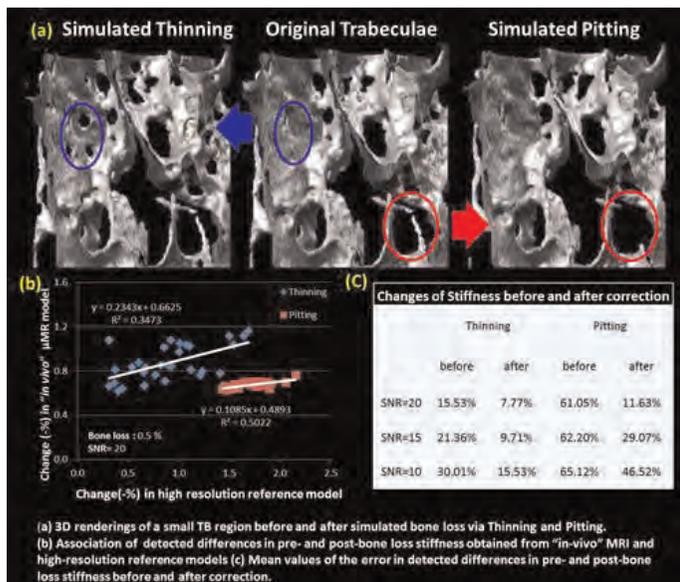

Fracture risk is elevated in patients with chronic kidney disease (CKD). We have previously reported that CKD patients with prevalent fractures have lower areal BMD (aBMD) by DXA at the ultradistal radius (UDR), and lower cortical and trabecular volumetric BMD (vBMD), thinner cortices and abnormal trabecular microarchitecture of the distal radius and tibia by high resolution peripheral computed tomography (HRpQCT). To ascertain whether microarchitectural abnormalities associated with CKD are progressive over time, we enrolled 60 patients in a longitudinal study. To date, we have measured aBMD by DXA at the lumbar spine (LS), total hip (TH), femoral neck (FN), 1/3 radius (1/3R) and ultradistal radius (UDR) and cortical and trabecular vBMD, geometry and microarchitecture of the distal radius and tibia by HRpQCT (voxel size 82 μ m) in 49 patients over a median (interquartile range) follow-up of 1.8 (1.2-2.0) years. Fasting serum was archived for batch analysis at study completion. Changes in bone parameters were annualized and compared by mixed models with adjustment for hemodialysis status and baseline measures of bone structure. Mean \pm SD age at baseline was 69 \pm 9 years; 55% were women, 37% had prevalent fractures, 16% were on dialysis. Mean GFR in non-dialyzed patients (36 \pm 17 mL/min) did not change (-0.4 \pm 6 mL/min, p=1.0). There were significant declines in aBMD at the TH (1.1 \pm 2.7%, p<0.01) and UDR (2.6 \pm 5.8%, p<0.01) but not the LS, FN or 1/3R. HRpQCT of the radius revealed significant declines in cortical area (2.6 \pm 3.8%, p<0.0001), density (1.1 \pm 1.5%, p<0.0001) and thickness (2.4 \pm 4.1%, p<0.0001). In contrast, trabecular vBMD and microarchitecture did not change, excepting a small but significant increase in trabecular area (0.7 \pm 0.7%, p<0.01). The amount, pattern and significance of changes were mirrored at the tibia. In summary, CKD is associated with progressive loss of cortical bone at both radius and tibia. The significant declines in cortical density, thickness and area, coupled with the increase in trabecular area suggest that endocortical cancellization is the primary mechanism of cortical loss. Pharmacologic interventions to decrease cortical bone loss in patients with CKD could represent a strategic therapeutic target to prevent deterioration of bone microarchitecture and lower fracture risk in this vulnerable population.

Changes in Bone Mineral Density over Time by Body Mass Index in the Health ABC Study. Jennifer Lloyd^{*1}, Dawn Alley¹, William Hawkes¹, Marc Hochberg², Shari Waldstein³, Tamara Harris⁴, Stephen Kritchevsky⁵, Ann Schwartz⁶, Elsa Strotmeyer⁷, Catherine Womack⁸, Denise Orwig¹. ¹University of Maryland, Baltimore, USA, ²University of Maryland School of Medicine, USA, ³University of Maryland, Baltimore County, USA, ⁴Intramural Research Program, National Institute on Aging, USA, ⁵Wake Forest Baptist Medical Center, USA, ⁶University of California, San Francisco, USA, ⁷University of Pittsburgh, USA, ⁸University of Tennessee, USA

Background: Cross-sectional studies have found a positive association between body mass index (BMI) and bone mineral density (BMD), but little is known about the longitudinal relationship between BMI and BMD in older adults. This relationship is important given the high prevalence of overweight and obesity. Methods: We examined average annual rate of change in BMD by initial BMI in the Health, Aging, and Body Composition Study, a cohort of White and Black well-functioning older adults age 70-79 years at enrollment. Baseline BMI (kg/m²) was categorized as normal (18.50-24.99), overweight (25.00-29.99), and obese (> 30.00). Repeated measurement of BMD (gm/cm²) was performed with DXA at baseline, and years 3, 5, 6, 8, 10. Multivariable generalized estimating equations analyses were used to predict mean BMD (femoral neck, total hip, and whole body) by baseline BMI group, adjusting for covariates. Results: The sample included 2,570 subjects [51% women] of whom 43% were overweight and 24% were obese with a mean baseline femoral neck BMD of 0.743 gm/cm² (SD=0.142), hip BMD of 0.888 gm/cm² (SD=0.169), and whole body BMD of 1.09 gm/cm² (SD=0.141). Obese older adults, compared to non-obese, had higher fat mass, higher rates of diabetes and hypertension, less physical activity, and less use of bisphosphonates, vitamin D and calcium supplements. There were no significant differences between BMI groups in the change in total hip or whole body BMD over time. However, there were significant differences between BMI groups in change in femoral neck BMD over time (p<0.001). Obese older adults lost 0.002 gm/cm² of BMD per year more compared with normal weight older adults (p<0.001). Femoral neck BMD change over time did not differ between the overweight and normal weight BMI groups (p=0.74). Indeed, obese older adults had the highest mean femoral neck BMD at baseline but had the lowest mean BMD by year 10. In year 10, mean femoral neck BMD ranged from 0.696 gm/cm² (SE=0.008) among obese, 0.719 gm/cm² (SE=0.005) among overweight, and 0.709 gm/cm² (SE=0.007) among normal weight older adults. In summary, this

Poor Bone Microarchitecture in Premenopausal Women with Recent Distal Radius Fracture Persists after Adjusting for Ultradistal Radius BMD.

Tamara Rozenal¹, Laura Deschamps¹, Alex Taylor², Brandon Earp³, David Zurakowski⁴, Charles Day¹, Mary Bouxsein^{*1}. ¹Beth Israel Deaconess Medical Center, USA, ²Massachusetts General Hospital, USA, ³Brigham & Women's Hospital, USA, ⁴Children's Hospital Boston, USA

Measurement of BMD by DXA combined with clinical risk factors is currently the gold standard for the diagnosis of osteoporosis and prediction of fracture risk. Yet, BMD does not always accurately reflect fracture risk as up to 50% of those who suffer fractures do not have osteoporosis by BMD testing. Advanced in vivo imaging has shown that older women and men with a history of fragility fracture have poor bone microarchitecture, often independent of their low BMD. As the origins of skeletal fragility may begin early in life, we asked whether premenopausal women with recent fracture have poor skeletal health. Thus, we recruited 40 premenopausal women with recent distal radius fracture (FX) and 80 fracture-free controls (CON). We assessed BMD of the hip, spine and radius; plus cortical (Ct) and trabecular (Tb) bone density and microarchitecture at the non-fractured/non-dominant distal radius and tibia by HR-pQCT. FX and CON did not differ with regard to age, race or BMI. BMD was similar in FX and CON at the fem neck, lumbar spine and 1/3 distal radius; but tended to be lower in the FX at the total hip and ultradistal radius (p=0.06). Ct and Tb microarchitecture differed between groups, both at the distal radius and tibia. At the distal radius, FX had lower total density, Tb density, Tb number and TbTh than CON (-6 to -14%, p<0.05 for all). Ct density and morphology at the distal radius did not differ between groups. At the distal tibia, total density, Tb density, TbTh, Ct thickness and Ct area were lower in FX vs CON (-7 to -17%, p<0.01). Conditional logistic regression showed that after adjustment for age and ultradistal radius BMD, radius Tb density, thickness, separation and distribution of Tb separation remained significantly associated with fracture (adjusted OR's: 1.94 - 2.04, p<0.05). At the tibia, after adjustment for age and femoral neck BMD, total density, Tb density, trabecular thickness, cortical area and cortical thickness remained significantly associated with fracture (adjusted OR's: 1.62 - 2.40, p<0.05). In conclusion, these findings show that despite similar BMD values, premenopausal women with recent distal radius fracture have significantly poorer bone density and microarchitecture at the distal radius and tibia compared to non-fracture controls. Early identification of women with poor bone health offers opportunities for interventions aimed at preventing further bone health declines.

Disclosures: Mary Bouxsein, None.

study found significant differences in femoral neck BMD over time by BMI groups but did not find differences in total hip or whole body BMD over time. Findings underscore the importance of looking at the longitudinal relationship between body composition and bone mineral density among older adults, indicating that weight may not be protective for osteoporosis over time.

Combined Hormonal Oral Contraceptive Use and Bone Mineral Density Change in the Premenopausal Population—10-year data from the Canadian Multicentre Osteoporosis Study. Jerilynn Prior¹, Heather Macdonald¹, Wei Zhou², Claudie Berger², Christopher Kovacs³, David Hanley⁴, Tassos Anastassiades⁵, Stephanie Kaiser⁶, and CaMOS Research Group⁷.
¹University of British Columbia, Canada, ²McGill University, Canada, ³Memorial University of Newfoundland, Canada, ⁴University of Calgary, Canada, ⁵Queen's University, Canada, ⁶Dalhousie University, Canada, ⁷, Canada

Combined hormonal oral contraceptives (COC) are used by 86% of Canadian premenopausal women. Three large cohort studies suggest past COC use is associated with higher postmenopausal fracture risk (Cooper 1993; Vessey 1998; Barad 2005) although reviews routinely cite improved bone health as a non-contraceptive COC benefit. A recent large prospective cohort study of young premenopausal women showed negative BMD changes in teenagers on higher dose COC (EE 30mg) vs. teenage controls (Scholes 2011). At baseline in the Canadian Multicentre Osteoporosis Study (CaMOS), premenopausal women who had ever vs. never used COC showed significantly lower lumbar spine (L1-4) and trochanter BMD values (Prior 2001). Prospective population-based data on COC and bone mineral density (BMD) changes are lacking. The purpose of this study was to document prospective 10-year (y) BMD changes in a population-based sample of premenopausal women, ages 25-45 at baseline, stratified by whether they reported never (N-COC), intermittent (I-COC), or continuous (C-COC) use of COC based on reports at baseline, 5 and 10-y examinations. To assess between-group differences, multivariable models of BMD change of L1-L4, total hip, femoral neck and trochanter were constructed using linear regression adjusting for age, body mass index (BMI), height and baseline BMD values. Results are reported as mean ± SD and by 95%CI of differences between groups (Table). In the 227 women mean age 35 ± 5y for whom 10-y premenopausal BMD change data were available, 28 women reported never use, 170 were I-COC users and 29 were C-COC. N-COC were less likely to be white and tended to be shorter than I-COC but did not differ in age, BMI, menarche age, parity, exercise, calcium, vitamin D, cigarette or alcohol use from COC user groups. C-COC tended to be more likely than I-COC to have started COC for non-contraceptive reasons. Adjusted BMD change results (Table) showed that L1-4 change was positive in N-COC (0.007 ± 0.057) vs. negative in I-COC (-0.001 ± 0.057) and C-COC (-0.017 ± 0.060) groups although these differences were not significant. At the total hip site N-COC showed no BMD change whereas small mean positive BMD changes occurred in the I-COC and C-COC users. In summary, these data suggest that community COC use in premenopause is not associated with important BMD loss, however larger prospective population-based studies are needed—adverse BMD changes by COC use in teenagers need confirmation in population data.

Evidence for Spontaneous Recovery of Bone Mineral Density after Treatment for Cushing's Syndrome: a Long-term Follow-up Study. Anke van der Eerden¹, Martin Den Heijer².
¹Radboud University Nijmegen Medical Centre, Netherlands, ²VU Medical CenterPostbus 70571007 MB Amsterdam, The Netherlands

Introduction: Cushing's syndrome gives a high risk of osteoporotic fractures. After treatment bone mineral density (BMD) improves, but recovery lasts years and full recovery probably does not occur in all patients. We evaluated BMD of the lumbar spine and femoral neck of patients with Cushing's syndrome, measured at the time of diagnosis and during long-term follow-up.

Methods and Materials: We collected all BMD measurements of the lumbar spine and the right femoral neck performed in patients diagnosed with Cushing's syndrome in our hospital, as measured by dual-energy X-ray absorptiometry. To analyse BMD data we used a non-linear model in which individual BMD is described as an age-related deviation from the population reference value.

Results: BMD values were available for 151 patients with Cushing's syndrome. Mean follow-up time after treatment was 12.5 years (total 1888 patient years). Before treatment, patients with Cushing's syndrome had a lower BMD compared to the NHANES reference population (lumbar spine Z-score -1.8 SD (95%CI -2.1 to -1.4 SD); femoral neck -0.9 SD (95%CI -1.4 to -0.6 SD)). Recovery was complete in most patients but not in certain groups. Reaching the estimated individual final BMD took 11.0 years (95%CI 9.5 to 12.5 years, lumbar spine) and 12.0 years (95%CI 10.0 to 13.5 years, femoral neck).

Conclusion: In most patients with Cushing's syndrome, BMD improves to normal in about one decade. In 2-2.5 years BMD-loss decreases 50%, e.g. from osteoporosis to osteopenia. This supports the practice of evaluating BMD in osteoporotic Cushing patients every 2 years until reaching osteopenia.

Fracture Risk is Increased in Severe Obesity with Low Bone Mineral Density. Sarah Cawsey*, Rajdeep S Padwal, Stephanie Li, Arya M Sharma, Kerry Siminoski. University of Alberta, Canada

Purpose: The bone-protective effect of body weight is controversial and recent studies have found increased risk of some fractures in obesity. Most published research has involved individuals with modest obesity; the relationship between bone mineral density (BMD) and fracture risk has not been well characterized in severe obesity.

Methods: A cross sectional study of 400 randomly chosen female patients admitted to the Edmonton Weight Wise Regional Obesity Program (Edmonton, Alberta, Canada) from November 2008 to June 2010. Historical information including self-reported fracture history was obtained at the time of dual-energy X-ray absorptiometry (Hologic 4500A). For fracture rates, the group comprising the lowest quintile of femoral neck BMD was compared to the remainder of the population. For certain risk factors, the lowest BMD quintile was compared to an equal number (n = 75) of age- and BMI-matched controls randomly selected from the remainder of the study group.

Results: Subjects were severely obese with a mean body mass index (kg/m²) of 46.0 (SD 7.4), had an average age of 43.8 years (SD 11.1 years), and 160 (40.0%) were postmenopausal. Women in the low BMD quintile had a mean BMD Z-score of -0.1 (SD 0.4) compared to +1.6 (SD 0.9) in the rest of the population. The low BMD quintile had significantly more total fractures (50.7% vs. 18.2%, p < 0.0001), fragility-type fractures (hip, vertebral, forearm, upper arm; 14.7% vs. 5.2%, p = 0.0039), and other fractures (34.7 vs. 12.9%, p < 0.0001) compared to the remaining population.

Among other fractures, the low BMD quintile had increased rates of hand/foot fractures (16.0% vs. 5.5%, $p = 0.0019$) and ankle/lower leg fractures (17.3% vs. 7.1%, $p = 0.0051$). The low BMD quintile did not differ from control subjects for menopausal history, smoking, parental history of hip fracture, doses of calcium and vitamin D supplements, serum 25-OH vitamin D, or other lab tests. The low BMD quintile had higher risks of osteoporotic fracture (3.4% (SD 2.4%) vs. 2.5% (SD 1.6%); $p = 0.0086$) and hip fracture (0.2% (SD 0.3%) vs. 0.02% (SD 0.04%); $p < 0.0001$) according to FRAX (Canadian FRAX tool).

Conclusions: Women with the lowest BMD values among those with severe obesity have a markedly elevated risk of fracture compared to those with higher BMD values, despite the fact that their BMD Z-scores are in the "normal" range. This population may require its own reference range to define "low" density.

FR0323

Race/ethnic Differences in Associations between Bone Mineral Density and Fracture History. Min-Ho Shin¹, Joseph Zmuda², Elizabeth Barrett-Connor³, Yahtyng Sheu², Alan Patrick⁴, Sun-Seog Kweon¹, Hae-Sung Nam⁵, Jane Cauley². ¹Chonnam National University Medical School, South Korea, ²University of Pittsburgh Graduate School of Public Health, USA, ³University of California, San Diego, USA, ⁴Tobago Health Studies Office, Scarborough, Trinidad & Tobago, ⁵Chungnam National University Medical School, South Korea

The aim of our study was to determine whether there are race/ethnic differences in bone mineral density (BMD) by fracture history in men aged 65 and older. We used a cross-sectional design. The datasets included the Osteoporotic Fractures in Men (MrOS) Study (5,342 White men, 243 African-American, 190 Asian, and 126 Hispanic men), Tobago Bone Health Study (641 Afro-Caribbean), Namwon Study (1,834 Korean rural), and Dong-gu Study (2,057 Korean urban). BMD was corrected according to the cross-site calibration results for all scanners. Linear regression analysis was used to estimate the difference in BMD between subjects with a positive fracture history and those without a fracture within each racial/ethnic group. Logistic regression was used to examine the association of BMD with fracture within each racial/ethnic group for fracture. In all models, we adjusted for age, body weight, height, smoking and alcohol use. Mean age (years) of the Korean combined cohorts, US white, US African-American, US Asian, US Hispanic and Afro-Caribbean were 71.2 ± 4.3 , 73.8 ± 5.9 , 71.7 ± 5.1 , 72.9 ± 5.1 , 72.0 ± 4.8 , and 72.3 ± 5.7 , respectively. The proportion with a history of non-traumatic fracture were 4.9%, 17.6%, 14.8%, 10.5%, 13.5% and 5.5% for Korean, US white, US African-American, US Asian, US Hispanic and Afro-Caribbean, respectively. The mean differences of hip and lumbar spinal BMD between subjects with fracture and without fracture were significant in all cohorts except US African American and US Asian men, Table. There was a significant race/ethnic difference in the mean lumbar spinal BMD between subjects with fracture and without fracture (p for interaction=0.049), but no difference in the mean BMD. Odds ratio (95% confidence interval) of fracture for 1 SD decrease in lumbar spine BMD were 1.37 (1.16, 1.62); 1.53 (1.41, 1.66); 1.45 (0.96, 2.19); 1.42 (0.84, 2.40); 3.34 (1.44, 7.74); and 1.96 (1.26, 3.02) for Korean, US White, US African-American, US Asian, US Hispanic and Afro-Caribbean, respectively. Our data show that BMD differences by fracture status were greatest for US Hispanic and Afro-Caribbean men with higher odds ratios of fracture for 1 SD decrease in BMD than Korean and US white, US African-American, and US Asian men. Our results suggest that there are race/ethnic differences in the association between lumbar spine BMD and fracture history.

Table. Adjusted mean and differences of BMD (g/cm³) according to history of fracture.

Physical Activity and Incident Fracture in Postmenopausal Women: The Women's Health Initiative Observational Study. Jean Wactawski-Wende^{*1}, Joseph C. Larson², Jane Cauley³, Zhao Chen⁴, Rebecca Jackson⁵, Andrea LaCroix⁶, Michael LaMonte¹, Meryl Leboff⁷, Judith K. Ockene⁸, John Robbins⁹. ¹University at Buffalo, USA, ²Fred Hutchinson Cancer Research Center, USA, ³University of Pittsburgh Graduate School of Public Health, USA, ⁴University of Arizona, USA, ⁵The Ohio State University, USA, ⁶Fred Hutchinson Cancer Research Center, USA, ⁷Brigham & Women's Hospital, USA, ⁸University of Massachusetts, USA, ⁹University of California, Davis Medical Center, USA

Approximately 2.0 million fractures occur annually in adult U.S. women with mortality from hip fracture approaching 20%. We assessed the role of physical activity in incident fracture in the Women's Health Initiative Observational Study (WHI-OS). The WHI-OS enrolled 71,187 postmenopausal women aged 50-79 between 1994 and 1998. Recreational physical activity and walking was self-reported at enrollment. Metabolic equivalents (MET-hours/week) were estimated for total energy expenditure as well as for sedentary, walking, and strenuous activities. Incident fractures were self-reported annually through 2005. Hazard Ratios (HR) were calculated comparing fracture incidence rates in those reporting no activity to those reporting activity, according to tertiles within those active. A total of 10,927 fractures occurred (760 hip; 2477 wrist; 1189 clinical vertebral) during an average follow-up of 7.6 years. In multivariable adjusted models, compared to those reporting no activity, those in the highest activity category (>17.5 MET-hours/week) had significantly fewer hip fractures (HR= 0.63, 95% CI: 0.48, 0.81) and significantly fewer clinical vertebral fractures (HR=0.80, 95% CI 0.66, 0.98) and marginally fewer total fractures (HR=0.95, 95% CI: 0.89, 1.02). Among those most active, wrist fracture occurred somewhat more frequently (HR=1.10, 95% CI: 0.96, 1.27). Walking and strenuous activity were similarly and significantly associated with these fracture outcomes. No evidence of effect modification by age, BMI or race/ethnicity was observed. Recreational physical activity is generally associated with fewer fractures in older women. Increased activity may be one strategy to prevent fractures in older women, especially in hip fracture where the associated morbidity and mortality are most profound.

A Proposed World-Wide Gene-Environment Interaction Study of BMD and Fracture Risk: Feasibility Analysis Based on the GEFOS-GENOMOS Collaboration. Jonathan Reeve^{*1}, Stephen Kaptoge², On behalf of the GEFOS & GENOMOS consortium³. ¹University of Cambridge, United Kingdom, ²University of Cambridge Bone Research Group, United Kingdom, ³Erasmus Medical Center, Netherlands

There is widespread general and scientific interest in how to modify the genetic determinants of fracture. The GEFOS & GENOMOS consortium has just reported on the genetic determinants of BMD and fracture (Estrada K et al Nature Genetics 2012 DOI 10.1038/ng.2249). Fourteen BMD loci were associated with fracture including genes previously not known to play a role in bone biology. Our purpose is two-fold: to summarize the collection of environmental exposure data by GEFOS and GENOMOS in participating GEFOS/GENOMOS subjects; and to make the case for enlarging our planned GxE meta-analysis into a world-wide collaboration.

Fifty four European, Australasian, Far-Eastern and N American studies expressed interest in participating of which 41 were permitted by their IRBs to share individual-level environmental exposure data. This report considers data from the 27 cohorts whose phenotypic data has been cleaned and reconciled in Cambridge UK and reports on the a priori statistical power available.

Environmental exposures and plasma biomarkers were supplied as continuous or categorical variables, with almost complete data available on age, height and weight and lower levels of availability for other variables. Studies, after sample-size weighting, declared more than 50% availability of data on alcohol, smoking, fracture history, physical activity (several aspects), several diet nutrients, rural-vs-urban domicile, fall history, and exposures to glucocorticoids and exogenous estrogen. A substantial minority of studies had measured plasma biomarkers. Calculations were done to determine the a priori statistical power of the planned meta-analysis at $p < 0.001$, with testing restricted to polymorphisms reported significant by Estrada et al. Using exemplary minor allele frequencies (MAF) of 0.2 and GxE interaction coefficients of 0.03 and 0.06 per categorical exposure (or per 1 SD higher outcome in the case of continuous exposures) we report the numbers of subjects needed to achieve 80% power for the most commonly collected categorical and continuous environmental exposure or biomarker data (Table).

Conclusions. These results provide a powerful basis for investigating the interplay of genes and environment in association with fracture susceptibility and intermediate phenotypes. To achieve this goal, ensuring maximal statistical power and proper standardization of exposures, a world-wide collaboration is needed building on the current GEFOS collaboration.

Objectively Measured Physical Activity and Bone Mineral Content from Age 5 to 15 Years: Iowa Bone Development Study. Kathleen F Janz*, Steven M Levy, Elena Letuchy, Trudy L Burns, Julie M Eichenberger Gilmore, James C Torner. University of Iowa, USA

Purpose: This study examined the longitudinal association between physical activity (PA) and bone mineral content (BMC; g) from middle childhood to middle adolescence (ages 5 to 15 yr, 10-year follow-up) and tested the premise that PA has a greater effect on BMC during specific periods of growth (window of opportunity hypothesis).

Methods: Participants in the Iowa Bone Development Study at ages 5, 8, 11, 13, and 15 yr (n = 369, 449, 452, 410, 307, respectively) were studied. Moderate-through-vigorous PA (MVPA, (min·day⁻¹) and vigorous PA (min·day⁻¹) were measured using the Actigraph accelerometer. Anthropometrics were used to measure body size and somatic maturity. BMC of the lumbar spine and hip was measured using dual-energy x-ray absorptiometry. Gender-specific multi-level models were used to create BMC growth curves for individual participants (level 1) and test the effect of PA (level 2) after considering weight (kg), height (cm) linear age (yr), non-linear age (yr²), maturity (pre peak height velocity = 0 or at/post peak height velocity = 1). To explore the possibility that bone is more sensitive to PA during certain periods of growth, we tested the interaction of PA × maturity and PA × age. The Akaike Information Criterion (AIC) was used to determine the best fitting models. Clinical significance was examined via the differences in BMC between the least (10th %) and most (90th %) active children.

Results: For boys and girls, PA added to the prediction of both spine and hip BMC throughout the 10-year follow-up (age 5 to 15 yr). There was no interaction between PA and maturity or PA and age. Models with vigorous PA had lower (better) AIC when compared to MVPA models. At age 5, the most vigorously active boys had 8.5% more hip BMC than the least active. At age 15, this difference was 2.0%. The most vigorously active girls at age 5 had 6.1% more hip BMC than the least active. The age 15 difference was 1.8%.

Conclusions: Objectively measured everyday PA, especially vigorous PA, is associated with BMC at weight-bearing skeletal sites from childhood to adolescence. Importantly, the effect of PA is the same regardless of maturity or age. The reduced contribution of PA to BMC as children age is primarily due to reductions in PA. This suggests the critical importance of early and sustained PA interventions that focus on vigorous PA. Current public health approaches focused on moderate PA may be inadequate for optimal bone health.

A Distal Forearm Fracture in Childhood Increases the Risk for Fracture during Adulthood in Men, but not in Women. Shreyasee Amin*¹, L. Joseph Melton¹, Sara Achenbach¹, Elizabeth Atkinson¹, Mark Dekutoski¹, Salman Kirmani¹, Philip Fischer¹, Sundeep Khosla². ¹Mayo Clinic, USA, ²College of Medicine, Mayo Clinic, USA

Distal forearm fractures are the most common type of fracture sustained during childhood. It remains unclear whether these fractures are related, in part, to transient bone strength deficits during growth or to deficits that may track into adulthood. If the latter, a distal forearm fracture in childhood would be expected to predict an increased risk for fractures in adulthood.

We identified 1776 Olmsted County, Minnesota residents who had sustained their first distal forearm fracture at ≤18 yrs of age between 1935 and 1992, and had available follow-up through to at least age 35 yrs. Subsequent incident fractures were identified through review of complete (inpatient and outpatient) medical records. Observed fractures (excluding pathologic fractures and those resulting from severe trauma) were then compared with the numbers expected from incidence rates in the Olmsted County population (standardized incidence ratios [SIR]). We also examined the risk for fractures at osteoporotic (OP), defined as hip, spine, wrist and shoulder, and non-osteoporotic (non-OP) sites. Analyses were stratified by sex, and then by age at the initial distal forearm fracture (<10 yrs, 11-13 yrs, 14-18 yrs).

We studied 1086 boys and 690 girls, whose mean age (± SD) at distal forearm fracture was 11 ± 4 yrs for boys and 10 ± 4 yrs for girls. Over 27,277 person-yrs of follow-up after age 35 yrs (to mean age 51 ± 11 yrs for men and 50 ± 11 yrs for women), there were 144 men and 74 women who had a fracture due to no more than moderate trauma. There was an increased risk for future mild-to-moderate trauma fractures in boys who had a distal forearm fracture, but not girls (Table). Results were similar when we considered fractures only after age 50 yrs. The increased risk was apparent irrespective of the age at initial distal forearm fracture in boys. In both men and women, the most common future fractures occurred at the spine and ribs.

A distal forearm fracture in boys may signal an increased risk for future fractures either due to persistent deficits in bone strength, continued high fracture risk activity, or both. If deficits in bone strength do track into adulthood, differences in findings between the sexes may be due to menopause in women having a greater net influence on subsequent fracture risk, but would require further study.

BMI-Associated Increases in Proximal Femoral Volumetric BMD, Size and Strength Are Not Sufficient to Compensate for Increased Fall Forces in Obese Older Men. Jian Shen*¹, Carrie Nielson¹, Lynn Marshall¹, David Lee², Tony Keaveny³, Eric Orwoll¹. ¹Oregon Health & Science University, USA, ²O.N. Diagnostics, USA, ³University of California, Berkeley, USA

Although higher body mass index (BMI) is associated with higher bone mineral density (BMD), recent evidence indicates that obesity may not be associated with reduced hip fracture risk. Substantial proportions of hip fractures occur among overweight and obese men and women. This evidence suggests that higher BMI may have deleterious effects on bone structure or volumetric BMD, but this issue has not been studied in detail. We conducted cross-sectional analyses of baseline BMI and quantitative computed tomography (QCT)-derived femoral bone density and structural dimensions in the Osteoporotic Fractures in Men Study (MrOS). Hip QCT scans were completed in 3056 subjects (mean age: 73 y). Finite element (FE) analysis based on QCT images was further completed in a random subcohort consisting of 669 men. FE was used to assess proximal hip strength in a sideways fall orientation. Fall forces on the hip were derived, and Phi was calculated as fall force-to-strength ratio with the value ≥ 1 indicating high risk of hip fracture during a sideways fall. We used non-parametric generalized additive models to identify nonlinearity in the associations between BMI and QCT measurements, and multivariable general linear models to test the linear associations. Higher BMI was associated with slightly greater volumetric BMD and size measures at femoral neck. However, the relationship was non-linear. For men with BMI < 30 (n=2387), there was a linear relationship between BMI and QCT measurements such that higher BMI was associated with greater integral BMD, trabecular BMD, cortical thickness and cross-sectional area (Table). However, there were no significant associations among those with BMI ≥ 30 (n=669). FE analysis suggested that compared to non-obese men, obese men had higher hip strength but also higher Phi (P = 0.0001) and a higher risk of Phi-estimated hip fracture (OR: 2.14 vs non-obese men; P=0.008). These findings indicate that the relationships of BMI with femoral BMD and structure are nonlinear. In non-obese men, increased BMI is associated with increased bone size, BMD and cortical thickness. In obese individuals, there is no further improvement of those structure parameters with additional increases in BMI. FE analyses suggest that the incremental increase in strength is not proportionate with increased fall force in obese men. These results provide some insight into mechanisms underpinning fracture risk in obese men.

Estimated Frax[®] 10-Year Fracture Risk at the Time of Incident Fracture and Upon Refracture: Results from the Optimus Initiative. Pierre-Marc April¹, Noémie Poirier², Sophie Roux³, Marie-Claude Beaulieu¹, Michèle Beaulieu⁴, François Cabana⁵, Gilles Boire². ¹Université de Sherbrooke, Canada, ²Centre hospitalier universitaire de Sherbrooke, Canada, ³University of Sherbrooke, Canada, ⁴Merck Canada Inc, Canada, ⁵CHUS, Canada

Introduction. Identification of patients who will sustain a fragility fracture (FF) is the main objective of the WHO Fracture Risk Assessment score (FRAX[®]).

Objectives. To describe the FRAX scores at the time of an incident FF and the rates of subsequent fractures over 4 years according to FRAX category following this clinical FF.

Methods. An ongoing prospective cohort of men and women over 50 years of age was followed up in the OPTIMUS study, an intervention aimed at increasing the rate of initiation and persistence on osteoporosis treatment after an incident FF leading to an orthopaedic consultation. After inclusion, participants were counselled about osteoporosis and its relationship to FF. A letter was sent to their Family Physician (FP) to stress the importance of treating osteoporosis unmasked by a FF, with reminders to FP of patients still untreated at the time of regular phone follow-ups. At year 1, use of anti-osteoporosis medication was checked with the patients' pharmacists and confirmed in 56%. New FF were reported during phone follow-ups with patients. FRAX scores (excluding BMD) were calculated from baseline and follow-up information.

Results. From January 2007 to July 2011, 1172 patients (961 women) with FF were included. FRAX score could not be calculated in 20 patients because of missing data.

Before the incident FF, 617/1152 (53.6%) were scored at Low, 291 (25.3%) at Moderate, and only 244 (21.2%) at High risk for FF (Table). After the incident FF, 27.3% patients were still considered at Low, 40.6% at Moderate and 32.0% at High Risk. FRAX scores were still estimated Low-risk in 5.8%, 22.8%, 26.0%, 35.3%, 49.3% and 36.4% of patients with incident FF at the Hip, Proximal Humerus, Wrist, Vertebra, Ankle and Other Minor sites, respectively.

Over 2285 patient-years of follow-up, 111 recurrent FF occurred. Rates of FF were 6.71, 6.60, 4.71, 4.44, and 3.76 FF/100 patient-years after FF at Other Minor sites, Hip, Wrist, Proximal Humerus and Ankle, respectively. The estimated 10-year risk was High in 74 (66.7%) patients before the recurrent FF. Odds ratios (ORs) for recurrent FF were 4.17 [CI 2.75-6.31] for High relative to Low/Moderate risk and 3.42 [CI 2.00-5.86] for High relative to Low risk only. Rates of recurrent FF for Moderate (19/468 patients) and Low (19/315) risk groups were similar (OR 0.70 [CI 0.36-1.35]).

Conclusions. FRAX High-risk category identifies less than 25% of patients who will present an incident FF. Once a FF has occurred, a High risk score is a moderately sensitive (66%) but clinically useful (OR > 4) predictor for subsequent FF. As FRAX was designed for use in untreated patients only, High-risk scores may overestimate fracture risk in those patients becoming treated, further strengthening our observations. However, FF patients classified at Moderate and Low risks had similar rates of recurrent FF, suggesting that this subdivision may not be clinically useful after a FF.

| Site of the initial fragility fracture (FF) (Number of patients with fracture*) | 10-year fracture risk according to FRAX [®] (High Risk: ≥20% Major Fracture and/or >3% Hip FF) (Moderate Risk: ≥10% and <20% Major Fracture and <3% Hip FF) (Low risk: <10% Major Fracture and <3% Hip FF) | | | | | |
|---|---|-------------------|-------------------|-----------------------|-------------------|-------------------|
| | BEFORE the incident FF | | | AFTER the incident FF | | |
| | Low n (%) | Moderate n (%) | High n (%) | Low n (%) | Moderate n (%) | High n (%) |
| Any fragility fracture (n= 1152) | 617 (53.6) | 291 (25.3) | 244 (21.2) | 315 (27.3) | 468 (40.6) | 369 (32.0) |

Fractures in Patients Diagnosed With HIV. Daniel Prieto-alhambra^{*1}, Arief Lalmohamed², Frank De Vries³, Peter Vestergaard⁴. ¹Institut Municipal D'Investigació Mèdica, United Kingdom, ²Department of Pharmacoepidemiology & Clinical Pharmacology, Utrecht Institute of Pharmaceutical Sciences, Netherlands, ³, ⁴Aarhus University Hospital, Denmark

Aim: To study the effects of a diagnosis of human immunodeficiency virus infection on fracture risk.

Subjects and methods: Case control study. From the Danish National Health Service, we identified 124,655 fracture cases and 373,962 age- and gender-matched controls. Odds ratios (OR) and 95% confidence intervals (CI) were estimated.

Results: A total of 50 patients in the fracture group and 52 in the control group had a prior HIV diagnosis, which is in the range expected in the Danish population. The risk of any fracture was thus significantly increased among HIV-infected patients (crude OR = 2.89, 95% CI 1.99-4.18). Similarly a significant increase in the risk of hip (crude OR=8.99, 95% CI 1.39-58.0), forearm (crude OR=3.50, 95 CI 1.26-9.72), and spine fractures (crude OR=9.00, 95% CI 1.39-58.1) was observed. After adjustment for alcoholism, stroke, working, co-habitation status, income, number of bed days in hospital in the previous year, number of contacts to GP or specialist in the previous year, use of anti-epilepsy drugs, use of anxiolytics or sedatives, prior fracture, and use of corticosteroids the OR for any fracture was still significantly increased (1.66, 95% CI 1.08-2.54). The trend was the same for hip fractures, but no longer statistically significant (9.93, 95% CI 0.90-109). The association with forearm (1.78, 95% CI 0.54-5.93) and spine (3.20, 95% CI 0.33-31.0) fractures was no longer statistically significant.

Conclusion: HIV infection is associated with a significant increase in the risk of fractures. Preventive measures against fractures may be considered in HIV-infected patients, especially as life-expectancy has improved significantly, and as fractures may negatively affect quality of life and increase the risk of death.

Iron Overload Accelerates Bone Loss in Healthy Postmenopausal Women and Middle-aged Men: a 3-year Retrospective Longitudinal Study. Beom-Jun Kim^{*1}, Seong Hee Ahn², Sung Jin Bae¹, Seung Hun Lee³, Jung-Min Koh¹, Ghi Su Kim³. ¹Asan Medical Center, South Korea, ²Division of Endocrinology & Metabolism, Asan Medical Center, University of Ulsan College of Medicine, South Korea, ³Asan Medical Center, University of Ulsan College of Medicine, South Korea

Despite extensive experimental and animal evidence about the detrimental effects of iron and its overload on bone metabolism, there have been no clinical studies relating iron stores to bone loss, especially in non-pathologic conditions. In the present study, we performed a large longitudinal study to evaluate serum ferritin concentrations in relation to annualized changes in bone mineral density (BMD) in healthy Koreans. A total of 1,729 subjects (940 postmenopausal women and 789 middle-aged men) aged 40 years or older who had undergone comprehensive routine health examinations with an average 3 years of follow-up were enrolled. BMD in proximal femur sites (i.e., the total femur, femur neck, and trochanter) was measured with dual-energy X-ray absorptiometry using the same equipment at baseline and follow-up. The mean age of women and men in this study was 55.8 ± 6.0 years and 55.5 ± 7.8 years, respectively, and serum ferritin levels were significantly higher in

men than in women ($P < 0.001$). The overall mean annualized rates of bone loss in the total femur, femur neck, and trochanter were $-1.14\%/yr$, $-1.17\%/yr$, and $-1.51\%/yr$, respectively, in women and $-0.27\%/yr$, $-0.34\%/yr$, and $-0.41\%/yr$, respectively, in men. After adjustment for potential confounders, the rates of bone loss in all proximal femur sites in both genders were significantly accelerated in a dose-response fashion across increasing ferritin quartile categories (P for trend = $0.043 < 0.001$). Consistently, compared with subjects in the lowest ferritin quartile category, those in the third and/or highest ferritin quartile category showed significantly faster bone loss in the total femur and femur neck in both genders ($P = 0.023 < 0.001$). In conclusion, these data provide the first clinical evidence that increased total body iron stores could be an independent risk factor for accelerated bone loss, even in healthy populations.

Is Bisphosphonate Therapy for Benign Bone Disease Associated with Impaired Dental Healing? Gelsomina Borromeo¹, John Wark^{*2}, Caroline Brand³, Michael McCullough⁴, John Clement⁴, Lisa Crighton³, Graham Hepworth⁵. ¹The University of Melbourne, Australia, ²University of Melbourne Department of Medicine, Australia, ³Melbourne Health, Australia, ⁴Melbourne Dental School, University of Melbourne, Australia, ⁵University of Melbourne, Australia

Delayed dental healing (DDH) and osteonecrosis of the jaw (ONJ) are potentially devastating conditions associated with use of intravenous bisphosphonate therapy for oncology indications. The relationship between bisphosphonate use for non-oncology indications (benign bone disease) and these conditions has not been determined.

A case controlled study design was employed to test whether or not DDH, defined as a persistent breach in the oral mucosa and/or exposure of bone in the mandible or maxilla that fails to heal within 6 weeks, is associated with oral bisphosphonate use for a non-oncology indication.

Potential cases of DDH were identified by consecutive screening of Specialist Oral and Maxillofacial and Special Needs Dentist clinic records for patients over 50 years, during a 6-month window, in the State of Victoria, Australia. Potential cases were confirmed by a Case Adjudication Panel and then matched for age and gender (1:4, n=160 controls) and source of dental referral with controls.

Variables of interest were: precipitants (dental extractions, implant placement, denture use, none), dental clinic type (public, private), smoking history, medical comorbidities, oral hygiene habits, socio-economic status (education level, household earnings).

4212 of 22,358 patient files met inclusion criteria, of which 69 were potential cases and 40 confirmed cases.

There was an estimated 13 times increased odds of developing DDH when taking an oral bisphosphonate (OR= 13.1, 95% CI 4.4 to 39.3).

There was a modest interaction between age, gender and clinic type (public versus private). There was insufficient power to show a significant effect of smoking despite a larger number of cases being smokers. There was however a link between having another illness (such as diabetes) and developing DDH (OR=2.3; 95% CI 1.0 to 5.2). Low socio-economic status was more prevalent amongst cases; low education (OR=13.7, 5.8 to 119), low household earnings (OR=10.55, 1.2 to 93.5).

39 out of 40 cases of DDH had a dental precipitant which did not threaten the association between bisphosphonate use and DDH.

In conclusion, this study highlights an important association between bisphosphonate use and DDH in individuals with a dental precipitant and taking oral bisphosphonates in the setting of benign bone disease. The relationship with other contributing factors requires further investigation.

FR0349

Older Men with either High or Low Serum 25-hydroxy Vitamin D levels have Significantly Increased Fracture Risk: Results from the Prospective CHAMP Study. Kerrin Bleicher^{*1}, Markus Seibel², Robert Cumming³, Vasikaran Naganathan⁴. ¹University of Sydney, Australia, ²Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, ³School of Public Health, University of Sydney, Australia, ⁴Centre for Education & Research on Ageing, University of Sydney, Australia

Introduction: The relationship between serum 25-hydroxyvitamin D (25OHD) and fracture risk is unclear. The aim of this study was to investigate the relationship between serum 25OHD and incident fractures in a large population based cohort of older men.

Background: As the relationship between serum levels of 25OHD and fracture risk remains unclear, we investigated this question in a large population-based cohort of older men in Sydney, Australia.

Methods: In the CHAMP study, 1705 community-dwelling men aged 70-97 years were followed for a mean of 4.4 years, during which time data on radiologically verified fractures was collected prospectively. Serum 25OHD levels were measured

using a radioimmunoassay detecting both D2 and D3 (DiaSorin). Information on potential confounders was collected at baseline using clinical measures and questionnaires. We accounted for bone mineral density (BMD), falls' history, physical activity, sun exposure, season of blood draw, country of birth, in addition to anthropometric and lifestyle factors, medical history, muscle strength, balance, and serum biochemistry. The relationship between fractures and serum 25OHD levels was analyzed using Cox's Proportional Hazard regression.

Results: There were 123 first incident fragility fractures in 1662 men with valid serum 25OHD measures. The relationship between baseline serum 25OHD and fracture risk was "U-shaped", with an increased fracture risk in men with either low or high serum 25OHD levels. In multivariate analysis, the risk of fracture was greatest in men with serum 25OHD in the lowest quintile (25OHD ≤ 36 nmol/L (14.4 ng/mL); HR= 4.5, 95% CI:2.0,10.2) and in men in the highest quintile (25OHD ≥ 73 nmol/L (29.2 ng/mL); HR=3.5, 95% CI:1.5, 8.0) compared to men in the 4th quintile (25OHD: 59 to 72 nmol/L (23.6-28.8 ng/mL)) (table 1).

Conclusion: In community-dwelling older men, fracture risk was significantly increased not only in vitamin D-deficient men, but also in men within the highest quintile of serum 25OHD. This effect was not explained by lower BMD, increased physical activity, falls' risk or other lifestyle or anthropomorphic factors.

| Serum 25OHD levels | ≤ 36 nmol/L | > 37 to ≤ 48 nmol/L | > 48 to ≤ 59 nmol/L | > 59 to ≤ 72 nmol/L | > 72 nmol/L |

FR0350

Wrist Fracture Incidence, Risk Factors, and Associations with Subsequent Fractures in Older Men. Elizabeth Barrett-Connor^{*1}, Carrie Nielson², Kristine Ensrud³, Eric Orwoll². ¹University of California, San Diego, USA, ²Oregon Health & Science University, USA, ³Minneapolis VA Medical Center / University of Minnesota, USA

Purpose: Distal radius is one of the most common fragility fracture sites in women ages 40 to 60 years old, and history of wrist fracture is a risk factor for future osteoporotic fractures. Incidence of wrist fracture is lower in men, and its risk factors are uncertain. We analyzed risk factors for incident wrist fractures, as well as the associations between a history of wrist fracture and incident fractures, in the Osteoporotic Fractures in Men (MrOS) study.

Methods: Men ages ≥ 65 were enrolled in the MrOS cohort in 6 US cities and followed for a mean of 8.9 years. Incident fractures were ascertained by triannual postcards and confirmed by radiographic reports. Baseline data on self-reported medical conditions, history of fractures, physical activity, and difficulty with instrumental activities of daily living (IADL) were collected by questionnaire, and a medication inventory was done. Arm BMD was obtained by DXA, and blood samples were provided. Grip strength was tested by handheld dynamometer. Men with follow-up time who were not using osteoporosis medications at baseline (N=5878, 98% of the full cohort) were included in the analysis. Multivariable Cox proportional hazards models were used to identify independent risk factors for incident wrist fracture. In separate models, age-adjusted hazard ratios quantified the association between baseline history of wrist fracture and incident nonspine, wrist, and hip fracture.

Results: The incidence of wrist fracture was 1.6 per 1000 man-years overall and ranged from 1.1 among that age 65-69 at baseline to 2.3 for men ≥ 80 . Independent predictors of wrist fracture were a baseline history of fracture since age 50 (hazard ratio [HR]: 2.1, 95% CI: 1.3-3.3), difficulty with any of 5 IADLs (HR: 1.6, 95% CI: 1.0-2.7), higher serum phosphate (HR: 1.3 per SD increase, 95% CI: 1.0-1.6), and lower arm BMD (HR: 2.0 per SD decrease, 95% CI: 1.5-2.6). Baseline history of wrist fracture since age 50 was associated with an increased risk of any nonspine fracture (age-adjusted HR [AHR]: 1.8, 95% CI: 1.4-2.4) and of incident wrist fracture (AHR: 2.9, 95% CI: 1.4-5.7) and hip fracture (AHR: 1.9, 95% CI: 1.1-3.2).

Conclusions: Although wrist fractures are much less common and occur later in men compared to women, they have similar risk factors and consequences. Risks for wrist fracture in older men included age > 79 , low BMD, and/or a prior nonspine fracture. Wrist fracture predicted incident fracture, including hip fracture.

Effect of Obesity on Healthcare Utilisation and Quality of Life after Fracture in Postmenopausal Women: the Global Longitudinal study of Osteoporosis in Women (GLOW). Juliet Compston^{*1}, Julie Flahive², Steven Boonen³, Adolfo Diez-Perez⁴, Stephen Gehlbach⁵, Susan Greenspan⁶, Frederick Hooven⁷, Robert Lindsay⁸, Christian Roux⁹, Philip Sambrook¹⁰, Frederick Anderson², Stuart Silverman¹¹. ¹University of Cambridge School of Clinical Medicine, United Kingdom, ²UMass Medical School, USA, ³Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁴Autonomous University of Barcelona, Spain, ⁵University of Massachusetts, USA, ⁶University of Pittsburgh, USA, ⁷University of Massachusetts Medical School, USA, ⁸Helen Hayes Hospital, USA, ⁹Hospital Cochin, France, ¹⁰Royal North Shore Hospital, Australia, ¹¹Cedars-Sinai/UCLA, USA

Aim: Fractures in obese postmenopausal women contribute significantly to the overall fracture burden. Reduced mobility and higher rates of co-morbidity prior to fracture in obese women may adversely affect healthcare utilisation and quality of life following fracture. Obese women with fracture may also be less likely to receive anti-osteoporosis medication (AOM). We compared these outcomes in obese, non-obese and underweight postmenopausal women following incident clinical fractures.

Methods: GLOW is an observational longitudinal study of non-institutionalized women aged ≥ 55 years recruited from 723 primary physician practices in 10 countries. Self-administered questionnaires were mailed, and data collected included demographics, fracture occurrence, medication and details on hospitalization, surgery and admission to rehabilitation or nursing homes. Quality of life was assessed before and after fracture using the SF-36 and EQ-5D. Data were available over a 3-year follow-up period in 90 underweight, 3270 non-obese and 941 obese women (BMI ≤ 18.5 , 18.5–30 and ≥ 30 kg/m², respectively).

Results: Following fracture, rates of treatment at an office, hospital or nursing home were similar in the three BMI groups and similar percentages underwent surgery. Underweight women were significantly more likely to be admitted to a rehabilitation centre than non-obese and obese women (25% vs 15% and 16%, respectively). Length of stay in hospital was significantly greater in obese than non-obese women (mean 11 vs 9 days; $p < 0.05$). Changes in quality of life after fracture were generally similar between the three BMI groups, but both before and after fracture, obese women had significantly lower physical function than non-obese and underweight women and a significantly lower vitality score than non-obese women. After fracture, 63% of underweight, 46% of non-obese and 33% of obese women were taking AOM.

Conclusions: Following fracture, obese postmenopausal women require longer hospital stay than non-obese women and have lower physical function and vitality scores. Our findings suggest that the economic costs of fracture may be higher in obese than non-obese women and that although the impact of fracture on quality of life is similar, there is greater impairment both before and after in obese women. Finally, the use of AOM in obese women with fracture is low.

Incident Bone Fracture in Men with, or at Risk for, HIV-infection in the Multicenter AIDS Cohort Study (MACS), 1996-2011. Vanessa Walker Harris^{*1}, Keri N. Althoff², Sandra Reynolds², Frank Paella³, Lawrence Kingsley⁴, Michelle Danielson⁵, Jordan E. Lake⁶, Todd Brown⁷. ¹Johns Hopkins University School of Medicine, USA, ²Johns Hopkins School of Public Health, USA, ³Northwestern School of Medicine, USA, ⁴University of Pittsburgh School of Public Health, USA, ⁵University of Pittsburgh, USA, ⁶UCLA School of Medicine, USA, ⁷Johns Hopkins University, USA

Background: Limited data are available comparing fracture incidence in HIV-infected (HIV+) and demographically similar HIV-uninfected (HIV-) persons.

Methods: Between October 1996 and 2011, fractures related to osteoporosis according to the FRAX definition (i.e. fracture of the hip, humerus, forearm, or spine) were prospectively reported or recalled during semi-annual study visits among men ≥ 30 years of age. Crude incidence rates (IR) per 100 person-years (PY), adjusted rate ratios (aIRR), and 95% confidence intervals (CI) were estimated using Poisson regression models with an interaction term for age (30-49, 50-64, ≥ 65 years) and HIV status.

Results: Among 5,106 men during 73,548 person-visits, 103 FRAX-defined fractures (53 HIV+, 50 HIV-) were reported. The crude IR of FRAX-defined fracture was 0.15 fractures/100 PY in HIV+ and 0.13 fractures/100 PY in HIV- men. After adjusting for body mass index (BMI) and race, the incidence rate of FRAX-fracture increased with age (30-49yo: reference; 50-64yo aIRR=1.19 [0.78, 1.83]; ≥ 65 yo: aIRR=2.93 [1.48, 5.80]) and HIV-infection (IRR=1.38 [0.93, 2.04]). The interaction of age and HIV status approached statistical significance ($p=0.14$). Compared to HIV-men age 30-49, the incidence rates of FRAX-defined fracture increased with age and were higher in HIV+ men compared to HIV- men, after adjustment for BMI and race (figure).

Conclusion: The rate of incident FRAX-defined, osteoporosis-related bone fractures in HIV+ and HIV- men increased with age. The increasing fracture rate is apparent in HIV+ men at younger ages as compared to HIV- men. These data provide support for recommendations for osteoporosis screening in HIV-infected men between ages 50-70 years.

Figure: Incidence rate ratios and 95% confidence intervals for FRAX-defined fractures in HIV+ and HIV- men in the Multicenter AIDS Cohort Study, by age and HIV status

A Phase IIb Study of MK-5442 Calcium Sensing Receptor (CaSR) Antagonist in Bisphosphonate-treated Patients. Felicia Cosman^{*1}, Nigel Gilchrist², Michael McClung³, Joseph Foldes⁴, Tobias de Villiers⁵, Boyd Scott⁶, Weili He⁷, John McGinnis⁷, Norman Heyden⁷, Suvajit Samanta⁷, Annepong Pong⁷, Arthur Santora⁸, Albert Leung⁸, Andrew Denker⁶, ¹Helen Hayes Hospital, USA, ²Department of Orthopaedic Medicine & Surgery, Christchurch Hospital, New Zealand, ³Oregon Osteoporosis Center, USA, ⁴Hadassah Hebrew University Hospital, Israel, ⁵Mediclinic Panorama, South Africa, ⁶Merck & Co., Inc., USA, ⁷Merck Sharp & Dohme Corp., USA, ⁸Merck Research Laboratories, USA

MK-5442 is an orally administered, agent that stimulates the secretion of endogenous PTH by antagonism of the calcium-sensing receptor of the parathyroid gland. The resulting pulse of endogenous PTH secretion is hypothesized to stimulate bone formation thereby increasing BMD. A previous study with MK-5442 in treatment naïve osteoporotic postmenopausal women (PMW) conducted in Japan demonstrated increased BMD following 3 months of treatment. The aim of this study was to assess the effect on BMD and bone turnover of switching from long-term bisphosphonate therapy to MK-5442 in patients with persistent low bone mass on BMD and bone turnover.

This randomized, placebo (PBO) and active-controlled, dose-finding study enrolled 526 PMW who had taken alendronate (ALN) for at least 12 months preceding the trial and an oral bisphosphonate for ≥ 3 of the 4 years before the trial, and with spine or hip BMD T-scores ≤ -2.5 (or ≤ -1.5 with ≥ 1 prior fragility fracture) and ≥ 4.0 . Subjects were randomly assigned to continue ALN or switch to either PBO or MK-5442 (5, 7.5, 10 or 15 mg daily). The primary endpoint was the change from baseline in lumbar spine (LS) BMD with MK-5442 treatment compared to continued ALN at 12 months. Additional endpoints included the change from baseline in total hip aBMD, u-NTx, s-PINP, serum calcium, s-PTH, and general safety. The 15 mg group was discontinued mid-study due to the incidence of hypercalcemia observed with that dose in another study.

In patients switched from ALN to MK-5442, there was a dose-dependent pulsatile increase in PTH which resulted in increased P1NP ($\sim 125\%$ at 12 months for all MK-5442 doses) and u-NTx ($\sim 70\%$ -100%, dose dependent). However, there was no change in spine BMD in any MK-5442 group compared with a small increase in the ALN group. In the hip BMD declined in the MK-5442 group with no change in the ALN group. There was a dose-dependent increase in the incidence of hypercalcemia but other adverse events were all similar among groups.

In bisphosphonate experienced PMW with osteoporosis, switching treatment from ALN to MK-5442 resulted in a pulsatile increase in PTH and corresponding increases in biomarkers of bone formation and resorption, but a decreased BMD response compared with continued ALN therapy.

FR0361

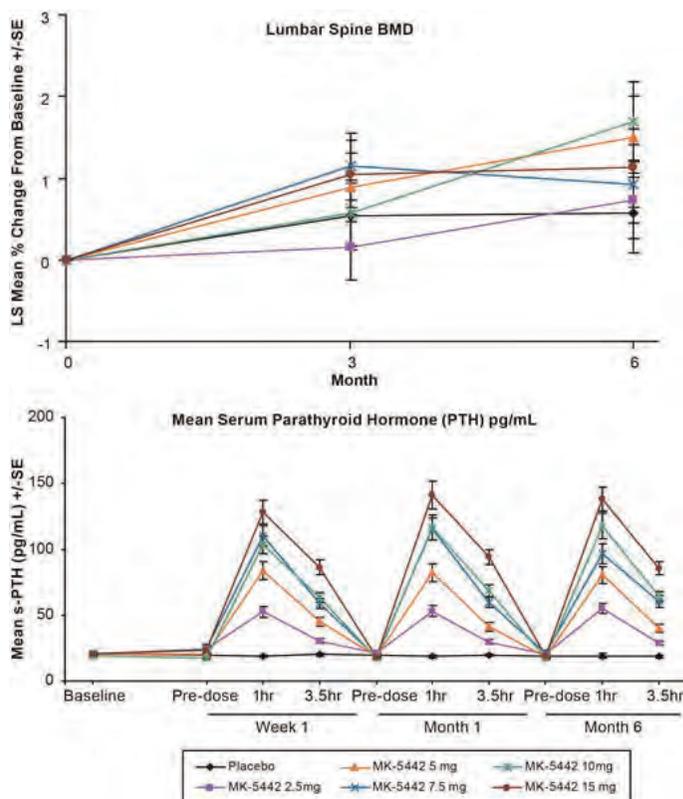

A Phase IIb, Randomized, Placebo-Controlled, Dose-Ranging Study of MK-5442 in the Treatment of Postmenopausal Women with Osteoporosis. Johan Halse^{*1}, Susan Greenspan², Felicia Cosman³, Graham Ellis⁴, Boyd Scott⁵, Norman Heyden⁶, Steven Doleck⁷, Sujavjit Samanta⁶, Weili He⁶, Arthur Santora⁷, Albert Leung⁷, Andrew Denker⁵. ¹Osteoporoseklinikken, Norway, ²University of Pittsburgh, USA, ³Helen Hayes Hospital, USA, ⁴Helderberger Osteoporosis Clinic, South Africa, ⁵Merck & Co., Inc., USA, ⁶MSD, USA, ⁷Merck Research Laboratories, USA

MK-5442 is an orally bioavailable, calcium receptor antagonist that stimulates the secretion of endogenous PTH. The resulting pulse of endogenous PTH secretion is hypothesized to stimulate bone formation and increase BMD. A previous study with MK-5442 in osteoporotic postmenopausal women (PMW) conducted in Japan demonstrated increased BMD following 3 months of treatment.

This was a multicenter, randomized, double-blind, placebo-controlled, parallel-group, dose-ranging study of MK-5442 in 383 PMW with osteoporosis defined by BMD T-Score in lumbar spine (LS), femoral neck, trochanter and/or total hip < -2.5. All had BMD \geq -3.5 at all 4 BMD sites. The objective of this Phase IIb dose-ranging study was to identify an appropriate dose of MK-5442 that would produce an osteoanabolic effect without causing excessive hypercalcemia. The effects of daily oral doses of MK-5442 (2.5, 5, 7.5, 10 or 15 mg) vs placebo (PBO) for 6 months on s-PTH, aBMD of the LS, hip sites, total body and 1/3 distal forearm, biochemical markers of bone turnover (u-NTx, s-CTX, s-BSAP, s-p1NP), serum calcium, and general safety were assessed.

A dose-dependant increase in PTH was observed at 1 hour post-dose, which resulted in increases in p1NP (20-40% at 6 months for 10 and 15 mg MK-5442), s-BSAP (4-17% at 6 months for 7.5, 10 and 15 mg MK-5442) and small decreases in uNTx (8-21%) for all doses except 15mg. There was no statistically significant difference between any of the MK-5442 doses and PBO in % change from baseline at Month 6 in LS aBMD or % change from baseline at month 6 in any other BMD endpoint. The MK-5442 treatment groups were generally similar to the PBO group regarding overall safety, with the exception of an expected dose-related increase in the incidence of hypercalcemia. (1.6%, 9.8%, 21.9%, 25.0% and 42.9% with 2.5mg, 5mg, 7.5mg, 10mg, 15mg MK-5442 respectively vs. 1.6% in PBO).

In PMW with low bone mass, treatment with MK-5442 resulted in a pulsatile increase in PTH and corresponding increases in biomarkers of bone formation however, no difference in LS BMD between MK-5442 treatment and PBO was observed.

Pharmacokinetic Results of a Phase 2 Clinical Study of an Oral Tablet Formulation of PTH(1-31)NH₂. Amy Sturmer^{*1}, William Stern², Jenna Giacchi², Ali Bolat², Sheela Mitta², Roxanne Tavakkol², John Trang³, Jeffrey Wald⁴, Lorie Fitzpatrick⁴, Nozer Mehta¹. ¹Unigene Laboratories, USA, ²Unigene Laboratories, Inc., USA, ³PK/PD International, Inc., USA, ⁴GlaxoSmithKline, USA

Pharmacokinetic (PK) data are presented from a 24 week double blind, randomized, repeat dose parallel group study of recombinant human [rhPTH(1-31)NH₂] or placebo tablets, compared to open label Forsteo[®] (teriparatide) in 97 postmenopausal women with osteoporosis. The primary endpoint was to characterize the percent change from baseline in bone mineral density of the lumbar spine after 24 weeks of treatment with rhPTH(1-31)NH₂. Plasma samples were collected to characterize the PK profile of the oral tablets and the Forsteo[®] subcutaneous (SC) injections after the first dose and at end of treatment. Blood samples were collected pre-study and at intervals up to 5.75 hr after administration of tablets and up to 2 hr after injection. Plasma concentrations of PTH(1-31)NH₂ were determined with a validated specific sandwich ELISA that recognizes the intact molecule with a lower limit of quantitation (LLOQ) of 10 pg/mL. Plasma concentrations of PTH(1-34)OH were measured by a validated sandwich ELISA with an LLOQ of 5 pg/mL. The PK profile for the oral tablets showed a pulsatile peak with durations of at least 1 hr but less than 5 hr which is consistent with the requirement for bone anabolic activity. The mean C_{max} value for the patients receiving tablets measured at week 0 (n=32) and week 24 (n=28) was 295 pg/mL and 207 pg/mL, respectively. The mean T_{max} for both periods was 3.25 hr, which is expected for an enteric-coated tablet. The mean AUC for week 0 and week 24 were 178 pg*hr/mL and 141 pg*hr/mL, respectively. No significant differences were observed between weeks 0 and 24 in any PK parameters tested, demonstrating good reproducibility, no time-dependent changes, and little or no accumulation. Following injection, mean plasma teriparatide concentrations were observed from 0.25 hr to 2 hr at week 0 and week 24. The mean C_{max} at week 0 (n=32) was 120 pg/mL at a mean T_{max} of 0.389 hr. The mean C_{max} value in these patients measured at week 24 (n=27) was also 120 pg/mL, at a mean T_{max} of 0.34 hr. The mean AUC for weeks 0 and 24 were 122 pg*hr/mL and 123 pg*hr/mL, respectively. These results demonstrated excellent reproducibility for the PK parameters tested for teriparatide at the two PK sampling times. Oral administration of PTH(1-31)NH₂ once daily at a 5 mg dose resulted in higher mean C_{max} and AUC values and similar median C_{max} and AUC values when compared to Forsteo[®] and demonstrated the appropriate pulsatile profile for bone anabolic activity.

FR0363

Short Term Treatment with Teriparatide Stimulates Circulating Osteogenic Precursor Cells in Postmenopausal Women with Osteoporosis. Jeri Nieves*¹, Felicia Cosman², Mishaela Rubin³, Sanil Manovalen³, Marsha Zion², David Dempster³, Nancy Barbuto², Robert Lindsay². ¹Columbia University & Helen Hayes Hospital, USA, ²Helen Hayes Hospital, USA, ³Columbia University, USA

The stimulatory effects of short-term treatment with teriparatide (TPTD) on bone formation may be mediated at least in part by an increase in osteoblast number. The existence of circulating osteogenic precursor cells (COP) which are associated with bone formation has recently been demonstrated. In hypoparathyroid patients, treatment with PTH(1-84) results in an increase in the number of COP cells as well as fewer markers of immaturity (Rubin MR et al JCEM 2010), while in another study TPTD did not increase COP cells at 3 months, although there was an increase in maturation of these cells (D'Amelio et al Osteop Int 2012). In the current study, we examined the COP cell response in treatment-naïve subjects with osteoporosis (n=21) treated with daily TPTD for 3 months. At baseline and 3 months blood was collected and peripheral blood mononuclear cells (PBMCs) were obtained. Osteogenic cells were characterized using flow cytometry and antibodies against osteocalcin and stem cell markers CD34 (a marker of early hematopoietic cells) and CD146 (a marker of early mesenchymal stem cells). Serum procollagen type I N-terminal propeptide (PINP) was measured by ELECSYS. Differences in PINP and osteogenic cells from baseline to 3 months were determined with paired t-tests. The subjects were on average (mean ± standard deviation), 65 ± 7.2 years of age and 16 ± 9.5 years from menopause, had a mean spine T-score of -2.9 ± 1.0 and total hip T-score of -2.1 ± 0.8, with one-third reporting a prior fracture. There was a significant increase in PINP from 57.7 ± 27 at baseline to 117.7 ± 65 after 3 months of TPTD (p < 0.001). The % of PBMC that were OCN+ increased from 1.1 ± 0.8 at baseline (similar to previous values for postmenopausal women) to 2.0 ± 1.4 (p < 0.005) after 3 months of daily TPTD. However, the co-expression of the early cell marker OCN+/CD34+ was unchanged (43.1 ± 17.4% at baseline to 45.4 ± 18.0% at 3 months). The correlation coefficient for the change in the COP cell number and the change in PINP was 0.39 (p = 0.09). The increase in the number of COP cells signifies an increase in osteoblast proliferation and in the size of the available osteoblast pool. We hypothesize that the recruitment of a greater number of circulating osteogenic cells is a major mechanism by which TPTD stimulates new bone formation during the first three months of therapy.

Treatment of Male Osteoporosis: Risedronate, Teriparatide or Both. Marcella Walker*¹, Natalie Cusano², Megan Romano², James Sliney², Chiyuan Zhang¹, Donald McMahon², John Bilezikian². ¹Columbia University, USA, ²Columbia University College of Physicians & Surgeons, USA

Most studies of combination therapy with teriparatide and bisphosphonates have not shown an advantage over monotherapy for the treatment of osteoporosis. Most combination therapeutic regimens have focused upon postmenopausal women with osteoporosis. This proof-of-concept study was directed to combination therapy of risedronate and teriparatide in men with osteoporosis. We studied 29 men with low bone mineral density (BMD) at the spine, hip, or distal 1/3 radius in a randomized, double-blinded 3-arm study. Subjects were randomized 1:1:1 to oral risedronate 35 mg weekly plus injection placebo, teriparatide 20 µg subcutaneously daily plus oral placebo, or both risedronate and teriparatide (combination) for 18 months. The primary endpoint was percentage (%) change in BMD at the lumbar spine at 18 months from baseline. Secondary endpoints included changes in BMD at other sites and at interim time points. All participants were Caucasian and age ranged from 37 to 81 years. A history of fragility fracture was present in 31% of the cohort; 24% had a history of vertebral fracture. There were no between-group differences in demographics, baseline BMD, medical or lifestyle characteristics except for history of fragility fracture, which was significantly greater in the combination therapy group vs. the risedronate group (60 vs. 0%, p < 0.05). At 18 months, lumbar spine BMD increased significantly with all 3 treatments (p < 0.05) but there were no between-group differences (p = 0.33). Total hip BMD (mean % change ± SE) increased to a greater extent in the combination group (3.86 ± 1.1%) versus teriparatide (0.29 ± 1.0%) and versus risedronate (0.82 ± 1.0%, p < 0.05 for both). Femoral neck BMD also increased to a greater extent in the combination group (8.45 ± 1.9%) versus risedronate (0.50 ± 1.7%, p = 0.002), but was not different from teriparatide alone (3.89 ± 1.7%, p = 0.07). At 18 months, there were no between-group differences in 1/3 radius BMD (p = 0.10). All therapies were well-tolerated. The results of this study indicate that 18 months of combination treatment with teriparatide and risedronate does not afford a densitometric advantage at the lumbar spine or femoral neck, but at the total hip, combination therapy shows greater improvement than teriparatide alone. Addressing the question of combination therapy in men with osteoporosis is providing new insights into this approach.

BMD Changes in Postmenopausal Women Over a 5-year Treatment-Free Period Following a 5-year Course of Alendronate. Brian McNabb*¹, Eric Vittinghoff², Ann Schwartz¹, Douglas Bauer¹, Elizabeth Barrett-Connor³, Kristine Ensrud⁴, Dennis Black¹. ¹University of California, San Francisco, USA, ²UCSF, USA, ³University of California, San Diego, USA, ⁴Minneapolis VA Medical Center / University of Minnesota, USA

Purpose: To describe bone mineral density (BMD) changes and develop a prediction model for BMD changes in postmenopausal women during a 5-year treatment-free period, following 5 years of alendronate (ALN).

Methods: We analyzed 372 postmenopausal women who had received a mean of 5 years of ALN therapy while participating in the Fracture Intervention Trial (FIT), and were then randomized to placebo and followed for 5 years while participating in the FIT Long Term Extension trial (FLEX). We describe the patterns of femoral neck, total hip, and lumbar spine BMD changes and analyze prediction of BMD changes over the 5-year treatment-free period. Predictor variables included BMD before ALN treatment, changes in BMD on ALN, BMD at the start of the treatment-free period, age, body mass index, and fracture history. Three markers of bone turnover were also analyzed as predictors in 76 women with available data. To find prediction models for the percent changes in BMD, we screened all possible linear combinations of variables, and implemented the deletion-substitution-addition (DSA) algorithm.

Results: After stopping ALN, mean femoral neck BMD losses were modest (1.4% over 5 years) with substantial variation (26% lost > 5%, and 12% gained > 5% BMD at the femoral neck). None of the variables tested were significantly predictive of percent loss over the treatment-free period. Table 1 shows the association of selected variables with the percent change in femoral neck BMD. Overall model-based prediction was poor (cross-validated R² 3.9% for best model). Results for analyses of total hip and lumbar spine BMD were similar to those for femoral neck BMD. Amongst bone turnover markers, only serum C-terminal telopeptide of type I collagen at baseline was marginally associated with percent change in BMD at the femoral neck. This weak association was not found when analyzing total hip or lumbar spine BMD, and may reflect the small sample size analyzed.

Conclusions: There was a wide range of changes in BMD over a 5-year treatment-free period, suggesting the need for a variable schedule for follow-up care and assessment of women after discontinuation of a 5-year course of ALN. We could not identify any combination of variables to predict these BMD changes. Like other candidate predictors, bone turnover markers were not convincingly associated with BMD changes, but a lack of power prevented us from ruling them out as useful predictors.

| Association of Select Predictors with the Percent Change in Femoral Neck BMD Across a 5-year Treatment-Free Period Following a 5-year Course of ALN | | |
|---|---|---------|
| Predictor of Interest | % Change in BMD with Each Increase in Predictor | |
| | Estimate (95% CI) | P-value |
| Age (5 years) | 0.22 (-0.29 to 0.74) | 0.395 |
| BMI (5 kg/m ²) | 0.66 (-0.04 to 1.35) | 0.064 |
| BMD (0.1 gm/cm ²) | | |
| At Start of ALN Treatment | 0.66 (-0.30 to 1.62) | 0.178 |
| After ALN Treatment | 0.32 (-0.53 to 1.17) | 0.464 |
| Change in BMD on ALN (1%) | -0.06 (-0.17 to 0.05) | 0.306 |
| BTM* | | |
| CTx (0.065 ng/mL)** | -1.24 (-2.48 to -0.01) | 0.049 |
| BSAP (2.86 ng/mL)** | 0.61 (-0.65 to 1.87) | 0.338 |
| PINP (11.8 ng/mL)** | 0.60 (-0.71 to 1.91) | 0.366 |

Abbreviations: BMD, bone mineral density; ALN, alendronate; 95% CI, 95% confidence interval; BMI, body mass index; BTM, bone turnover marker; CTx, serum C-terminal telopeptide of type I collagen; BSAP, bone specific alkaline phosphatase; PINP, N-propeptide of type I collagen.

Crosstalk between Oral Microbiome and Host Innate Immune Response in the Tissues of Patients with Bisphosphonate Related Osteonecrosis of the Jaw. Smruti Pushalkar¹, Satoko Matsumura¹, Lalitha Ramanathapuram¹, Zoya Kurago¹, Kenneth Fleisher², Robert Glickman¹, Wenbo Yan³, Yihong Li¹, Xin Li⁴, Deepak Saxena*². ¹NYU College of Dentistry, USA, ²New York University College of Dentistry, USA, ³Nyack College, USA, ⁴New York University, USA

Bisphosphonates (BPs) are the standard of care for patients with metastatic cancer and multiple myeloma to prevent skeletal complications (e.g., severe bone pain, pathologic fracture, etc.) and to treat osteoporosis. The cause and effect relationship between BPs and BP-related osteonecrosis of the jaws (BRONJ) is not well established. Current research suggests that bacterial biofilms may play a significant role in the pathogenesis of BRONJ. Recently, we have shown that BRONJ lesions are heavily colonized by oral bacteria and present many clinical challenges as they are difficult to culture and antibiotic resistance may result in misguided antibiotic therapy. Here we highlight the crosstalk among the oral bacteria and host immune response in BRONJ subjects. Using 16S rDNA molecular technique we characterize the total bacterial profile of BRONJ, BP and control subjects. Denaturing gradient gel

electrophoresis cluster analysis revealed three clusters each representing the three groups, control, BP and BRONJ indicating that the microbiome present in tissue samples was distinct to each group. DGGE band pattern indicated that the BRONJ group had less bacterial diversity as compared to control indicating that high abundance of specific bacteria colonizing the BRONJ lesion. 16S sequencing and clonal analysis showed 6 phyla in all three groups. The phylum *Firmicutes* was predominant in BRONJ group (72%) followed by BP group (70%) as compared to control group (59%). The Chi-square test also showed significant differences in percent relative distribution of phyla, between control/BP groups ($p < 0.001$), control/BRONJ ($p < 0.001$) and BP/BRONJ ($p < 0.05$). There was significantly increase in the gram positive bacteria in BRONJ group. PCR Array analysis indicated that the host genes responsible for antibacterial response such as MPO, CTSG, and NOD2 were significantly down regulated. Deficient innate immune responses to microorganisms together with poor healing and repair provide continuous opportunities for expanding microbial colonization, further perpetuating the pathologic process in BRONJ. The bacterial phylotypes we identified in our studies can trigger inflammation and acute, neutrophil-dominated responses that could cause direct damage by impairment of bone remodeling processes. The study supports the hypothesis that a unique type of oral bacterial infection contributes to the pathophysiology of BRONJ and provides a target for BRONJ prevention and treatment.

Effect of Zoledronic Acid on Acute Bone Loss after Spinal Cord Injury.

Thomas Schnitzer¹, Danielle Barkema¹, Kristina Herrmann¹, Ki Kim².
¹Northwestern University, USA, ²Rehabilitation Institute of Chicago, USA

Objective: To assess the efficacy and safety of zoledronic acid 5mg iv compared to placebo to prevent bone loss in patients after acute spinal cord injury.

Methods: A randomized, placebo-controlled trial of zoledronic acid 5mg was undertaken in patients who had suffered an acute spinal cord injury (SCI) within 6 months of study entry. Patients at entry had to exhibit motor loss and be non-ambulatory. Exclusion criteria included the presence of other factors that could affect bone metabolism. All subjects had normal renal function and 25-OH vitamin D at time of infusion. BMD of the spine, total hip and femoral neck was determined at baseline, 3 months and 6 months by DXA using a Hologic 4500A densitometer. Scans were done in duplicate when possible. Data affected by technical considerations (movement, heterotopic ossification) were not included. An interim analysis was done after the first 10 subjects were enrolled. An intent-to-treat analysis including all subjects receiving an infusion and having one post-baseline assessment was undertaken using a two-sample Student's T-test of BMD results. Adverse events were collected.

Results: 10 patients, all male, 6 Caucasian, 2 Latino, 2 African-American, mean age 43.6±19.7 yr signed consent and were randomized. Baseline BMD at spine (1.066 vs 1.128 gm/cm²), total left hip (1.037 vs 1.110 gm/cm²), total right hip (1.043 vs 1.124 gm/cm²), left femoral neck (0.955 vs 0.967 gm/cm²) and right femoral neck (0.957 vs 0.971 gm/cm²) were similar between the placebo and zoledronic acid group, $p > 0.05$. 6 months after infusion, the change in BMD of the group receiving placebo compared to the group receiving zoledronic acid at the spine was -2.6±1.7% vs 2.0±1.6%, $p = 0.004$; left total hip -16.3±0.3% vs -1.7±2.8%, $p = 0.002$; right total hip -11.2±8.6% vs 2.0±5.8%, $p = 0.10$; left femoral neck -14.9±12.9% vs 0.0±6.7%, $p = 0.08$; right femoral neck -21.7±4.2% vs -1.0±7.4%, $p = 0.005$. No unanticipated serious adverse events related to the study medication were reported.

Conclusion: After acute spinal cord injury, subjects receiving placebo had a significant decrease in BMD compared to those who received zoledronic acid. Zoledronic acid was effective in maintaining bone density in the lower extremities of most subjects with acute SCI for 6 months after infusion. The treatment was generally well tolerated. Although the duration of efficacy is not known, zoledronic acid may help to reduce the bone loss after acute SCI.

FR0376

Relationship Between Change in Total Hip BMD in Response to Zoledronic Acid 5 mg and Post-treatment Change in Total Hip BMD: the HORIZON-PFT Extension Study.

Richard Eastell¹, Lisa Palermo², Brian McNabb², Steven Boonen³, Felicia Cosman⁴, Ian Reid⁵, Steven Cummings⁶, Dennis Black².
¹University of Sheffield, United Kingdom, ²University of California, San Francisco, USA, ³Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁴Helen Hayes Hospital, USA, ⁵University of Auckland, New Zealand, ⁶San Francisco Coordinating Center, USA

There is a small mean decrease in hip bone mineral density (BMD) after stopping zoledronic acid 5 mg annually. It would be helpful to better understand the determinants of this bone loss. The purpose of this study was to determine whether greater rates of bone loss after stopping therapy are associated with greater BMD gain in response to initiation of anti-resorptive therapy or to baseline bone turnover and change in bone turnover. In the Health Outcomes and Reduced Incidence with Zoledronic acid Once Yearly-Pivotal Fracture Trial (HORIZON-PFT) Extension

study, one group of women who were randomized to receive zoledronic acid 5 mg annually for 3 years (years 0, 1 and 2) were then randomized to receive placebo annually for three infusions (at years 3, 4 and 5, Z3P3 treatment group, n=617). We measured total hip BMD by DXA at baseline, 1, 2, and 3 years after annual zoledronic acid 5 mg and at 4.5 and 6 years after annual placebo. Total PINP was measured by automated immunoassay analyser at 0, 3, 4.5, and 6 years, but results were excluded if patients had a fracture in the past year (PINP increases for up to a year following a fracture). The change in total hip BMD in years 0-3 was related to the change in total hip BMD on placebo in years 3-6 ($r = -0.15$, $P = 0.0015$). Thus, those with greater gains during years 0-3 had greater loss during years 3-6. The PINP at baseline was correlated with the change in total hip BMD in years 0-3 on zoledronic acid 5 mg annually ($r = 0.32$, $P = 0.0002$) and to the change in total hip BMD in years 3-6 after stopping treatment ($r = -0.26$, $P = 0.007$). The change in PINP (years 0-3) was correlated with the change in total hip BMD in years 0-3 on zoledronic acid 5 mg annually ($r = -0.35$, $P = 0.0003$) and the change in PINP (years 3-6) was correlated with the change in total hip BMD in years 3-6 on zoledronic acid 5 mg annually ($r = -0.18$, $P = 0.0005$). We conclude that the BMD loss after stopping zoledronic acid is greater in those with greater gains in BMD on zoledronic acid treatment. One possible mechanism for this association is that higher bone turnover before initiating treatment is associated with both greater BMD response to zoledronic acid and greater rates of loss when stopping therapy.

Resolution of Effects on Bone Turnover Markers and Bone Mineral Density after Discontinuation of Long-term Bisphosphonate Use.

Bente Langdahl¹, Claude Laurent Benhamou², C. Conrad Johnston³, Kenneth Saag⁴, TOBIE DE VILLIERS⁵, Andrew Denker⁶, Annpey Pong⁷, John McGinnis⁷, Elizabeth Rosenberg⁶, Arthur Santora⁸.
¹Aarhus University Hospital, Denmark, ²CHR ORLEANS, France, ³Indiana University School of Medicine, USA, ⁴University of Alabama at Birmingham, USA, ⁵PANORAMA HOSPITAL, South Africa, ⁶Merck & Co., Inc., USA, ⁷Merck Sharp & Dohme Corp., USA, ⁸Merck Research Laboratories, USA

Background: While bisphosphonates (BP) have been well studied in long-term trials of up to 4 years' duration, relatively less is known about the immediate consequences of continuing vs. interrupting long-term treatment. This report describes changes in bone turnover and BMD in a 1-year trial of the calcium-sensing receptor antagonist MK-5442 in postmenopausal women who, after taking BP for ≥ 3 years, were randomized to continued alendronate (ALN) 70 mg weekly, switch to placebo (PBO), or switch to MK-5442. Primary results for MK-5442 are presented separately.

Methods: 526 postmenopausal women who had taken ALN for ≥ 12 months preceding the trial and an oral BP for ≥ 3 of the 4 years before the trial, with spine or hip BMD T-scores ≤ -2.5 (or ≤ -1.5 with ≥ 1 prior fragility fracture) and ≥ -4.0 , were recruited into a dose-finding study of MK-5442. Statistical tests of within-group changes and comparison between the PBO and ALN groups were performed post-hoc.

Results: At baseline, women switched from ALN to PBO (n=88) or continued on ALN 70 mg weekly (n=87) were of mean age 67 years and had mean T-scores at lumbar spine of -2.5 and total hip of -1.6, and mean baseline urine NTX/Cr= 26.6 nmolBCE/mmolCr and serum PINP= 26.0 ng/mL. Median length of previous BP use was 5.2 years. After 1 month, women switched from ALN to PBO experienced increases from baseline in urine NTX/Cr (28.4% vs. continued ALN, $p < 0.0001$), while serum PINP was unchanged. Both NTX/Cr and PINP increased by 3 months (33.7% and 37.8%, respectively vs. ALN, both $p < 0.0001$). After 12 months of PBO, least squares mean concentrations of NTX/Cr and PINP rose to 42.2 nmolBCE/mmolCr and 40.1 ng/mL (both $p < 0.0001$, Table). The markers were unchanged from baseline with continued ALN. After 12 months, the women who continued ALN had an increase in lumbar spine BMD while those switched to PBO experienced no change; total hip BMD did not change in those remaining on ALN but was reduced in women switched to PBO. BMD at both sites was significantly lower in women who switched to PBO vs. those who stayed on ALN (Table).

Conclusions: Discontinuation of alendronate after a median of 5 years resulted in an increase in NTX/Cr as early as 1 month and PINP by 3 months. After 1 year, both bone turnover markers returned to levels similar to those expected in untreated postmenopausal women. These increases were accompanied by significantly lower spine and total hip BMD vs. continued treatment with ALN.

12 Month Least Squares Mean % Change from Baseline (95% CI)

| | uNTX/Cr | sPINP | Lumbar Spine BMD | Total Hip BMD |

FR0388

A Randomized Open-Label Study to Evaluate the Safety and Efficacy of Denosumab and Ibandronate in Postmenopausal Women Sub-Optimally Treated With Daily or Weekly Bisphosphonates. Christopher Recknor*¹, Edward Czerwinski², Henry Bone³, Sydney Bonnick⁴, Neil Binkley⁵, Alfred Moffett⁶, Suresh Siddhanti⁷, Irene Ferreira⁸, Pravashi Ghelami⁹, Rachel Wagman¹⁰, Jesse Hall⁷, Michael Bolognese¹¹.

¹United Osteoporosis Center, USA, ²Medical College Jagiellonian University, Poland, ³Michigan Bone & Mineral Clinic, USA, ⁴Clinical Research Center of North Texas, USA, ⁵University of Wisconsin, Madison, USA, ⁶OB-GYN Associates of Mid-Florida, P.A., USA, ⁷Amgen, Inc., USA, ⁸Amgen Inc, United Kingdom, ⁹Ovatech Solutions, United Kingdom, ¹⁰Amgen, Incorporated, USA, ¹¹Bethesda Health Research, USA

Purpose: Denosumab, a fully human monoclonal antibody that specifically targets RANKL to inhibit osteoclast formation, function, and survival, reduces risk for vertebral, non-vertebral, and hip fractures.¹ In subjects who were treatment naïve or previously treated with alendronate, denosumab was associated with greater gains in bone mineral density (BMD) and decreases in bone turnover markers when compared with alendronate-treated subjects.^{2,3} The purpose of this open-label trial was to compare the safety and efficacy of denosumab with ibandronate over 12 months in postmenopausal women with low BMD who were sub-optimally treated with prior bisphosphonate therapy.

Methods: This was a multicenter, randomized, open-label, parallel-group study in which postmenopausal women age 55 and older were randomized 1:1 to receive open-label denosumab 60mg subcutaneously every 6 months or ibandronate 150mg orally every month for 12 months. Percent change from baseline in total hip (TH, primary endpoint), femoral neck (FN), and lumbar spine (LS) BMD at month 12, percent change from baseline in serum CTX (sCTX) at 1 and 6 months, and safety were assessed.

Results: Randomized subjects (n=833; 417, denosumab; 416, ibandronate) had a mean (SD) age of 66.7 (8.0) years and mean (SD) BMD T-score of -1.8 (0.7), -2.1 (0.7), and -2.5 (0.8) at the TH, FN, and LS, respectively. Denosumab significantly increased TH BMD compared with ibandronate at 12 months (2.2% vs 0.9%, respectively; $p<0.0001$). Denosumab also significantly increased BMD at the FN (1.7% vs 0.5%) and LS (4.1% vs 2.1%) compared with ibandronate ($p<0.0001$ at both sites). Denosumab significantly decreased sCTX at 1 month with a median change from baseline of -81.1% compared to -35.0% for ibandronate ($p<0.0001$), and sCTX remained decreased through 6 months of treatment. In this open-label study, overall adverse events were similar between groups. Reports classified as serious adverse events (SAEs) were more frequent in subjects treated with denosumab than with ibandronate. No organ system accounted for a preponderance of these reports. The incidence of SAEs involving infection and malignancy was similar between groups.

Conclusions: Denosumab treatment resulted in greater increases in BMD at all measured sites compared with ibandronate. No new safety risks were identified in this open-label study.

FR0389

Antiresorptive Action is Dependent on Access to Remodeling Upon Cortical and Trabecular Surfaces: Comparison of Denosumab and Alendronate. Roger Zebaze*¹, Cesar Libanati², Matthew Austin², John Bilezikian³, Ego Seeman¹.

¹Austin Health, University of Melbourne, Australia, ²Amgen Inc., USA, ³Columbia University College of Physicians & Surgeons, USA

Purpose: Antiresorptives differ in the extent to which they suppress remodeling. Since remodeling is surface dependent, the degree to which antiresorptives suppress remodeling could be due, in part, to differences in their accessibility to bone surfaces. Cortical bone has a low surface/bone volume configuration so accessibility to remodeling on intracortical surfaces, the main site of bone loss during aging, may be more difficult than to trabecular surfaces. Denosumab rapidly and markedly reduces remodeling and does so more than alendronate. We hypothesized that differences in distribution and mechanism of action between denosumab and alendronate will result in a greater reduction in intracortical porosity with denosumab.

Methods: Postmenopausal women aged 61 ± 5 years were randomized double-blind to denosumab 60 mg Q6M (N=83), alendronate 70 mg QW (N=82), or placebo (N=82) for 12 months. Trabecular bone volume fraction (BV/TV) and porosity in both the compact and the trabecularized cortex (outer and inner transitional zones) were measured from HRpQCT distal radius images obtained at baseline, 6 months,

and 12 months using Strax 1.0 software. Reported results are from repeated measures models fit separately for each compartment allowing for heterogeneity in variance between treatment groups.

Results: Both denosumab and alendronate improved trabecular BV/TV compared with placebo at 6 and 12 months. Alendronate reduced porosity at month 6 in the compact and trabecularized cortex compared with placebo; however, at month 12 there was no evidence of a difference with alendronate relative to placebo in any of these cortical compartments (Table). Denosumab reduced porosity at both 6 and 12 months in all cortical compartments compared with baseline and placebo. These reductions were larger than those with alendronate at month 12 in all cortical compartments (Figure). Furthermore, denosumab resulted in a more homogeneous response in the compact cortex and outer transitional zone.

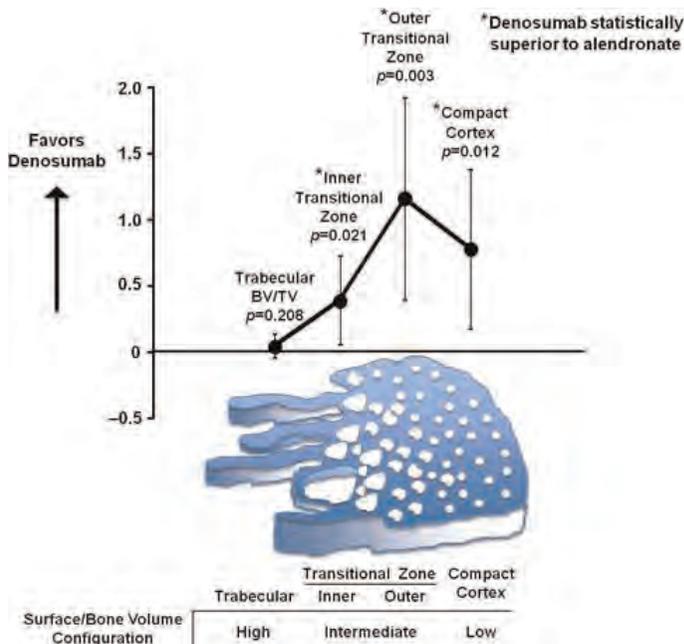

Conclusions: Cortical bone comprises most mineralized volume and increasingly determines bone strength as trabeculae disappear with aging. Access to cortical bone by therapeutic agents is a challenge because of its surface/bone volume configuration. The broader distribution of denosumab compared with alendronate is associated with greater and more uniform reductions in porosity throughout the cortex, effects likely to increase bending and compressive strength.

Table: Changes (Percentage Points Difference) From Baseline at 12 Months

| | Porosity | | | |
|-------------|------------------|-------------------------|-------------------------|----------------|
| | Trabecular BV/TV | Inner Transitional Zone | Outer Transitional Zone | Compact Cortex |
| Placebo | +0.08** | -0.54*** | -0.20 | -0.13 |
| Alendronate | +0.19***, 4 | -0.78*** | -0.81* | -0.48 |
| Denosumab | +0.25***, 4 | -1.17***, 4 | -1.97***, 4 | -1.26***, 4 |

p value relative to baseline: ***<0.001, **<0.01, *<0.025
 p value relative to placebo: 4<0.001, 4<0.025

Long-term Denosumab Treatment Maintains Low Incidence of Fracture in Postmenopausal Women ≥ 75 Years With Osteoporosis. Socrates Papapoulos^{*1}, Michael R. McClung², Nathalie Franchimont³, Jonathan D. Adachi⁴, Henry G. Bone⁵, Claude-Laurent Benhamou⁶, Jordi Farrerons⁷, J. Christopher Gallagher⁸, Johan Halse⁹, Kurt Lippuner¹⁰, Zulema Man¹¹, Salvatore Minisola¹², Ove Törring¹³, Nadia Daizadeh³, Andrea Wang³, Rachel B. Wagman³, Steven Boonen¹⁴. ¹Leiden University Medical Center, Netherlands, ²Oregon Osteoporosis Center, USA, ³Amgen Inc., USA, ⁴Charlton Medical Centre, Canada, ⁵Michigan Bone & Mineral Clinic, USA, ⁶INSERM U658, France, ⁷Hospital de la Santa Creu I Sant Pau, Spain, ⁸Creighton University Medical Center, USA, ⁹Osteoporoseklinikken, Norway, ¹⁰University Hospital, Switzerland, ¹¹Centro Tiemp, Argentina, ¹²Sapienza, Università di Roma, Italy, ¹³Karolinska Institutet Sodersjukhuset, Sweden, ¹⁴Leuven University, Belgium

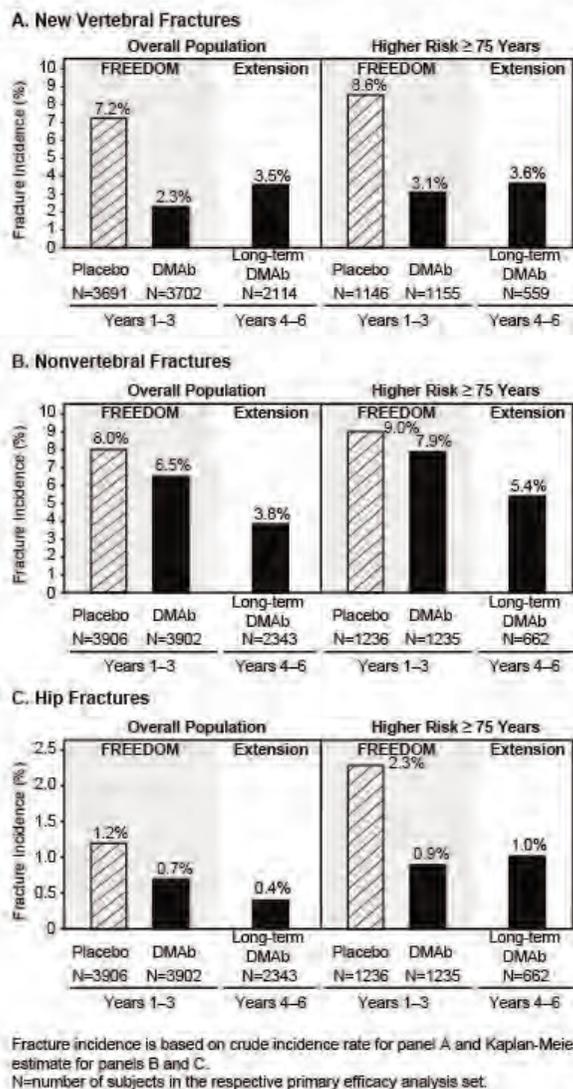

Purpose: In the pivotal fracture trial, FREEDOM, denosumab (DmAb) increased bone mineral density (BMD) and reduced the incidence of new vertebral, nonvertebral, and hip fractures in postmenopausal women with osteoporosis (Cummings 2009). In women at higher risk for fracture based on age ≥ 75 years, DmAb reduced the risk of hip fractures by 62% (Boonen 2011). The effects of long-term DmAb treatment up to 10 years are being evaluated in the FREEDOM extension study. As fracture incidence increases with age, and in particular, hip fracture in women ≥ 75 , we have further characterized the fracture incidence and BMD gains in women ≥ 75 years who have been treated with DmAb for a total of 6 years.

Methods: During the extension, each woman is scheduled to receive 60 mg DmAb every 6 months and supplemental calcium and vitamin D daily. We evaluated the fracture incidence and BMD gains in women who completed 6 years of DmAb treatment (overall long-term group) and in the subset of these women who were ≥ 75 years at FREEDOM baseline (higher-risk group).

Results: The FREEDOM baseline characteristics for the overall long-term DmAb group (N=2343) and the higher-risk group (N=662) were similar except that those subjects in the higher-risk group were older (mean age: 72 years for overall and 78 years for higher risk), and had a lower mean total hip BMD T-score (-1.9 for overall and -2.1 for higher risk). Despite the increase in age of the subjects, DmAb treatment during years 4-6 continued to be associated with a low incidence of new vertebral, nonvertebral, and hip fractures. Furthermore, the incidence of fractures in the higher-risk group during years 4-6 was similar to what was originally observed in years 1-3 in women ≥ 75 years treated with DmAb (Figure). BMD progressively increased over 6 years at the lumbar spine and total hip and was similar in women ≥ 75 compared with women in the overall long-term group. Despite advanced age, adverse events (AEs) and serious AEs in the higher-risk group in the extension were similar to the higher-risk group from FREEDOM and these events did not increase over time with DmAb treatment.

Conclusions: These results underscore the robust and consistent anti-fracture efficacy and safety profile of continued denosumab treatment over 6 years. Denosumab is a therapeutic option for women at higher risk for fracture, notably those ≥ 75 years, in whom fractures such as those at the hip increase exponentially due to cortical bone decay.

FR0392

Odanacatib Improved Estimated Femoral Strength in Postmenopausal Women - Results of a 2-year Placebo-controlled Trial. Tony Keaveny^{*1}, Kim Brixen², Roland Chapurlat³, Angela Cheung⁴, Thomas Fuerst⁵, Bernie Dardzinski⁶, Nadia Verbruggen⁷, Shabana Ather⁸, Elizabeth Rosenberg⁶, Anne De Papp⁶. ¹University of California, Berkeley, USA, ²Institute for Clinical Research, Denmark, ³E. Herriot Hospital, France, ⁴University Health Network, Canada, ⁵Synarc Inc, USA, ⁶Merck & Co., Inc., USA, ⁷Merck Sharpe & Dohme, Belgium, ⁸Merck & Co, Inc., USA

Background: In prior clinical trials, the cathepsin K inhibitor odanacatib increased areal BMD at the spine and hip of postmenopausal women. In an ovariectomized primate model, odanacatib increased cortical thickness and periosteal bone formation, and maintained normal biomechanical properties of the femoral neck and central femur. To gain additional insight into the clinical effects of odanacatib, we assessed femoral strength and geometry by QCT in postmenopausal women treated with odanacatib.

Methods: This international, randomized, double-blind, placebo-controlled, 2-year, phase 3 trial enrolled 214 postmenopausal women with a mean age of 64 years and mean BMD T-scores of -1.8 at the lumbar spine and at the femoral neck. Hip QCT scans at 2 years were available for a subset of these women (n=129). Overall proximal femoral strength was assessed as an exploratory endpoint for a simulated

sideways fall using finite element analysis (FEA). Within the femoral neck, volumetric BMD (vBMD), BMC and volume of the cortical and trabecular compartments as well as cortical thickness and cross-sectional area were assessed by morphometric analysis of the QCT images using Mindways QCTpro and BIT software (Austin, TX). Periosteal and endosteal boundaries were estimated using a global vBMD threshold and thus were sensitive to changes in vBMD with treatment. Results are presented as percent changes from baseline after two years of treatment.

Results: Treatment with odanacatib significantly increased the finite element-estimated overall femoral strength ($p < 0.001$, see Table). At the femoral neck, integral (cortical and trabecular combined) vBMD and trabecular vBMD were significantly higher in the odanacatib group, whereas cortical vBMD did not differ from placebo (Table). Estimated femoral neck cortical thickness, cortical volume, and cortical BMC were significantly higher in odanacatib-treated women; and cross-sectional area of the cortical compartment increased with odanacatib, whereas total cross-sectional area did not (Table). Taken together, these results suggest that cortical bone mass increased with odanacatib due to the accrual of bone mass at the endosteal envelope of the femoral neck.

Conclusions: In this study in postmenopausal women treated for 2 years, odanacatib appeared to improve overall proximal femoral strength by FEA, in part, by increasing cortical thickness and endosteal bone apposition along with integral and trabecular BMD at the femoral neck.

Table. Differences between weekly odanacatib 50 mg and placebo in QCT measurements at the femoral neck and total hip after 24 months of treatment

| Exploratory Endpoint: | LS Mean % Change from Baseline: | | | | Difference in % changes from baseline (ODN-PBO) | P value |

The Effect of Denosumab on Bone Mineral Density (BMD) Assessed by Baseline Bone Turnover in Men With Low BMD. Paul Miller¹, Ugis Gruntmanis², Steven Boonen³, Yuqing Yang⁴, Rachel Wagman⁵, Jesse Hall⁶, Eric Orwoll⁷. ¹Colorado Center for Bone Research, USA, ²University of Texas Southwestern Medical Center, Dallas, USA, ³Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁴Amgen Inc, USA, ⁵Amgen, Incorporated, USA, ⁶Amgen, Inc., USA, ⁷Oregon Health & Science University, USA

Purpose: Denosumab (DMAb), a fully human monoclonal RANKL antibody, has been shown to increase BMD in postmenopausal women with high and low bone turnover,¹ and reduce the risk for new vertebral, non-vertebral, and hip fractures.² ADAMO evaluated DMAB in men with low BMD and demonstrated increases in BMD at all skeletal sites measured and reductions in serum CTX (sCTX).³ We assessed the efficacy of DMAB in men across a range of baseline bone turnover in ADAMO.

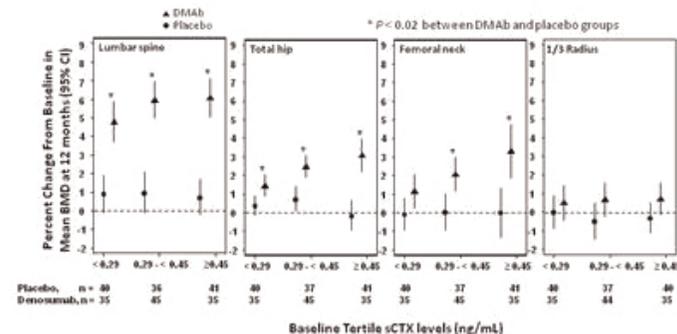

Methods: ADAMO was a multicenter, randomized, double-blind, placebo-controlled study. Subjects were randomized 1:1 to receive either 60mg DMAB or placebo administered subcutaneously once every 6 months over a 12-month period. Subjects were included if they were aged ≥ 30 and ≤ 85 yrs; had a BMD T-score ≤ -2.0 and ≥ -3.5 at the lumbar spine (LS) or femoral neck (FN), or had a prior major osteoporotic fracture and a T-score ≤ -1.0 and ≥ -3.5 at the LS or FN. Subjects received ≥ 1000 mg calcium and ≥ 800 IU vitamin D supplementation daily. Percent change in sCTX was assessed at day 15. Percent change in BMD from baseline to month 12 at the LS, total hip (TH), FN, trochanter (TR), and 1/3 radius (1/3R) BMD was assessed by tertile baseline sCTX levels.

Results: A total of 242 subjects (121, placebo; 121, DMAB) were enrolled. After 12 months of treatment with DMAB, BMD increased from baseline by 5.7%, 2.4%, 2.1%, 3.1%, and 0.6% at the LS, TH, FN, TR, and 1/3R, respectively (all $p < 0.02$ compared

with placebo and adjusted for multiplicity). sCTX was reduced by 81% (DMAB) vs 7% (placebo) from baseline at day 15. Subjects treated with DMAB, compared with placebo, demonstrated greater gains in LS and TH BMD at month 12 at each tertile of baseline sCTX (Figure). Subjects in the highest tertile of baseline resorption had numerically greatest gains in BMD when compared with the lowest tertile, although differences were not statistically significant. Associations between baseline sCTX and 12-month BMD improvements were weaker at the FN and 1/3R, sites with greater variability in measurements.⁴

Conclusions: Men with low BMD treated for one year with DMAB, compared with placebo, demonstrated greater gains in BMD independent of baseline sCTX at key skeletal sites routinely used to diagnose and manage patients with osteoporosis. The data also suggest that men at all levels of bone turnover may benefit from DMAB therapy.

Effects of Age and Vitamin D on Parathyroid Hormone Levels. Frank Blocki¹, Sudhaker D. Rao², Andre Valcour³. ¹DiaSorin Incorporated, USA, ²Bone & Mineral Research Laboratory, Henry Ford Hospital, USA, ³Center for Esoteric Testing, LabCorp, USA

Osteoporosis & primary hyperparathyroidism (PHPT) are two common bone & mineral disorders whose clinical expression is affected by prevailing 25OHD & calcium status. Numerous studies suggest that serum 25OHD levels supporting optimal skeletal health be defined as those where PTH declines to a minimum: results, however, are widely disparate with sufficient levels positioned anywhere from 12 to 44ng/mL. Limitations common to these studies were small sample sizes (<100 to ~30,000). Here, nearly 313,000 subjects were tested for 25OHD & PTH from July 2010 to June 2011. Median PTH values & % patients exceeding the clinical PTH threshold of 65pg/mL from groups of 6259 patients each plotted against 25OHD provided smooth, exceptionally well-fitted curves (Mean PTH=11.9+140.6(25OHD)^{-0.46}; R²=0.994 & (%High=57.2 +166.7(25OHD)^{-0.21}; R²=0.995) & evidenced no inflection points or horizontal asymptotes. Parsed across four levels (<20, 20-40, 40-60, >60 years), the same groups disclose a striking dependency upon age. Data presented here provides cause for a closer contemplation of the Institute of Medicine's recent guidance of 20ng/mL as that level assuring 25OHD sufficiency for the majority of Americans: 85,000 (27%) subjects fell below this conservative threshold. Of greater clinical relevance, 40% (27,950/70,000) & 51% (7,650/15,000) of subjects with 25OHD <20 & 10ng/mL, respectively, had biochemical hyperparathyroidism with PTH levels >65pg/mL. Despite significant limitations, several important clinical observations are germane. 1st, median PTH levels of a very large sample set plotted across the continuum of patient 25OHD levels reveals NO threshold above which increasing 25OHD fails to further suppress PTH. 2nd is the sheer magnitude of subjects >60 years old with frank deficiency whose PTH levels were above the reference range UL. This preponderance of abnormal results reinforces the 3rd International Workshop on Asymptomatic PHPT's call for 25OHD repletion (to levels minimally above 20ng/mL) of suspected PHPT subjects before consideration of elective surgery. Finally, the strong age dependency of PTH levels with 25OHD likely reflects the composite of depleted calcium stores, calcium malabsorption &/or renal malfunction. This population based study may well move the clinical community away from fixed values of 20 vs 30 vs 40ng/mL as defining vitamin D sufficiency toward patient management based upon an age dependent, PTH-25OHD continuum.

The Efficacy of High-Dose Oral Vitamin D₃ Administered Once a Year: Increased Fracture Risk Is Associated With 1,25 Vitamin D Level at 3-Months Post Dose. Kerrie Sanders*¹, Gustavo Duque², Peter Ebeling³, Thomas McCorquodale², Markus Herrmann⁴, Catherine Shore-Lorenti⁵, Geoffrey Nicholson⁶. ¹NorthWest Academic Centre, ²The University of Melbourne/Western Health, Australia, ³Ageing Bone Research Program, University of Sydney, Australia, ⁴ANZAC Research Institute, The University of Sydney, Concord, Australia, ⁵NorthWest Academic Centre, University of Melbourne, Australia, ⁶The University of Queensland, Australia

We have previously reported an increased rate of falls and fractures in a RCT using a single annual dose of 500,000IU cholecalciferol administered orally to 2,256 older women in fall or winter for 3 to 5 years¹. The increased rate of falling in the vitamin D group was higher in the first 3 months following dosing (p=0.017) suggesting an adverse mechanism in the immediate post-dose period. There was evidence of a temporal pattern of fracture risk but this was not significant. Serial biochemistry including 1,25 dihydroxyvitamin D levels (1,25D) were assessed on a sub-study of 65 randomly selected participants. Serum 25-hydroxyvitamin D (25D) and 1,25D were measured using DiaSorin immunoassays. Falls were ascertained using a monthly calendar and fractures were radiologically confirmed.

The median baseline serum 25D and 1,25D were 49nmol/L and 55pmol/L, respectively. In the vitamin D group, 25D levels at pre-dose, 1- and 3-month median post dose levels were 82, 130, and 97nmol/L, respectively and 1,25D levels were 93, 120 and 100pmol/L, respectively. Our post-hoc analysis used a binomial logistic regression with fracture (yes/no) as the outcome. The model included age and 1,25D at 3-months post-dose as the covariates. There was a 10% increased risk of fracture with increasing 1,25D levels (odds ratio {OR}: 1.10; 95% C.I: 1.02, 1.18, p<0.000). The increased risk of falls was not associated with 1,25D levels (OR: 1.02, 95% C.I: 0.98, 1.06, p=0.34). The normal range for 1,25D is 47 to 203pmol/L and may be high in hyperparathyroidism². We have previously reported evidence increased bone turnover in this group of participants³ although PTH levels were lower in the vitamin D than placebo group (3-month post-dose: 4.2 vs 5.7 pmol/L, respectively, p=0.007).

These findings suggest high 1,25D levels following a 500,000IU dose of cholecalciferol are associated with an increased fracture risk in older Caucasian women. The finding does not explain the increased risk of falls but progresses our understanding of a mechanism underlying the occurrence of increased fracture risk following annual high-dose vitamin D supplementation.

The Safety of Long-Term Use of Different Doses of Vitamin D₃ Plus Calcium in Older Caucasian and African American Women. Vinod Yalamanchili*¹, Munro Peacock², Lynette Smith³, J. Christopher Gallagher¹. ¹Creighton University Medical Center, USA, ²Indiana University Medical Center, USA, ³University of Nebraska Medical Center, USA

Background: Long-term use of vitamin D₃ and calcium supplements is common in older women. But there is no long-term data on the incidence of hypercalcemia and hypercalciuria with these supplements. In the WHI study, after seven years there was a significant increase in renal stones in the women treated with vitamin D₃ 400IU/d and 1000 mg extra calcium but no laboratory data.

Methods: 163 Caucasian and 110 African American women, ages 57-94 years, randomized to one of the doses of vitamin D₃ - 400, 800, 1600, 2400, 3200, 4000, 4800 IU/day or placebo for one year. The main inclusion criterion was vitamin D insufficiency with serum 25 hydroxyvitamin D (25OHD) < 20ng/ml (Diasorin assay). Exclusion criteria were illness or medications known to affect calcium and vitamin D metabolism. Calcium intake was increased to 1200-1400mg/d with calcium citrate. Definition of hypercalcemia and hypercalciuria was a value greater than the normal range established at baseline for each group. Serum and 24-hour urine calcium were measured at baseline and every 3 months for one year. Any abnormal event was verified after one week and if high values continued to occur then the vitamin D and calcium supplements were reduced or stopped. Multiple regression analysis was used that included the variables age, dose, calcium intake, serum 25OHD, serum and urine calcium.

Results: Mean baseline serum 25OHD for all subjects was 14.5 ng/ml, there was a curvilinear increase in serum 25OHD and reached a plateau at ~45 ng/ml. In Caucasians mean daily calcium intake at baseline was 685 mg and at the end 1230 mg; in African Americans mean baseline was 551 mg and at the end 1100 mg. The number of events of hypercalcemia and hypercalciuria are shown in table and the incidence was high. Final 24-hour urine calcium was not related to vitamin D₃ dose in both groups but was significantly related to serum 25OHD level in Caucasians only. There was no significant relationship between the events of hypercalcemia or hypercalciuria and the vitamin D₃ dose or serum 25OHD. No kidney stones were reported.

Summary: There was a high incidence of hypercalciuria especially in Caucasian women compared to African American women and both groups had events of

hypercalcemia. These events were not related to the vitamin D₃ dose. Hypercalciuria and hypercalcemia could lead to an increase in kidney stones and measurement of serum and 24-hour urine calcium is advisable with long-term use of vitamin D₃ and calcium.

Table 1. Incidence of Hypercalciuria and Hypercalcemia

| | | Hypercalcemia | Hypercalciuria |
|--|-------------------|---------------|----------------|
| Subjects (percentage with one event) | Caucasians | 11% | 33% |
| | African Americans | 15% | 11% |
| Events (percentage out of total tests) | Caucasians | 4% | 15% |
| | African Americans | 5% | 4% |

Long-term Sclerostin Antibody Treatment in Cynomolgus Monkeys: Sustained Improvements in Vertebral Microarchitecture and Bone Strength Following a Temporal Increase in Cancellous Bone Formation. Michael Ominsky*¹, Rana Samadfam², Jacquelin Jolette³, Susan Y. Smith², Hua Zhu Ke¹, Rogely Waite Boyce⁴. ¹Amgen Inc., USA, ²Charles River Laboratories, Canada, ³Charles River Laboratories, Preclinical Services Montreal, Canada, ⁴Amgen Inc, USA

Sclerostin antibody (Scl-Ab) increases bone formation, bone mass, and bone strength in rodents and cynomolgus monkeys (cynos) in studies of up to 10 weeks duration. To investigate the long-term effects of Scl-Ab treatment, adolescent (3-5 year old) cynos were treated for 6 months with weekly subcutaneous injections of vehicle (Veh), 3, 10, or 100 mg/kg Scl-Ab (n=4/group). The data reported here are from male cynos, though similar results were observed in females.

The bone formation marker serum osteocalcin peaked within the first 3 months of Scl-Ab treatment and returned toward baseline levels at month 6, at which time the L2 vertebra bone formation rate (BFR/BS) was similar across all treatment groups. At the tibia diaphysis, endocortical BFR/BS remained dose-dependently elevated. Despite the normalization of cancellous BFR/BS at month 6, Scl-Ab dose-dependently increased DXA BMD by 15-30% at the lumbar spine compared with Veh (Table).

By ex vivo microCT, Scl-Ab resulted in dose-dependent increases in BMD at L3 vertebral bodies and L6 cancellous cores, and in bone area, cortical thickness (Ct.Th), trabecular bone volume (BV/TV), and trabecular thickness (Tb.Th) (Table). The improvements in bone microarchitecture resulted in increases in yield load for all dose levels at both L3 (+33-92%) and L6 (+83-142%) compared with Veh. Stiffness and energy to failure were also dose-dependently increased after Scl-Ab treatment at both sites. Strength properties were normalized to BV/TV to approximate material properties, and no group differences were found in yield strength, modulus, or toughness. Positive correlations between BMD and yield load were observed across all groups for both vertebral specimens, further supporting the maintenance of material properties. No group differences were found in the ratio of ash to dry weight in vertebral samples, reflecting normal matrix mineralization during Scl-Ab treatment.

These data demonstrate that 6 months of Scl-Ab treatment in cynos resulted in marked improvements in vertebral BMD, cortical and trabecular microarchitecture, and bone strength, with maintenance of bone material properties. Together, these data highlight the unique mode of action of Scl-Ab, which temporally increases cancellous bone formation, resulting in a rapid increase in bone volume of normal quality that is maintained after indices of trabecular bone formation return to baseline.

Negative Effect of N-Cadherin on the Anabolic Action of Parathyroid Hormone (PTH). Leila Revollo*¹, Jin Norris², Gabriel Mbalaviele³, Roberto Civitelli³. ¹Washington University Division of Bone & Mineral Diseases, USA, ²WASHINGTON UNIVERSITY, USA, ³Washington University in St. Louis School of Medicine, USA

Interaction between PTH/PTHrP receptor (PTH1R) and low-density lipoprotein receptor-related protein 6 (LRP6) contribute to the osteo-anabolic action of PTH through activation of β -catenin signaling. Others have shown negative regulation of canonical Wnt/ β -catenin signaling by N-cadherin interaction with LRP5/6 via axin. We previously reported that PTH1R interacts with LRP6 but not LRP5 or N-cadherin. We also find that both LRP5 and LRP6 interact with N-cadherin, but not with cadherin-11, another osteoblast cadherin; and that PTH induces rapid LRP5 and N-cadherin translocation from cytoplasmic pools to the cell surface. These results are compatible with a model whereby N-cadherin regulates PTH-PTH1R responses by sequestering LRP5/6, thus diminishing PTH-induced LRP5/6-signaling. To begin testing this model, we used mice harboring a selective deletion of the N-cadherin gene (*Cdh2*) in osteoblasts, driven by the *Osterix* promoter (*Cdh2^{fllox/flox}::Ox-Cre*: *Cdh2*-cKO). Consistent with previous models of conditional *Cdh2* ablation, *Cdh2*-cKO mice have a smaller skeleton and decreased bone mass, but normal trabecular and cortical architecture. Intermittent administration of human PTH₁₋₃₄ (80 μ g/kg bw, sc, 5x/week, 4 weeks) to 3-months-old male mice produces changes of larger magnitude in *Cdh2*-cKO (n=4) relative to control (*Cdh2^{fllox/flox}*) (n=9) mice with respect to trabecular bone volume/tissue volume (110.13 \pm 40.03% vs. 38.71 \pm 9.21% above baseline, respectively, p<0.05), and bone mineral density (31.90 \pm 8.70% vs. 12.68 \pm 3.41% above baseline, p<0.05), assessed by *in vivo* μ CT imaging. PTH treatment also increases cortical thickness in both *Cdh2*-cKO mice and control (34.14 \pm 20.18% vs. 26.28 \pm 5.90% above baseline, p>0.1), but has minimal effects on cortical tissue mineral density (3.36 \pm 0.38% vs. 2.13 \pm 1.88% from baseline, p>0.1). Cross-sectional marrow area does not change in either *Cdh2*-cKO and control group (0.58 \pm 4.68% vs. 0.35 \pm 4.97% from baseline, p>0.1). Thus, intermittent PTH administration increases trabecular bone mass and cortical thickness in mice, the latter presumably by increasing periosteal bone apposition. Osteoblast N-cadherin appears to have a restraining effect on PTH anabolic effect on trabecular but not cortical bone. We hypothesize this action of N-cadherin occurs through interference with PTH1R-LRP5/6 signaling interactions.

Treatment with an Inhibitor of Fatty Acid Synthase Reverses Bone Loss in Ovariectomized Mice. Sandra Bermeo*¹, Wei Li², Christopher Vidal³, Daniele Cultrone⁴, Mamdouh Khalil⁵, Gustavo Duque⁶. ¹PhD Student, Australia, ²University of Sydney, Nepean Clinical School, Australia, ³University of Sydney, Australia, ⁴Ageing Bone Research Program, Sydney Medical School Nepean, The University of Sydney, Australia, ⁵ANZAC Research Institute, Australia, ⁶Ageing Bone Research Program, University of Sydney, Australia

In the bone marrow, bone and fat have an antagonistic relationship with fat having a toxic effect on bone cells. This lipotoxic effect is exerted through the accumulation of fatty acids, which are synthesized by fatty acid synthase (FAS) in marrow adipocytes. In this study, we hypothesized that FAS inhibition would have a potential beneficial effect on bone mass of ovariectomized (OVX) mice. Nine-month-old C57BL/6 mice underwent OVX or SHAM surgery, and 8 wks later were treated three times a week with cerulenin (30 and 60 mg/Kg, SC) or vehicle (VEH) for 6 wks. Both SHAM and OVX mice showed a significant decrease in both body weight ($-10 \pm 2\%$) and subcutaneous fat thickness ($-25 \pm 10\%$) compared to VEH. μ CT and histomorphometry measurements indicated that trabecular bone volume/total volume (BV/TV) was significantly increased in both SHAM and OVX groups (33 \pm 10% and 52 \pm 18% respectively) as compared to VEH (p<0.001). Furthermore, treatment with low dose cerulenin induced a significant increase in mineral apposition rate (MAR) in both SHAM and OVX groups (52 \pm 8%) as compared with VEH. Overall, this anabolic effect was also associated with higher osteoblast number (~ 2 fold) with no changes in osteoclast number being observed in the OVX and SHAM groups. Changes in cell numbers corresponded with higher serum levels of P1NP (2 fold) with no changes in serum C-telopeptide in the treated groups. Additionally, *ex vivo* cultures of bone marrow stromal cells showed similar levels of osteoblastogenesis and very low levels of adipogenesis in the treated mice as compared with VEH. This evidence was supported by Western blot and RT-PCR analysis of osteogenic and adipogenic genes. Both OVX and SHAM groups showed a significantly lower expression of adipogenic genes (PPAR γ , C/EBP α and AP2, p<0.001) with no changes being observed in osteogenic genes in the treated groups. Histological quantification of marrow fat showed a significant decrease of fat volume/total volume (FV/TV) in both OVX (-26%) and SHAM (-18%) groups as compared to VEH (p<0.01). Finally, treatment of OVX mice with cerulenin improved BMD to levels equal to SHAM and VEH controls. Taken together, our results demonstrate that inhibition of FAS decreases adipogenesis and fat marrow content and stimulates bone formation by inducing an ideal marrow milieu for osteoblast function without affecting bone resorption, thus providing strong evidence that inhibition of FAS may be a novel anabolic therapy for osteoporosis.

A New Peptide Derived from the Matrix Protein Chondroadherin Reduces Motility of Osteoclast Precursors and Breast Cancer Cells through Inhibition of the Nitric Oxide Synthase 2 Pathway: Pre-clinical Evidence for Therapy. Nadia Rucci*¹, Mattia Capulli², Ole Kristoffer³, Kaare Gautvik⁴, Lisbet Camper⁵, Dick Heinegard⁶, Anna Teti¹. ¹University of L'Aquila, Italy, ²Department of experimental Medicine, University of L'Aquila, Italy, ³Department of Clinical Chemistry, Ullevaal University Hospital & Institute of Medical Biochemistry, University of Oslo, Norway, ⁴Oslo University Hospital, Norway, ⁵Department of Experimental Medical Science, Lund University, Sweden, ⁶Lund University, Sweden

The Nitric Oxide Synthase (NOS) 2 is implicated in many cellular functions through its ability to produce NO in an inducible manner. We isolated a cyclic peptide representing the $\alpha 2\beta 1$ integrin binding sequence of the matrix protein chondroadherin (cCHAD), which displays antiosteoclastogenic and antitumoral effects. We noted that in mouse bone marrow preosteoclast cultures cCHAD potency was greater at low cellular density suggesting an effect on cell motility. A scratch-healing assay confirmed a 88% reduction of migration in cCHAD-treated preosteoclasts vs. control. Likewise, cCHAD-treated osteotropic breast cancer cells MDA-MB231 showed reduced migration and invasion (-30% and -40%, respectively) suggesting a common mechanism of action. A real-time RT-PCR array showed that cCHAD downregulated NOS2 expression in preosteoclasts. We treated preosteoclasts with the NO donor S-nitroso-N-acetyl-D,L-penicillamine, which blocked the effect of cCHAD, rescuing normal preosteoclast motility and differentiation. In contrast, the NOS2 inhibitor N5-(1-iminoethyl)-l-ornithine mimicked the effect of cCHAD abrogating both motility and osteoclastogenesis. In healthy mice treated with cCHAD we observed dose-dependent reduction of osteoclast number and surface/bone surface (-40% and -50%, respectively) and increase of trabecular bone volume (1.55-fold), with no adverse effects. Daily treatment of ovariectomized (OVX) mice with cCHAD starting 3 days (preventive protocol) or 5 weeks (curative protocol) after OVX showed that cCHAD significantly prevented bone loss and rescued bone mass, respectively, by inhibiting osteoclast increase. *In vivo* antiresorptive effect of cCHAD was also observed in mouse models of breast cancer-induced bone metastases by intracardiac injection of MDA-MB231 cells, in which cCHAD strongly decreased the incidence of osteolytic lesions (-78%). Consistent with its antitumoral activity, cCHAD reduced visceral metastases and orthotopic tumor growth as well, confirming a direct *in vivo* effect on cancer cells. In conclusion, we provided pre-clinical evidence that cCHAD is a new potent inhibitor of the NOS2/NO pathway through which it i) increases bone mass in healthy mice, ii) counteracts bone loss in OVX-induced osteoporosis, iii) inhibits osteolytic bone metastases acting on both bone resorption and tumor expansion, iv) inhibits tumor growth. These results suggest the use of cCHAD as a new experimental therapy for bone diseases.

Central Roles of Adiponectin on Bone Formation Through a Hypothalamic Relay. Yuwei Wu*¹, Qisheng Tu², Jin Tang², Dana Murray², Jessica Cheng², Maribel Rios³, Zhihui Tang⁴, Jake Jinkun Chen². ¹Tufts University, USA, ²Tufts University School of Dental Medicine, USA, ³Tufts University School of Medicine, USA, ⁴Peking University School of Stomatology, China

Objective: Adiponectin is an adipose tissue derived hormone. Our previous studies have shown that adiponectin inhibits osteoclastogenesis and bone resorption. Adiponectin receptors (AdipoR1, AdipoR2, T-cadherin) are expressed in the brain. However, the effects of adiponectin in the central nervous system and the underlying mechanism are still unknown. We hypothesized that adiponectin regulates bone homeostasis through hypothalamus relay in adjusting sympathetic tone.

Methods: Male C57BL/6J and adiponectin knockout mice were used in this study. A 28-gauge cannula was implanted into the third ventricle and attached with Tygon tubing to a subcutaneous micro-osmotic pump. Recombinant globular adiponectin or artificial CSF was delivered at a rate of 0.22 μ l/hr (20 ng/hr) for 28 days. The animals were sacrificed and samples were collected at the end of the experiment. The hypothalamus, brown fat tissue (BFT), bone marrow cells, and the femur without bone marrow cells were dissected for RNA or protein extraction. Genes related to bone metabolism were determined by real-time PCR and western blot.

Results: Hypothalamus APPL1 protein was decreased after the microinjection of adiponectin into third ventricle (p < 0.05). Adiponectin dramatically down-regulated the expression of BFT uncoupling protein-1 (UCP1) that was previously found to be positive correlated with sympathetic tone. Adiponectin microinjection reduced bone marrow cells RANKL and TRAP transcription, which reflected the pathway that promotes osteoclast differentiation and their capability to resorb bone was inhibited. Alternatively, adiponectin microinjection promoted femur bone NFATC1 RNA transcription and protein expression, which had been shown to promote osteoblast proliferation and bone formation.

Conclusions: For the first time, these results suggest that, in addition to its peripheral effects on bone metabolism, central administration of adiponectin can also influence hypothalamus APPL1 pathway to promote bone formation through inhibiting sympathetic tone and osteoclast activity and enhancing osteoblast activity.

Therefore, adiponectin may serve as a potential therapeutic drug to treat osteoporotic fractures, obesity, and T2DM through a combination of its peripheral and central effects in enhancing insulin sensitivity and promoting bone formation and regeneration.

Comparing Treatment Effects of Odanacatib and Alendronate in Lumbar Vertebrae of Ovariectomized Rhesus Monkeys using Quantitative Computed Tomography. Sangeetha Somayajula¹, Ghassan Fayad², Randolph Crawford³, Seetha R. Kummari⁴, Belma Dogdas³, Mona L Purcell⁵, Paul McCracken⁶, Jacquelyn J Cook⁵, Sherri L Motzel⁷, Le Thi Duong⁶, Don Williams⁸, Antonio Cabal⁸. ¹Merck, USA, ²Merck Research Laboratories - Modeling & Simulations, USA, ³Merck Research Laboratories - Informatics IT, USA, ⁴Case Western Reserve University, USA, ⁵Merck Research Laboratories - Imaging, USA, ⁶Merck Research Laboratories, USA, ⁷Merck Research Laboratories - Lab Animal Resources, USA, ⁸Merck & Co., Inc., USA

Clinically translatable evaluation of disease progression and treatment response is critical to the development of new therapies for osteoporosis. Quantitative computed tomography (QCT) is a clinically translatable three dimensional *in vivo* imaging modality that enables localized assessment of the effects of disease and therapy on volumetric bone mineral density (vBMD). We evaluated the effects of odanacatib (ODN) and alendronate (ALN) in comparison to Vehicle (VEH) in trabecular, endo-cortical, peripheral, and whole bone compartments within the L4 vertebra of the ovariectomized (OVX) Rhesus monkey. QCT data was obtained (in-plane spatial resolution 500 μm) for three groups (n=13 each) of OVX animals treated with VEH, 2 mg/kg ODN daily, and 15 μg/kg twice weekly ALN. Longitudinal QCT measurements are presented at 0 and 18 months post-treatment. Previous work on evaluating these therapies on Rhesus vertebrae used Mindways software for vertebra analysis in an elliptical trabecular core. Here we performed a more detailed analysis using custom software that applied image processing techniques to automatically extract 4 regions of interest (ROIs) – trabecular core, endo-cortical (a ring adjacent to the cortical bone), peripheral (a ring including cortical bone and adjacent region), and whole vertebra regions. The ROIs are shown in Fig. 1. For consistency of ROI in longitudinal vBMD measurement, we performed rigid registration of the baseline to 18 month QCT image, transformed the baseline ROIs to the 18 month QCT space, and measured vBMD in the transformed ROIs. Longitudinal percent changes in vBMD in the ROIs considered are shown in Fig 2. Both treatment groups differentiated from VEH in all the ROIs considered, demonstrating efficacy of ODN and ALN. ODN differentiated from ALN in the peripheral region (p<0.05) but not in the trabecular core, endo-cortical or whole vertebra BMD (Fig 2). The differentiation in the peripheral region could be due to an increase in cortical thickness. An increase in cortical thickness was observed in high resolution peripheral QCT of the radius and these results suggest that similar effects may be occurring in vertebra as well.

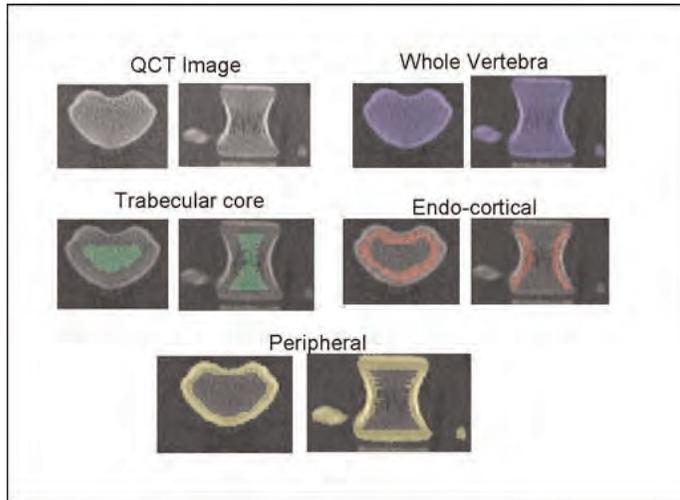

Fig 1: Regions of interest for vBMD measurement shown in transaxial and sagittal views of a subject

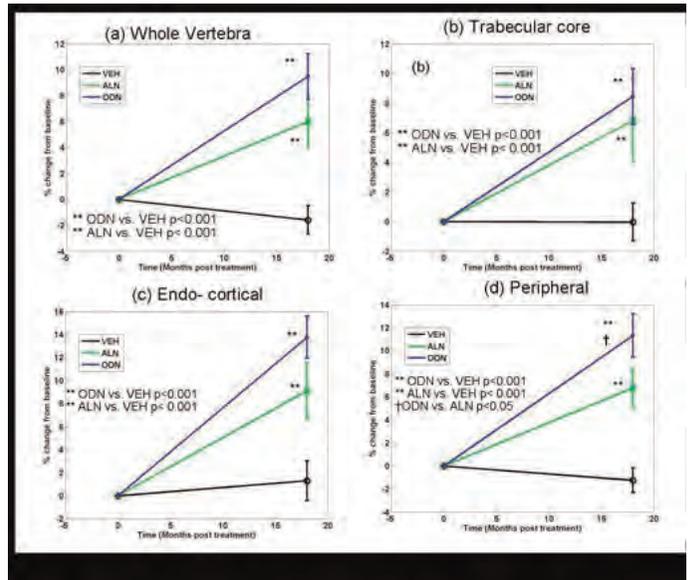

Fig 2: Percent change with respect to baseline of vBMD in the ROIs shown in Fig 1

Efficacy of Odanacatib or Alendronate following Parathyroid Hormone Treatment in Estrogen-Deficient Rabbits. Brenda Pennypacker¹, Christopher Winkelmann², John Szumiloski², Randolph Crawford², Mary Belfast³, Le Thi Duong¹. ¹Merck Research Laboratories, USA, ²Merck & Co., USA, ³Merck & Company, USA

The cathepsin K inhibitor odanacatib (ODN) and alendronate (ALN) have been shown to prevent bone loss in ovariectomized (OVX) rabbits. While ALN reduces bone remodeling, ODN preserves trabecular and cortical bone formation (BF) in this model. Intermittent administration of human parathyroid hormone 1-34 (PTH) is an approved anabolic agent for the treatment of osteoporosis. Here, we compare the effects on bone mass and remodeling in rabbits treated with ODN or ALN following PTH treatment for 6-mo, or to the respective monotherapy. Adult (7-mo) rabbits had Sham (N=20) or OVX surgery (N=120) 6-mo prior to study start. OVX-rabbits were randomized by lumbar vertebrae (LV) 5-6 into the following treatment groups: Vehicle (Veh), PTH (15μg/kg, 5x/wk), ALN (100μg/kg, 2x/wk) or ODN (~7μM·24hr, in food). After 6-mo, rabbits treated with PTH were switched to Veh (PTHswVeh), ALN (PTHswALN) or ODN (PTHswODN) for an additional 4-mo. Trabecular (Tb) vBMD by QCT of LV6 and in-life aBMD by DXA LV5-6 were determined at baseline, 3, 6 and 10-mo. Baseline Tb.vBMD in OVX decreased by 9% (p<0.05) vs. Sham. Tb.vBMD was significantly increased (p<0.001) by ODN (19%), ALN (11%) and PTH (16%) vs. Veh at 6-mo. aBMD from all groups provided similar results as Tb.vBMD measurements. PTHswVeh returned BMD to OVX levels, while switching to ODN or ALN maintained bone mass. ALN reduced mineralized surface (MS/BS) and bone formation rate (BFR/BS) of Tb.LV and CF endocortical (Ec) surfaces. Unlike ALN, the BF parameters in ODN were comparable to those in Veh. PTH significantly increased BF parameters at all sites and increased CF cortical thickness (CtTh) and area by 20% (p<0.001) and 16% (p<0.001), respectively vs. Veh. Cortical porosity (CtPo) was also increased with PTH treatment. PTHswALN and PTHswODN maintained increased CtTh and area, while switching to ALN reduced CtPo by 80% (p<0.001) and ODN by 29% (NS) compared to PTH alone. CF peak load was significantly increased by PTHswODN and PTHswALN. In LV4 and CF, positive correlations between pQCT BMC and peak load were observed (r²= 0.7318, p<0.001 and r²= 0.5386, p<0.001, respectively). In this study, ODN as follow-on treatment to PTH preserved bone mass similar to ALN in osteopenic rabbits. However, ODN maintains the window of bone formation post-PTH therapy. This supports the potential cycling usages of these agents that may offer long-term benefits to patients with severe osteoporosis.

Odanacatib Treatment Reduces Remodeling and Stimulates Modeling-based Bone Formation in Central Femur and Lumbar Vertebra of Adult OVX Monkeys. Charles Chen*¹, Mei-Shu Shih², Hellen Zheng³, Le Thi Duong⁴. ¹Merck & Co., Inc., USA, ²RS Medical, USA, ³MDS, USA, ⁴Merck Research Laboratories, USA

Odanacatib (ODN), a selective and reversible Cathepsin K inhibitor has been demonstrated to reduce trabecular (Tb) and intracortical (Ic) bone turnover while preserving endocortical (Ec) and stimulating bone-site specific periosteal (Ps) bone formation in OVX-monkeys. The aim of this study is to investigate the bone site specific mechanism of ODN on bone modeling (Mo) and remodeling (Re). Adult newly OVX-rhesus monkeys (13-19 yrs, n =8-11 per group) were treated with vehicle or ODN (6 or 30mg/kg, q.d., p.o.) for 21-months. Calcein labels at 15-d interval were given at 12-mo. of dosing. Lumbar vertebrae (LV) longitudinal sections (~8-um) and central femur (CF) cross sections (50-um) were subjected to analyses for cement line and dynamic histomorphometric measures. Only newly formed hemiosteons (Ho) were evaluated. At LV Tb surface, ODN at 6 and 30mg/kg dose-dependently reduced the number of remodeling hemiosteons (Re.Ho.N) without changing the mean wall thickness (Re.W.Th) as compared to vehicle. Although modeling was very low at Tb surface of the aged monkeys, ODN did not change Mo.Ho.N/BS and Mo.W.Th. vs. Veh. Overall in Tb.LV, ODN dose-dependently reduced mineralizing surface (MS/BS), mineral apposition rate (MAR), bone formation rate (BFR/BS) and thus activation frequency (Tb.AcF). In the CF, both low and high doses of ODN also decreased Ic remodeling as in Tb LV. ODN dose-dependently reduced Ec.Re.Ho.N by 51% and 66% (p<0.05), respectively and the high dose tended to reduce remodeling formation parameters BFR/BS, MS/BS and AcF. Also similar to Tb surface, Ec.Re.W.Th was unchanged in ODN vs. Veh. Remarkably, ODN increased modeling bone formation in the CF at both Ec and Ps surfaces. ODN dose-dependently increased Ec modeling parameters, including Mo.Ho.N/BS, Mo.AcF, Mo.W.Th and bone formation parameters. At Ps surface, ODN increases all BF parameters in a dose-dependent manner. In summary, the results demonstrate that ODN reduces remodeling and stimulates modeling-based bone formation, and thus changes the ratio of modeling to remodeling hemiosteons. The findings may thus explain the bone site specific actions of ODN on trabecular and cortical surfaces. Furthermore, the dual mechanisms of ODN on bone formation clearly differentiate this agent from the standard anti-resorptives.

Down-regulation of FoxO3a/SIRT1 Signaling by Measles Virus Nucleocapsid Protein is Implicated in Paget's Disease. Feng-Ming Wang*¹, Benedicte Sammut², Quanhong Sun³, Jolene Windle⁴, G. David Roodman¹, Deborah Galson³. ¹Indiana University, USA, ²University of Pittsburgh Hillman Cancer Center, USA, ³University of Pittsburgh, USA, ⁴Virginia Commonwealth University, USA

Measles virus plays an important role as an environmental factor in the pathogenesis of Paget's disease. Previous studies have shown that IL-6 is increased in the bone marrow of Paget's patients and that measles virus nucleocapsid protein (MVNP) induces IL-6 secretion by pagetic osteoclasts. Further, we have shown that IL-6 contributes to the formation of pagetic osteoclasts. However, the mechanisms regulating IL-6 production by MVNP remain unclear. Here we demonstrate that expression of MVNP resulted in a down-regulation of FoxO3a/SIRT1 signaling. The presence of MVNP impaired the expression of *Sirt1* mRNA both under basal conditions and upon activation of its upstream regulator FoxO3a by LY294002 (a PI3K/AKT inhibitor). MVNP impairment of LY294002 induction of FoxO3a-driven *Sirt1* mRNA expression is likely due to the decreased FoxO3a protein levels observed in MVNP-expressing NIH3T3 cells, and therefore the LY294002-induced nuclear accumulation of FoxO3a was attenuated. Protein stability assays revealed that FoxO3a was degraded more rapidly in MVNP-expressing cells than in control cells following the addition of cycloheximide. Similarly, co-transfection of MVNP and FoxO3a into HEK293 cells demonstrated that MVNP decreased the protein levels of the over-expressed FoxO3a in a dose-dependent manner. Luciferase activity assays showed that constitutively active FoxO3a abolished the repressive effect of MVNP on luciferase reporters driven by either FoxO3a response elements or the *Sirt1* promoter. Consistent with the high levels of IL-6 present in *Sirt1* deficient MEF cells, MVNP-expressing cells displayed increased levels of IL-6, which could be inhibited by over-expression of SIRT1 or treating the cells with the SIRT1 activator, resveratrol. Finally, activation of SIRT1 by resveratrol blocked the formation of osteoclasts in bone marrow cultures and diminished the differences in osteoclast formation between cells from wild-type and TRAP-MVNP transgenic mice. These data suggest that modulation of FoxO3a/SIRT1 signaling plays an important role in MVNP's contribution to Paget's disease through its effects on IL-6 production.

Cushing Disease: Restoration of Bone Mass and Microarchitecture after Hypercortisolism Normalization. Eugénie Koumakis*¹, Renaud Winzenrieth², Laurence Guignat³, Catherine Cormier⁴. ¹Rheumatology Department A, Cochin Hospital, APHP, France, ²Med-imaps, Hôpital X. Arnoz, PTIB, Pessac, France, France, ³Endocrinology department, Cochin Hospital, APHP, France, ⁴AP-HP Groupe Hospitalier Cochin, France

Cushing disease (CD) is considered as a true model of a glucocorticoids (GCs) effects on bone metabolism because of the minimization of confounding factors. Hypercortisolism frequently induces bone loss which is more pronounced at the lumbar spine than at the femoral neck due to a higher content in trabecular bone. This bone loss results in osteoporosis, and leads to an increased fracture risk. Besides, several studies have shown bone mass restoration in patients with CD after treatment. The aim of our study was to examine treatment effects on bone mineral density (BMD) and on bone microarchitecture assessed by TBS in subjects with CD.

We present a longitudinal study on 11 subjects (6 women and 5 men) with CD. Mean age and BMI were 39.9 ± 12.7 years and 27.1 ± 5.0 Kg/m² respectively. Mean 24h urinary cortisol before treatment was elevated in 10 patients 326 ± 287 (149-1079) µg/24h, and one patient had very elevated levels (7268 µg/24h). All subjects were cured, i.e. 24h urinary cortisol normalization after treatment. Among these 11 subjects, 10 underwent transphenoidal surgery whereas one subject only received medical treatments. BMD and TBS were evaluated at AP Spine (L1-L4) with DXA prodigy (GE-Lunar), QDR 4500 (Hologic), and TBS iNsight® (Med-Imaps) before and after treatment. Both DXA were cross-calibrated using a custom-made phantom. Linear regression was used to evaluate TBS and BMD modifications over time. Results were normalized at 1 and 2 years after treatment. BMD and TBS gains were expressed in % in comparison to baseline.

Normalized gains in % for TBS and BMD are presented figure 1 (mean + SD). After treatment, BMD and TBS increased by 3.7 and 7.3% respectively after 1 year, and by 7.9 and 13.5% after 2 years. BMD and TBS were not correlated before (p=0.35) and after treatment (p=0.20).

To our knowledge, the present study is the first to report data on bone recovery at the spine both by DXA and TBS in cured subjects with CD. The absence of correlation between TBS and BMD and the better improvement of microarchitecture assessed by TBS than BMD suggest qualitative rather than quantitative bone alterations in hypercortisolism-induced osteoporosis. This may explain some of the discrepancies between fracture rates and relatively preserved BMD measures in GC induced bone loss. Bone microarchitecture assessment could be a useful and supplementary tool for fracture risk evaluation in GC induced bone loss.

Hypothalamic-pituitary-adrenal Axis is Essential for the Regulation of both Bone and Fat Metabolism via Melanocortin 2 Receptor. Tsvuyoshi Sato*¹, Dai Chida¹, Takanori Iwata², Michihiko Usui³, Yuichiro Enoki¹, Masahito Matsumoto¹, Ren Xu⁴, Satoko Sunamura⁵, Hiroki Ochi³, Toru Fukuda⁶, Shu Takeda⁷, Tetsuya Yoda¹. ¹Saitama Medical University, Japan, ²Tokyo Women's Medical University, Japan, ³Showa University Dental School, Japan, ⁴Tokyo Medical & Dental University, Japan, ⁵Keio University, Japan, ⁶Keio University School of Medicine, Japan, ⁷Keio University, Dept. of Nephrology, Endocrinology & Metabolism, Japan

The hypothalamic-pituitary-adrenal (HPA) axis is involved in maintaining homeostasis under stress conditions. Glucocorticoids (GCs) which are the end

products of the HPA axis via adrenocorticotropic hormone (ACTH) are crucial factors in the regulation of body adiposity and bone metabolism. GCs promote differentiation in adipocytes and cause glucose intolerance and central obesity. While several animal models have been developed to analyze the role of GCs in skeletal development in vivo, those results have been conflicting. Transgenic mice selectively overexpressing 11 β -hydroxysteroid dehydrogenase type2 (11 β -HSD2) within osteoblasts and osteocytes revealed that endogenous GCs are not required for normal skeletal development. Paradoxically, bone mass were lower in the transgenic mice overexpressing 11 β -HSD2 within osteoblasts and in the conditional knockout mice in which glucocorticoid receptor is specifically disrupted in osteoblasts under the control of Runx2 promoter fragments. On the one hand, the activation of the HPA axis by mental stressor has been implicated in high fat mass and low bone mass. However, the role of the HPA axis in both bone and fat metabolism is not fully elucidated. Here we characterized the bone and fat phenotype of melanocortin 2 receptor (i.e., ACTH receptor) knockout mice (MC2R $^{-/-}$ mice) disrupted of the HPA signaling pathway. We found that MC2R $^{-/-}$ mice were lean in old age and reduced fat mass. Adipose tissue weight was decreased in MC2R $^{-/-}$ mice, while adipocyte size in epididymal white adipose tissue were comparable between MC2R $^{-/-}$ mice and MC2R $^{+/+}$ controls, suggesting that white adipose cell number is decreased in MC2R $^{-/-}$ mice compared to MC2R $^{+/+}$ controls. MC2R $^{-/-}$ mice at 6 months old exhibited a high bone mineral density. Cortical thickness, bone formation rate, osteoblast surface/bone surface and serum osteocalcin were significantly increased whereas bone volume/tissue volume and osteoclast number/bone surface were normal in MC2R $^{-/-}$ mice. Accordingly, gene expression of osteocalcin in MC2R $^{-/-}$ mice was significantly increased in vivo, suggesting that the augmentation of cortical thickness was due to the enhancement of bone formation. Taken together, the HPA axis is essential for the regulation of both bone and fat metabolism through melanocortin 2 receptor. We will discuss the role of endogenous GCs and ACTH in mesenchymal stem cells differentiation and the influence of mental stress on both bone and fat metabolism.

The Role of Osteocalcin in Glucocorticoid-Induced Metabolic Dysfunction.

Tara Brennan-Speranza¹, Holger Henneicke^{*1}, Sylvia Gasparini², Caren Gundberg³, Colin Dunstan⁴, Hong Zhou¹, Markus Seibel¹. ¹Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, ²Bone Research Program, ANZAC Research Institute, Australia, ³Yale University School of Medicine, USA, ⁴University of Sydney, Australia

We recently demonstrated that osteoblast-targeted disruption of glucocorticoid (GC) signaling attenuates GC-induced metabolic dysfunction and obesity, while preventing the marked decrease in circulating osteocalcin (OCN) usually seen with GC treatment. In the present study, we investigated the role of OCN in the pathogenesis of GC-induced insulin resistance, glucose intolerance and obesity.

Seven-week-old CD1 outbred mice were treated with placebo or corticosterone (1.5mg/week) for 28 days. On day 8, OCN was replaced via hepatic transfection of a non-viral DNA plasmid containing the osteocalcin gene driven by the albumin promoter (pLIVE, Mirus). We transfected either a wild-type OCN construct (wt-OCN) able to undergo gamma-carboxylation, or a mutant construct (mOCN) which cannot be carboxylated. Empty vectors were used as controls. Successful transfection was confirmed via detection of the GFP-containing pLIVE-vector in mouse hepatocytes 7 to 28 days post transfection. Insulin tolerance tests (ITT) and oral glucose tolerance tests (oGTT) were performed 0, 7, 14, 21 and 28 days into GC treatment. Body weight and composition were monitored throughout.

GC-treatment resulted in complete suppression of serum OCN levels and marked insulin resistance from day 7 onwards over the 4-week observation period. GC-treated mice receiving the wtOCN or mOCN constructs on day 8 regained their insulin tolerance in a time-dependent manner, with glucose levels falling to 60% of baseline in response to insulin on day 28. Glucose tolerance followed the same pattern (see Fig. 1). In contrast, GC-treated mice transfected with the empty vector remained insulin resistant and glucose intolerant. Furthermore, while GC-treated mice receiving the empty vector gained 60% in fat mass throughout the course of the study, hepatic osteocalcin expression attenuated the development of GC-induced obesity.

In conclusion, the adverse effects of exogenous GC on insulin sensitivity, glucose tolerance and adiposity in mice can be overcome by hepatic heterotopic expression of non-carboxylated or carboxylated osteocalcin. These data provide evidence that the osteoblast-specific peptide, osteocalcin, plays a central role mediating the effects of exogenous GC on systemic energy metabolism.

Low Femoral and High Vertebral Bone Phenotype in α_{2C} AR Knockout Mice.

Marilia Teixeira^{*1}, Gisele M Martins², Cristiane Costa², Cecilia Gouveia³.

¹University of Sao Paulo, Brazil, ²Institute of Biomedical Science, Brazil,

³University of Sao Paulo, Institute of Biomedical Sciences, Brazil

Evidences demonstrate that sympathetic nervous system (SNS) activation causes osteopenia via β_2 -adrenoceptor (β_2 -AR) signaling. In a recent study, we showed that female mice with chronic sympathetic hyperactivity due to double knockout of adrenoceptors that negatively regulate norepinephrine release, α_{2A} -AR and α_{2C} -AR (α_{2A}/α_{2C} -ARKO), present an unexpected and generalized phenotype of high bone mass with decreased bone resorption and increased bone formation. Furthermore, we found that these animals are resistant to the thyrotoxicosis-induced osteopenia. These findings suggest that β_2 -AR is not the single adrenoceptor involved in bone mass regulation and show that α_2 -AR signaling may also mediate the SNS and thyroid hormone actions in the skeleton. To further investigate the participation of α_2 -ARs and its possible interaction with thyroid hormone in the regulation of bone mass, we are evaluating the bone phenotype of α_{2C} AR knockout mice (α_{2C} AR $^{-/-}$). A cohort of 30 day-old female congenic α_{2C} AR $^{-/-}$ mice, in a C57BL/6J background, and their wild-type (WT) controls (n=8/group) were treated with a supraphysiological dose of triiodothyronine (T3=7 μ g/100gBW/day) for 30 or 90 days. Surprisingly, a microtomography analysis showed that the trabecular bone volume (BV/TV) of the distal metaphysis of the femur and of the fifth lumbar vertebra (L5) were, respectively, 15%-45% lower and 31%-83% higher in α_{2C} AR $^{-/-}$ mice, when compared with WT animals (p<0,05 for all). Unlike the double knockout mice (α_{2A}/α_{2C} -ARKO), α_{2C} AR $^{-/-}$ mice were as sensitive to the thyrotoxicosis-induced osteopenia as WT animals. These findings suggest that α_{2C} AR may have a role in mediating the deleterious effects of the sympathetic activation in trabecular bone of vertebra and the opposite effects in the femur. In addition, these findings suggest that thyroid hormone does not interact with the SNS, via α_{2C} -AR, to regulate trabecular bone volume.

The Role of Activation Functions 1 and 2 of Estrogen Receptor- α for the Effects of Estradiol and Selective Estrogen Receptor Modulators (SERMs) in Male Mice.

Anna Borjesson^{*1}, Sara Windahl¹, Marie Lagerquist², Cecilia Engdahl¹, Helen Farman¹, Antti Koskela³, Klara Sjogren⁴, Jenny Kindblom², Alexandra Stubelius¹, Ulrika Islander¹, Maria C Antal⁵, André Krust⁵, Pierre Chambon⁵, Juha Tuukkanen³, Claes Ohlsson⁶.

¹Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden, ²Sahlgrenska University Hospital, Sweden, ³University of Oulu, Finland,

⁴Centre for Bone & Arthritis Research, Sweden, ⁵Institut de Génétique et de Biologie Moléculaire et Cellulaire, France, ⁶Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden

Studies, in both man and mouse, show that estradiol (E2) is important for male skeletal health. The effect of E2 on bone is mainly mediated via estrogen receptor (ER)- α , as demonstrated by the findings that men with an inactivating mutation in aromatase or a non-functional ER α experience osteopenia and continued longitudinal growth after sexual maturation. To evaluate the role of different domains of ER α for the estrogenic effects on bone mass in males, we analyzed mice with a complete inactivation of ER α (ER α $^{-/-}$), a deletion of ER α activation function (AF)-1 (ER α AF-1 0) or a deletion of ER α AF-2 (ER α AF-2 0).

E2 treatment increased the amount of trabecular and cortical bone together with bone strength, and reduced the thymus weight and bone marrow cellularity in orchidectomized (orx) wild type (WT) mice. These tissues did not respond to E2 treatment in orx ER α $^{-/-}$ or ER α AF-2 0 mice. However, the effects of E2 in orx ER α AF-1 0 mice were tissue dependent, with a clear response in bone strength, cortical bone and bone marrow cellularity (68 \pm 17%, 45 \pm 6% and 33 \pm 6%, respectively, of E2 response in WT mice, p<0.05) but no significant response in trabecular bone or thymus.

To determine the tissue specific effects of selective ER modulators (SERMs) and the role of ER α AF-1 for their effects in male mice, we treated orx WT and ER α AF-1 0 mice with E2, Raloxifene (Ral), Lasofoxifene (Las), Bazedoxifene (Bza) or vehicle. Compared to the E2 response in orx WT mice, Ral, Las and Bza treatment resulted in tissue dependent effects, where the decrease in fat mass was normal after Ral and Las treatment, while the Bza treatment was less effective. The increase in trabecular bone mineral density was apparent for all SERMs, but less effective than the E2 effect. Las was the most effective SERM in increasing cortical bone mass, while none of the SERMs reduced the thymus weight. In contrast to E2, all effects of these SERMs were absent in the orx ER α AF-1 0 mice.

In conclusion, ER α AF-2 is required for the estrogenic effects on all parameters evaluated, while the role of ER α AF-1 is tissue specific. The effects of Ral, Las and Bza, in orx WT mice, are tissue dependent. In contrast to E2, all evaluated effects of these SERMs are dependent on a functional ER α AF-1. Our findings might contribute to the development of improved SERMs, with minimal side effects in males.

Disclosures: Anna Borjesson, None.

FR0431

Control of Post-Gonadarche Bone Mass Acquisition via Expression and Action of Heterogeneous Nuclear Ribonucleoprotein D (hnRNP D). Hong Chen¹, Linda Gilbert², Thomas Lisse³, Martin Hewison⁴, Mark Nanes⁵, John Adams^{*4}. ¹VA / Emory University School of Medicine, USA, ²Atlanta VA Medical Center, USA, ³Mount Desert Island Biological Laboratory, USA, ⁴University of California, Los Angeles, USA, ⁵VA Medical Center & Emory University, USA

Proteins in the hnRNP subfamily are scaffold proteins that move back and forth between the cell cytoplasm and nucleus. In the nucleus hnRNP D, also known as the estrogen response element binding protein (ERE-BP) or AUF1, interacts in trans with DNA and RNA cis elements to control gene expression by regulating chromatin remodeling, transcription, transcript splicing as well as the handling of coding and noncoding RNA. Based on the temporal sequence and configuration of hnRNP D-protein interaction, elucidated by a combination of co-immunoprecipitation and yeast two hybrid analyses in cultured cells, with the estrogen receptor alpha (ER α), the estradiol (E2) binding chaperone heat shock protein-27, and the Wnt3a signaling molecules, β -catenin and IKK α/β in the cytoplasm, hnRNP D regulates the availability of proteins (and small molecules bound to those proteins) for transnuclear transport and genomic action. Global over-expression of hnRNP D results in diminished post-gonadarche bone mass and size in vivo. This event occurs through the actions of hnRNP D to: 1) thwart movement of the E2-liganded ER α to the nucleus; 2) act in a dominant-negative mode by competing in trans with the E2-ER α binding for binding to cis-acting EREs in control of the genomic, anabolic actions of E2; and 3) operate in an E2-independent manner to promote trans-stimulation of RANKL, RANK expression and bone resorption. Here we present evidence that global knockdown or knockout of hnRNP D results in progressive increase in bone mass and size in the post-gonadarche, 7-week-old female mouse by μ CT analysis; compared to wildtype, bone mass increased by 28% and 31% in hnRNP +/- and -/- mice, respectively, and bone size by 28% and 54%, respectively. 6-month-old adult hnRNP-null mice had evidence of persistence of the anti-anabolic actions of hnRNP D, demonstrating a significant 2-4-fold increase in osteocalcin and alkaline phosphatase gene expression in primary culture of osteoblasts (OB) from hnRNP -/- compared to wildtype marrow. In conclusion, up or down regulation of hnRNP D expression in the extreme can control female bone mass and size by i) antagonizing the anabolic action of E2 on OB gene expression, ii) promoting E2-independent effects on OB-driven osteoclastogenesis, and iii) influencing the traffic of trans-acting factors from the cytoplasm to the nucleus.

Transgene Expression of CYP27B1 in Osteoblasts Promotes Bone Formation without Altering Bone Resorption. Andrew Turner^{*1}, Paul Anderson², Rebecca Sawyer¹, Peter O'Loughlin¹, Gerald Atkins³, Howard Morris⁴. ¹Musculoskeletal Biology Research, Chemical Pathology, SA Pathology, Australia, ²Musculoskeletal Biology Research, University of South Australia, Australia, ³University of Adelaide, Australia, ⁴SA Pathology, Australia

The endocrine hormone 1,25-dihydroxyvitamin D (1,25D) is best known as a regulator of calcium and phosphate homeostasis, providing the necessary mineral to maintain skeletal health. Less understood are 1,25D's direct actions on bone cells, including its role in bone remodelling. In this context, it is intriguing that bone cells themselves are capable of synthesizing 1,25D by virtue of the activity of the CYP27B1 enzyme⁽¹⁾. We hypothesise that the local production of 1,25D within the osteoblast lineage serves specialized functions within the framework of bone remodelling. Moreover, we have evidence that the mechanisms that regulate Cyp27b1 gene expression in osteoblasts are specific to that lineage, and consider this key for understanding the physiological role of vitamin D activity within osteoblasts. Therefore we have adopted both in vitro and in vivo studies to investigate the regulation, as well as function, of Cyp27b1 expression within osteoblasts. We created a transgenic mouse model in which transcription of the human Cyp27b1 sequence is driven by the 3.6kb human osteocalcin promoter (OSCyp27b1) limiting the transgene expression to mature osteoblast lineage cells. In adult (20 wk) mice, BV/TV in the lumbar vertebra is 10.8% greater in OSCyp27b1 males versus wild-type littermates ($p < 0.05$, $n = 12$), and 10.1% greater in females ($p = 0.08$, $n = 15$), with similar increases in bone also observed in OSCyp27b1 femoral metaphyses. Histological analyses reveal no difference in TRAP+ osteoclast surface measures. In adult female OSCyp27b1 mice, the higher femoral BV/TV was correlated with bone formation rate ($R^2 = 0.67$, $p = 0.01$). To further pursue the effect of the OSCyp27b1 transgene on osteoblast function we have isolated osteoblasts from neonatal OSCyp27b1 calvaria. Differentiated cultures produced a mineralised extracellular matrix and expressed high levels of the human Cyp27b1 transgene, as well as osteocyte related genes such as DMP1 and SOST, suggesting that the transgene may have effects in osteocytes as well as osteoblasts. Transiently transfected deletion constructs of the CYP27B1 promoter-luciferase reporter in the osteocyte-like MLO-Y4 cells reveal an expression profile similar to that of osteoblasts⁽²⁾. Taken together, our data suggest that vitamin D metabolism within the osteoblast lineage is anabolic and is uniquely regulated.

Parathyroid Hormone-related Protein (PTHrP) Potentiates Myeloid-Derived Suppressor Cells (MDSCs) within the Bone Marrow via Osteoblast-Derived Interleukin (IL)-6 and Vascular Endothelial Growth Factor (VEGF)-A. Serk In Park^{*1}, Amy Koh², Fabiana Soki³, Laurie McCauley³. ¹Vanderbilt University, USA, ²University of Michigan, USA, ³University of Michigan School of dentistry, USA

Bone is an essential partner for tumor progression, supplying a variety of cells critical for tumor establishment. Among bone marrow (BM)-derived cells, MDSCs, expressing CD11b and Gr1 surface markers, suppress the host immune response and infiltrate tumor tissue to promote tumor growth and angiogenesis. Much of this understanding comes from primary tumor interactions whereas regulation of MDSCs in the BM of tumor hosts remains unclear. Prostate cancer cell lines with altered levels of PTHrP were used to show that subcutaneous prostate cancer-derived PTHrP correlates with MDSC recruitment in tumor tissues and also with tumor microvessel density. MDSCs derived from the BM of mice harboring subcutaneous tumors highly expressing PTHrP and co-implanted with prostate cancer resulted in greater tumor growth and angiogenesis than MDSCs from low PTHrP tumors, suggesting PTHrP contributes to pre-metastatic microenvironment in the BM. The angiogenic effect was associated with MDSC-derived matrix metalloproteinase (MMP)-9. However, as MDSCs do not express receptors for PTHrP, subsequent studies elucidated the mechanism of MDSC activation. Osteoblasts were examined for their role in PTHrP-dependent MDSC activation. Conditioned media from saline- or PTHrP-treated primary calvarial osteoblasts were collected and added to CD11b⁺Gr1⁺ BM cells *ex vivo*, followed by quantitative PCR for *Mmp9* (a marker for MDSC activation). Additionally, mice were treated with recombinant PTHrP (1-34) 12 hours prior to flow cytometric analyses and sorting of CD11b⁺Gr1⁺ BM cells. PTHrP significantly increased *Mmp9* expression and activating phosphorylation of Src family kinases (SFKs) in MDSCs. Furthermore, CD11b⁺Gr1⁺ BM cells were isolated and treated with osteoblastic cytokines including receptor activator of nuclear factor κ B ligand (RANKL), IL-6, VEGF-A, and C-C chemokine ligand (CCL)-2. Interestingly, VEGF-A and IL-6 increased *Mmp9* expression, which was reversed by PP2, a pharmacological inhibitor of SFKs. There was no alteration in gene expression for other markers of MDSC activation including integrin β 1, CCL2, CXCR-2, or CXCR-4. In summary, tumor-derived PTHrP circulates and stimulates osteoblasts to release IL-6 and VEGF-A, contributing to activating phosphorylation of SFKs in MDSCs and subsequent expression of MMP-9. These data suggest that tumors positively regulate the bone marrow microenvironment via PTHrP expression to promote tumor angiogenesis and immune suppression.

Thrombospondin-1 Regulates Bone Density in Healthy and Skeletal Metastatic States by Regulating Osteoclast-osteoblast Coupling. Sarah Amend^{*1}, Ozge Uluckan², Michelle Hurchla¹, Li Jia¹, William Frazier², Katherine Weilbaecher³. ¹Washington University in St. Louis, USA, ²Washington University in Saint Louis, USA, ³Washington University in St. Louis School of Medicine, USA

Thrombospondin-1 (TSP1) is a secreted ligand for 10 receptors including CD47. Under healthy remodeling, osteoclasts (OCs) and osteoblasts (OBs) are tightly regulated. In skeletal metastasis, however, tumor cells secrete factors that promote OC and OB activity, resulting in the release of growth factors that stimulate local tumor growth, leading to a vicious cycle of aberrant bone cell activation and tumor cell proliferation. We demonstrate that TSP1/CD47 ligation is essential for healthy OC/OB coupling and contributes to the vicious cycle of bone metastasis.

TSP1^{-/-} mice have 25% higher bone volume than wild type (WT) at 6 months. TSP1^{-/-} mice also show decreased serum CTX, indicative of decreased OC activity. TSP1^{-/-} OC formation and function are disrupted in culture, and OC formation is increased upon addition of CD47-binding peptide. Nitric oxide (NO) exerts a biphasic effect, with toxic effects at high and low concentrations. CD47^{-/-} mice have defective OCs rescued by inhibition of NO synthase (NOS). TSP1 antagonism in OC cultures causes 30-fold increased expression of iNOS. Pharmacological inhibition of NOS restores WT levels of serum CTX in TSP1^{-/-} mice.

TSP1^{-/-} mice also exhibit OB dysfunction. TSP1 is a component of the mineralized bone matrix. We show that OCs do not resorb TSP1^{-/-} bone normally compared to WT bone. Failure of OCs to resorb TSP1^{-/-} OB secreted matrix leads to an imbalance in remodeling, with normal OB-recruitment of OCs, but failure of the OCs to resorb the bone, leading to the TSP1^{-/-} osteopetrotic phenotype. TSP1 signaling in OC and OB coupling also plays a critical role in bone metastasis.

Contrary to their typical anti-tumor roles, TSP1 and CD47 are induced in bone metastatic cell line C42b compared to the parental non-metastatic LnCaP. We employed tumor models to uncover a paradoxical role for TSP1 in cancer progression in primary versus metastatic disease. Tumor-derived TSP1 promotes OC activity and bone cell derived TSP1 promotes tumor cell proliferation. These data indicate a role for both tumor- and host-derived TSP1 in bone metastatic tumor progression and osteolysis. These findings are especially important in light of research to develop TSP1 mimetics to treat cancer. Our data indicate that these mimetics may have detrimental effects on metastatic disease.

We show that TSP1 is a critical coupling factor, both to promote homeostatic OC/OB remodeling and to promote tumor growth and osteolysis in skeletal metastasis.

Inverse Biological Coupling Between the Bone-specific Transcription Factor RUNX2 and the Tumor Suppressor p53 Levels in Osteosarcoma. Hanna Taipaleenmaki*, Margaretha van der Deen, Ying Zhang, Jane Lian, Janet L. Stein, Gary Stein, Andre Van Wijnen. University of Massachusetts Medical School, USA

Osteosarcoma (OS) is the most common malignant bone tumor. RUNX2, a key regulator of osteoblast differentiation and suppressor of cell growth, is aberrantly expressed in OS. The latter suggests a context dependent function of RUNX2 as tumor suppressor or oncoprotein. We examined pathological roles of RUNX2 in OS and the mechanisms by which RUNX2 expression is deregulated to account for its tumor-related elevation. RUNX2 is expressed in OS tissue micro-arrays and positively correlates with increased staining of the proliferation marker Ki67, suggesting that RUNX2 may support osteosarcoma cell growth. Indeed, knockdown of RUNX2 inhibits cell growth in U2OS osteosarcoma cells. The frequency of RUNX2 elevation in OS (~50%) is comparable to the predisposing inactivation of tumor suppressor p53 in ~50-70% of osteosarcomas. Consistently, RUNX2 levels are elevated in the absence of p53 in distinct OS cell lines and diverse proliferating mesenchymal cells. Conversely, stabilization of p53 with the MDM2 inhibitor Nutlin-3 increases p53 protein expression, but drastically decreases RUNX2 protein levels. Thus, RUNX2 expression is inversely linked to loss of p53. The strong reduction of RUNX2 protein expression can only partially be explained by transcriptional control as indicated by the absence of p53 binding sites in the RUNX2 promoter, a less than 30% decline in RUNX2 gene promoter activity and a modest two-fold decrease in Runx2 mRNA levels after Nutlin-3 exposure. Therefore, we examined microRNA (miRNA) dependent post-transcriptional mechanisms. We monitored expression of validated miRNAs that directly target RUNX2 in human OS cells and mesenchymal progenitor cells. Elevated RUNX2 protein expression is directly linked to diminished expression of several RUNX2 targeting miRNAs, including the p53 dependent miR-34c which is the most strongly down-regulated RUNX2 targeting miRNA in OS. Ectopic expression of miR-34c markedly decreases RUNX2 protein levels, and 3'UTR reporter assays established RUNX2 as a direct target of miR-34c in OS cells. Importantly, stabilization of p53 with Nutlin-3 increases miR-34c expression while decreasing RUNX2 protein levels. We propose a novel RUNX2-p53-miRNA regulatory network that controls proliferation of osseous cells and is compromised in osteosarcoma.

Osteoclast Activation by IAP Antagonists Opposes their Potential Anti-cancer Effects and Enhances Bone Metastasis. Chang Yang*¹, Jennifer Davis², Lynne Collins³, Suwanna Vangveravong³, Robert Mach³, David Piwnicka-Worms³, Katherine Weilbaecher⁴, Roberta Faccio¹, Deborah Novack⁴. ¹Washington University in St Louis School of Medicine, USA, ²Washington University in St. Louis, USA, ³Washington University in St Louis, USA, ⁴Washington University in St. Louis School of Medicine, USA

IAP (inhibitor of apoptosis) proteins play a central role in many types of cancer, and IAP antagonists are in development as anti-cancer agents. Since IAP antagonists cause apoptosis in myeloid cells as well as tumor cells, we hypothesized that these agents might also kill osteoclasts, making the bone microenvironment less favorable for metastasis. In order to focus on the effect of these drugs on bone, we used the 4T1 mouse breast cancer line, resistant to IAP antagonist BV6 *in vitro*. BALB/c mice were treated with BV6 or vehicle weekly for 4 weeks, and 4T1 cells were injected into the tibia (IT) or left ventricle (LV) between the 3rd and 4th doses. A control set of mice received tumor cells subcutaneously (SQ). Remarkably, BV6 increased tumor growth in bone by 5.5-fold (IT) and 3.2-fold (LV) on day 10 after tumor inoculation. In contrast, there was no significant difference in the growth of SQ implanted tumor cells or in visceral tumor growth following LV injection, indicating that tumor-enhancing effects of BV6 are specific to bone. To further elucidate the effects of BV6 on bone, we treated tumor-naïve mice with BV6 for 4 weeks, and found that bone mass was decreased by 35%. Indices of both osteoclast and osteoblast activity were significantly increased, indicating high turnover osteoporosis. To determine whether osteoclasts were responsible for increased bone metastasis, we gave zoledronic acid (ZA) and BV6 prior to LV injection of 4T1 cells. In BV6-treated mice, ZA increased bone mass and decreased tumor burden in bone to the levels in mice receiving only vehicle. To expand our study to BV6-sensitive tumor cells, we inoculated human breast cancer MDA-231 cells into nude mice. BV6 strongly inhibited growth of SQ inoculated tumor cells, whereas MDA-231 cells were still able to grow in bone, indicating a site-specific reduction in anti-tumor efficacy. Other IAP antagonists, 52S and ML183, also enhanced osteoclastogenesis *in vitro* in both murine and human cells, suggesting universal osteoclast-activating effects among IAP antagonists. Mechanistically, all 3 IAP antagonists tested activate alternative NF- κ B through NIK, and NIK-deficient mice were completely resistant to BV6-induced bone loss. Thus, IAP antagonists induce high turnover osteoporosis via the osteoclast, making the bone

microenvironment favorable for metastasis. Anti-resorptive agents will likely prevent osteoclast activation and preserve the anti-tumor efficacy of IAP antagonists.

Parathyroid Hormone-related Peptide (PTHrP) blockade Inhibits Tumor Progression in a Model of Human Melanoma. Dao Chao Huang*¹, Xian Fang Yang², Anne Camirand¹, Richard Kremer¹. ¹McGill University, Royal Victoria Hospital, Canada, ²McGill University Health Center, Canada

Parathyroid hormone-related peptide (PTHrP) is crucial to breast tumor invasion and metastasis but its role in melanoma is still obscure. We studied *in vitro* and *in vivo* effects of PTHrP in human A375 amelanotic melanoma cells by inactivating both alleles of the human *Pthrp* gene by homologous recombination, creating knock-out (KO) and wild-type (WT) A375 cells which were examined for growth, invasion and motility changes. Green fluorescent protein (GFP)-transduced KO A375 and WT A375 cells were implanted into the left cardiac ventricle (LCV) of nude mice and metastases investigated by GF imaging. A monoclonal antibody (mAb) against the N-terminus of PTHrP was used to treat mice injected (LCV) with WT A375 cells. Tumor cells were also injected s.c. and tumor growth compared between mice treated with the mAb or vehicle s.c. 3 times/wk (up to 4 wks). Compared to WT controls, homozygous KO clones (PTHrP-null), had a less transformed and less invasive phenotype, with decreased growth rate and motility, decreased anchorage-independent growth, rounder morphology and significant inhibition of Matrigel invasion. Matrix metalloproteinase-9, actin polymerization, and focal adhesion kinase expression and phosphorylation were significantly reduced in PTHrP-null cells. The more transformed and invasive phenotype was partially restored by addition of conditioned medium from WT cells. In mice sacrificed at timed intervals, disseminated GFP-expressing tumor cells were observed in liver and lungs. Osteolytic bone metastases were detected by high sensitivity X-ray analysis, and whole body scanning with GFP detection. Bone staining and osteoclast-specific TRAP staining showed that *Pthrp* blockade strongly decreased osteoclast numbers. Dissemination of GFP-labeled tumor cells was greatly reduced in mice injected with KO A375 vs controls. Total number of metastases and % of animals with metastases in each organ analyzed were markedly reduced in nude mice with KO A375 compared to WT A375 cells. Kaplan-Meier analysis showed significant survival benefit in nude mice injected with KO A375 or WT A375 cells and treated with the anti-PTHrP mAb, compared to animals injected with WT A375 cells alone or with vehicle. Overall, we provide direct evidence that PTHrP plays a major role in human melanoma tumor invasion and metastasis, and that agents aimed at suppressing PTHrP may impair melanoma progression.

The Cancer Stem Cell Marker CD44 Promotes Bone Metastasis of Breast Cancer by Enhancing Tumorigenicity, Cell Motility, and Matrix Production. Toru Hiraga*¹, Susumu Ito², Hiroaki Nakamura¹. ¹Matsumoto Dental University, Japan, ²Shinshu University, Japan

CD44, an adhesion molecule that binds to extracellular matrix, primarily to hyaluronan (HA), has been implicated in cancer cell migration, invasion, and metastasis. CD44 has also recently been recognized as a marker for stem cells of several types of cancer, including breast cancer. We found that CD44 is highly expressed in a number of cancer cell lines of different origin that preferentially metastasize to bone in a mouse model. However, the roles of CD44 in the development of bone metastasis still remain unclear. To explore this, we established the MDA-MB-231 human breast cancer cells stably expressing short hairpin RNA against CD44 (MDA/shCD44). Although there was no change in cell proliferation in monolayer culture, tumorsphere formation in suspension culture was reduced in MDA/shCD44 compared with the control cells (MDA/shLuc). Cell motility and invasion of MDA/shCD44 determined by wound healing assay and matrigel invasion assay were also significantly suppressed. Furthermore, tumorigenicity in the orthotopic site and the development of bone metastasis following intracardiac cell inoculation in nude mice were markedly decreased in MDA/shCD44. Microarray analysis revealed that the expression of HA synthase 2 (HAS2) was down-regulated by CD44 knockdown, which was confirmed by real-time RT-PCR analysis. HASs are the enzymes responsible for HA synthesis and HAS2 is the most abundantly expressed isoform in MDA-MB-231 cells. Immunohistochemical examination showed that, in the bone metastases of MDA/shLuc, HA was more densely localized in the lesions compared with surrounding bone marrow tissues and was frequently co-localized with CD44 expressed by cancer cells. In contrast, HA was sparsely distributed in the metastases of MDA/shCD44. To further study the role of HA in bone metastasis, the effects of 4-methylumbelliferone (4-MU), an inhibitor of HA synthesis, were then examined. 4-MU decreased mRNA expression of CD44 and HAS2 in MDA-MB-231 cells *in vitro* and suppressed osteoclast-like cell formation in bone marrow cultures in a dose-dependent manner. Moreover, 4-MU significantly inhibited bone metastases of MDA-MB-231 cells with reduced number of osteoclasts. These results suggest that CD44 expression in cancer cells contributes to promote bone metastasis by enhancing tumorigenicity, cell motility and invasion, and HA production. Our results also suggest the possible involvement of CD44-expressing cancer stem cells in the development of bone metastasis.

SA0003**Dietary Restriction Improves Age-related Decline of Trace Minerals in Bone.**

Keiji Kobayashi^{*1}, Hidetoshi Nojiri², Tashihiko Toda¹, Yoshitomo Saita², Daichi Morikawa¹, Masato Koike¹, Yusuke Kozai³, Isamu Kashima³, Kazuya Yoshida⁴, Mitsuru Segawa⁴, Kazuo Kaneko², Takahiko Shimizu¹.

¹Department of Advanced Aging Medicine, Chiba University Graduate School of Medicine, Japan, ²Department of Orthopaedics, Juntendo University School of Medicine, Japan, ³Division of Radiology, Department of Maxillofacial Diagnostic Science, Kanagawa Dental College, Japan, ⁴Research Laboratory, La Belle Vie Incorporated, Japan

Dietary restriction (DR) extends the lifespan of animals, but beneficial or deleterious effects of DR on bone tissue have not been fully elucidated. In this study, we investigated the bone phenotypes such as bone mass, strength and trace mineral contents in aged and DR rats.

F344 male rats were used at 4 months (young), 12 months (middle) and 25 months (aged) of age. DR male rats were restricted food by 60% until 25 months of age. We analyzed bone density and structure of femur using pQCT and 3D micro-CT, respectively. Bone strength was measured by three-point bending test. Trace mineral content in bone tissue was measured by inductively coupled plasma mass spectrometry (ICP-MS). Serum oxidative stress marker, d-ROM, was measured using a FRAS4 system in the blood

DR rats extended the mean lifespan by 124.8% and reduced body weight by 61% compared with those of *ad libitum* rats. DR treatment also normalized serum d-ROM values in aged rats, indicating that DR treatment showed anti-aging effects on aged rats. pQCT analysis revealed that DR rats showed age-related changes of cortical and trabecular bone densities as like aged rats. Micro-CT analysis also indicated that DR treatment did not normalized age-related bone atrophy of femur. In bone strength test, we did not observe the improvement of elastic modulus and maximum bending stress in aged bone by DR. These results indicated that DR did not show beneficial or deleterious effects in age-related changes of bone mass and strength. Next, we measured mineral contents in bone tissues by ICP-MS. We found that most of bone minerals were significantly decreased in an age-dependent manner. Interestingly, DR treatment significantly increased trace mineral contents, including (zinc, selenium, barium, nickel, cobalt, chromium, lead, vanadium). These results suggested that sustained trace minerals in aged bone by DR might regulate bone quality in aging.

The Effects of Simulated Microgravity on Articular Cartilage. Liliana Mellor^{*1}, Julia Oxford¹, Warren Knudson². ¹Boise State University, USA, ²East Carolina University, USA

It has been shown that astronauts experience bone density loss after space flight resembling osteoporotic conditions due to prolonged exposure to microgravity. Although bone density loss in space is a growing field of interest in space related biomedical research, little is known about the effects of microgravity on the adjacent articular cartilage. Articular cartilage is constantly exposed to mechanical forces produced by daily activities. Similar to bone, cartilage is a type of connective tissue that requires a balance between synthesis and degradation of extracellular matrix components to maintain tissue homeostasis; changes in this balance leads to cartilage degradation. Unlike bone tissue, cartilage lacks innervation, blood supply and cell-cell contact, and has a very limited regeneration capacity. Proper communication between individual chondrocytes and the extracellular matrix is crucial to maintain cartilage

homeostasis, and disruption in cell-matrix interactions can trigger cartilage degradation. Our hypothesis is that cartilage homeostasis can be disrupted by lack of gravity during space missions, resulting in early stages of arthritis. Our proposed research addresses the molecular mechanisms involved in articular cartilage loss after exposure to microgravity, which can result in impaired mobility and painful joints. We use two chondrocyte cell lines widely used in arthritis cell research, and expose them to a modeled simulated microgravity environment using a rotating wall vessel (RWV) bioreactor. Preliminary data of chondrocytes exposed to modeled microgravity for 7 days show changes in the actin cytoskeleton morphology when compared to control cells cultured under normal gravitational forces. In addition, up-regulation of IL-8, a biomarker found in sera samples of dogs with induced and natural arthritis, was also up-regulated in cells exposed to simulated microgravity. Additional genes as well as protein expression of receptors associated with extracellular matrix interactions such as CD44 will be evaluated. A better understanding of the molecular signaling pathways involved in cartilage degradation, will not only help prevent astronauts developing osteoarthritis from exposure to microgravity, but will also help us prevent further degradation in patients experiencing early stages of arthritis on Earth.

Bone Loss, not Cartilage Loss, Is Linked to Reduced Muscle Function. Shu Sun^{*1}, Anders Fabricius Nedergaard², Morten Karsdal¹, Kim Henriksen¹.

¹Nordic Bioscience A/S, Denmark, ²Nordic Bioscience, Herlev Hovedgade 207, Denmark

Introduction: Muscle loss is an important clinical problem usually manifesting as a comorbidity to metabolic or inflammatory disease or simply as a consequence of age and inadequate muscle stimulation. In both cases it leads to loss of functional capacity and operational independence and is a strong predictor of mortality and morbidity. Loss of muscle mass is associated with parallel losses of other connective tissues, e.g. bone, tendon and cartilage.

The aim of the present study was to characterize changes in different connective tissue compartments in an animal model using Botulinum toxin (botox)-induced hindlimb immobilization, and serological biomarkers.

Method: Botox was injected into the right hind limb of the Wistar rats in the Botox group. Serum were collected at the baseline and every week after the injection until the end of the study in week 4. Bone turnover biomarkers: Alkaline phosphatases (ALP), Tartrate-resistant acid phosphatase (TRACP), and C-terminal cross-linking telopeptide of collagen type I (CTX-I) were measured. In addition, C2M (MMP-cleaved Collagen II fragment, marker of cartilage degradation), C3M (MMP-cleaved Collagen III fragment, marker of tissue ECM degradation), C6M (MMP-cleaved Collagen VI fragment, marker of muscle degradation), PIIINP (Collagen III N-terminal propeptide, marker of ECM synthesis) and PVINP (Collagen VI N-terminal propeptide, marker of muscle synthesis) were measured.

Results: Botox injection resulted in increases in C6M at week 1 and 2 (p=0.05), after which it leveled off. No changes in PVINP were observed. Furthermore, CTX-I and TRACP were elevated at week 2 (p=0.03), but ALP showed a trend towards a reduction in the botox group. These effects appeared to be slightly delayed compared to the changes in muscle degradation. No changes in cartilage degradation, or connective tissue turnover C3M and P3NP no significant changes were observed.

Conclusions: In this study we showed that increasing muscle loss results in rapidly increased bone loss, through induction of bone resorption and a reduction in bone formation; however, within the short time frame no changes in cartilage degradation was observed. These data underscore that in the Botox immobilization model, the loss of muscle and bone tissue and function are quantitatively and temporally related.

Characterising Sex- and Age-related Differences in Musculoskeletal Phenotype in Sub-Saharan Africa. Kate Ward^{*1}, Yankuba Sawo², Landing Jarjou², Ann Prentice¹. ¹MRC Human Nutrition Research, United Kingdom, ²MRC Keneba, Gambia

Low calcium intake, low BMD and high PTH are characteristic in The Gambia yet documented fragility fractures in older people are low. We reported similar or increased bone loss in Gambian compared to UK females. This cross-sectional study aimed to characterise sex differences and associations between age and bone mass and geometry, muscle area and density, using peripheral QCT.

Males (M) and females (F) aged ≥ 40 years residing in rural areas of The Gambia were recruited stratified by 5 year age-band. Outcome measures were: 4% tibia(T4)-total(tot) and trabecular(trab) BMD, total area(totA); 38% tibia(T38)-bone mineral content (BMC), cortical(cort) BMD, totA, medullary area(medA), stress-strain index(SSI); 66% tibia (T66)- muscle area(muA), muscle density(muD). The occurrence of peripheral vascular calcification (PVcal) was documented. Independent samples t-tests tested sex differences in anthropometry, ² tested differences in PVcal between M/F and age group. Univariate regression tested the relationship between age and bone/

muscle in M and F. ANCOVA tested sex differences after adjustment for age, height and weight. Sex effects are presented as % mean difference [95% CI].

Two-hundred and fifty-five individuals (120M) were recruited, mean(SD) (p<0.05 for all) age M 61.1(13.2)yrs, F 59.4(12.1)yrs, height M 1.7(0.1)m, F 1.6 (0.1)m; weight M 60.9(10.2)kg, F 56.3(10.5)kg; BMI M 21.0(3.0)kg/m², F 22.2(3.5) kg/m². Pvc occurred in 18% of scans; M/F² 0.2 NS; age gp² 173.5 p<0.001.

Age was negatively associated (R² 9-46%, p<0.001-0.06) with: T4 totBMD, trabBMD; T38 BMC,SSI; T66 muA and muD in M and F. MedA was positively, and cortBMD negatively, associated with age at T38 in F. Tota was negatively associated with age in M at T38.

M had higher tot(18%[13,22]) and trab(13%[7,20]) BMD than F at T4. At T38 M had larger bones (13%[10,16]) with higher BMC (30%[24,35]), BMD (3%[2,4]) and SSI (26%[21,30]); medA was not significantly different to F (-5%[-1,0]). At T66 muA (25%[11,19]), muD (3%[2,4]) were greater.

These data provide evidence for age-related differences in bone and muscle strength in M and F. Higher strength in M is through smaller medA and higher cortBMD, indicating thicker cortices and greater mass. Higher incidence of Pvc compared to other populations may reflect altered calcium/phosphate metabolism in The Gambia. Further exploration of musculoskeletal phenotype and the contribution of lifestyle are required.

Disclosures: Kate Ward, None.

Early Frailty in Postmenopausal Women with Human Immunodeficiency Virus (HIV) Infection. Polly Young¹, Elizabeth Shane², Chiyuan Zhang¹, David Ferris³, Matthew Scherer⁴, Binsheng Zhao⁵, Ivelisse Colon⁶, Donald McMahon², Thuy-Tien Dam⁵, Michael Yin¹. ¹Columbia University, USA, ²Columbia University College of Physicians & Surgeons, USA, ³St Lukes-Roosevelt Hospital, USA, ⁴Columbia University, USA, ⁵Columbia University, USA, ⁶Columbia University Medical Center, USA

Aging often manifests as frailty, a syndrome predictive of falls and fractures. Studies suggest frailty occurs at a younger age in HIV+ men, but data from postmenopausal women with HIV, a group at high risk for osteoporosis and fracture, are lacking. To assess frailty prevalence, we measured frailty phenotype in a subset of 36 HIV+ and 28 HIV- postmenopausal women in a cohort study of bone metabolism. Subjects meeting 3+ criteria were classified as frail: weakness by grip strength, slow walk speed, low physical activity, unintentional weight loss, self-reported exhaustion. Appendicular lean mass was measured by dual xray absorptiometry. HIV+ women were younger (56+1 vs 59+1, p=0.03) and tended to weigh less (71+3 vs 79+3kg, p=0.08) than HIV- women, but had similar ethnicity (60% Hispanic, 40% African-American). Unadjusted results for frailty components are presented (Table). After adjustment for age and BMI, grip strength was lower in HIV+ women (p=0.015). Appendicular lean mass was similar in HIV+ and HIV- (19.4+1 vs 19.8+1kg, p=0.71). In conclusion, despite younger age, prevalence of frailty tended to be higher among HIV+ postmenopausal women than HIV- controls. Adjusted grip strength was lower in HIV+ than HIV- women despite similar appendicular mass. More challenging strength and performance measures may be necessary to detect differences in HIV+ and HIV- women. As HIV+ women age, deficits in strength may translate into frailty, falls and fractures.

| Frailty Measures | HIV+ (N=36) | HIV- (N=28) | Unadjusted p-value |
|-------------------------------|--------------|--------------|--------------------|
| Grip Strength (kg) | 22.3 +/- 3.1 | 25.2 +/- 3.5 | 0.12 |
| Walk Speed (seconds) | 5.9 +/- 0.4 | 5.9 +/- 0.8 | 0.80 |
| Physical Activity (kcal/week) | 2549 +/- 381 | 3831 +/- 501 | 0.04 |
| Weight Loss | 18% | 4% | 0.03 |
| Exhaustion | 8 (22%) | 2 (7%) | 0.03 |
| Pre-Frail (1-2 criteria) | 17 (47%) | 14 (50%) | 0.12 |
| Frail (3+ criteria) | 4 (11%) | 0 (0%) | 0.12 |

Effects of 3 Monthly Vitamin D Supplementation Strategies among Fallers age 70 Years and Older: a Double-blind Randomized Controlled Trial. Heike Bischoff-Ferrari¹, Bess Dawson-Hughes², John E Orav³, Walter Willett⁴, Hannes Staehelin⁵, Eduard Sidelnikov⁶, Daniel Grob⁷, Robert Theiler⁸, Andreas Egli Linder⁹. ¹University of Zurich, Switzerland, ²Tufts University, USA, ³Dept. of Biostatistics, Harvard School of Public Health, USA, ⁴Dept. of Nutrition, Harvard School of Public Health, USA, ⁵Dept. of Geriatrics, University of Basel, Switzerland, ⁶University of Zurich, Switzerland, ⁷Dept. of Geriatrics, City Hospital Waid, Switzerland, ⁸Stadtspital Triemli, Switzerland, ⁹Centre on Ageing & Mobility, Switzerland

Methods: We randomized 200 seniors who had a fall in the year prior to enrollment to 3 groups with monthly oral vitamin D supplementation: (1) 24'000 IU D3 = control, (2) 60'000 IU D3, (3) 24'000 IU D3 plus 300 µg 25(OH)D (NCT01017354). Clinical visits were at baseline, 6 and 12 months, with additional monthly phone interviews to assess incident falls. The primary endpoint was the probability of reaching the 25(OH)D threshold of 30 ng/ml and the prevention of functional decline measured by the short physical performance test battery. The secondary endpoint was the risk of falling.

Results: Baseline 25(OH)D serum concentrations in 200 senior fallers (mean age = 78; 67% women) did not differ by group: mean was 18.5 ng/ml. The adjusted (age, gender, BMI, visit, baseline level) increment in 25(OH)D increase and probability of reaching the 25(OH)D threshold of 30 ng/ml in groups 1 to 3 were: (1) 10.0 ng/ml / 28%, (2) 15.3 ng/ml / 68%, (3) 25.4 ng/ml / 89% at 6 months, and (1) 9.9 ng/ml / 39%, (2) 18.3 ng/ml / 81%, (3) 25.5 ng/ml / 89% at 12 month, with significant differences between groups (2) and (3) and compared to group (1). The adjusted probability of maintained or improved function at 6 and 12 months did not differ between groups and was about 80%. In the 12 month of treatment 121 participants fell (60.5%) and reported 275 falls (141 in the first and 134 in the second 6 months of observation). The rate of falls differed by treatment group, with groups (2) and (3) having a greater risk of falling compared to group (1). In the multivariate Poisson regression model group (2) had a 58% (95% CI: 14 to 102%), and group (3) had a 45% increased rate of falls (95% CI: -2 to +92%) compared to group 1. The same pattern occurred if we analyzed fallers. Based on a Lowess plot, both low and very high achieved 25(OH)D levels at 12 month were associated with an increased risk of falling, the nadir being reached at about 30 ng/ml.

Conclusion: Our trial provides evidence that higher doses of vitamin D3 or a combination with 25(OH)D supplementation are needed to shift senior fallers to a threshold of 30 ng/ml 25(OH)D. Notably, the probability of maintained or improved function was similar for 24'000 IU vitamin D3 per month (800 IU / day) compared to the two higher dose groups. Further, fall risk may be increased with higher dose vitamin D, which in our analysis could not be explained by a toxic effect on any of the muscle / function endpoints.

Comparison of Bone Metabolism among RA Population on Chronic DMARD Therapy and Those on anti TNF Blocker, Treatment Naive RA Patients and Normal Population. Mie Jin Lim¹, Won Park¹, Seong Ryoul Kwon², Kyung Hee Jung², Kwoon Joo², Min Jung Son². ¹Inha University Hospital, South Korea, ²Inha University Hospital, South Korea

Introduction: Bone metabolism is disturbed in rheumatoid arthritis (RA) patients. Effects of oral disease modifying antirheumatic drug (DMARD) and anti tumor necrosis factor (TNF) blockers on bone metabolism are still unknown.

Objective: We sought to compare the bone metabolism among RA population on chronic DMARD, anti TNF treatment, age and sex matched naive RA patients and normal control.

Method: Thirty-three seropositive RA patients (5 male, 28 female) were enrolled. More than 90% of patients had been receiving methotrexate with or without other DMARD for more than 6 months. Etanercept was administered, twice a week. Venous blood was drawn at baseline on DMARD therapy and 12-16 weeks after etanercept use, respectively. Treatment naive RA patients who did not receive any DMARD treatment prior to the study were recruited along with normal control. Bone

metabolism was assessed using bone specific alkaline phosphatase (BSAP) and sclerostin for bone formation and c-telopeptide (CTX) for bone resorption.

Statistical differences between two groups were examined by independent samples T test. As RA on DMARD group and RA on TNF blocker group came from same population at different time point, their difference was assessed using paired samples T test. A p value of equal and less than 0.05 was denoted statistically significant.

Results: RA on DMARD group showed significantly lower level of BSAP compared to naïve RA population (p=0.044). Both BSAP and sclerostin increased after etanercept treatment, but was slightly significant only for sclerostin (p = 0.055). Serum CTX level was markedly lower in DMARD group than naïve RA population (p=0.008). It also increased after etanercept treatment which was significant (p = 0.026). Naïve RA population showed highest CTX level among all four groups.

Conclusion: In general, bone metabolism markers in RA on DMARD group showed lower serum level compared to naïve RA population which tended to increase after etanercept treatment. The normal control showed highest level of sclerostin and BSAP among all groups and those trends suggest bone metabolism might be depressed in RA patients. The bone metabolism was even more depressed after DMARD treatment and it recovered by anti TNF treatment.

Early Increased Subchondral Bone Wnt/ β -catenin Signaling in a Murine Destabilization Osteoarthritis Model Followed by Accompanying Increased Signaling in Articular Cartilage. Danese Joiner¹, Kennen Less², Bart Williams¹. ¹Van Andel Research Institute, USA, ²Van Andel Research Institute, USA

Wnt/ β -catenin signaling is a key regulator of bone and cartilage development and homeostasis, and the degree of signaling may represent a pathological mechanism for osteoarthritis (OA) development (Zhu, M. *et al.* Arthritis Rheum. 2008; Zhu, M. *et al.* JBMR 2009). During OA progression, reduced articular cartilage and subchondral bone integrity occurs and is likely influenced by adaptive responses to altered mechanical loading (Thambyah, A. *et al.* Osteoarthr. Cartilage 2007). We hypothesized that temporal and spatial differences in Wnt/ β -catenin signaling are involved and examined articular cartilage and subchondral bone during arthritis progression post injury in mice. Ligament and meniscus transections were performed on the right knee (RK) of 8-week old WT mice (n=24). The left knees (LK) served as an untouched control. After 28 and 60 days, animals were euthanized, dissected knees micro CT scanned (Skyscan, Germany) and reconstructed onto 10 micron voxels. Knees were fixed, decalcified, paraffin embedded and sagittal sectioned at 5 um for pentachrome staining and β -catenin IHC. Knee samples were aseptically harvested from animals, homogenized, and RNA extracted with an RNeasy Mini Kit (Qiagen, Valencia, CA). Relative mRNA transcript levels of Wnt receptors and target genes were measured by RT-PCR and t-test statistics applied. Pentachrome stains showed reduced articular cartilage proteoglycan content in surgery knees at both time points (blue) and structural disorganization (Fig. 1A). Osteophytes and nuclear β -catenin (brown) in the articular cartilage and subchondral bone were present in transected knees at day 60 (Figs. 1B, 1C, 1D). Cytoplasmic β -catenin was present in subchondral bone 28 days post surgery and nuclear β -catenin, however to a lesser extent than day 60 (Figure 1D). Fold increases in Wnt receptors and target genes expressed for the RK relative to the LK occurred at day 60 and Lrp6 and cyclin D1 values were significant compared to day 28 (Fig. 2). Increased relative c-jun occurred at day 28; however was less than the day 60 value (Fig. 2). Wnt/ β -catenin signaling increased with OA progression post injury in mice and was observed early in subchondral bone and later in both subchondral bone and articular cartilage. Tissue specific therapeutics targeting regional difference in Wnt/ β -catenin signaling during injury induced OA and delivery timing could improve disease treatment.

Inhibition of TGF β signaling in Nestin⁺ Stem Cells Prevents Onset of Osteoarthritis. Gehua Zhen¹, Chunyi Wen², Simon Mears³, Frederic Askin³, Xiaofeng Jia³, Frank Frassica³, Weizhong Chang⁴, Janet Crane⁴, Jie Yao⁵, Tariq Nayfeh³, Carl Johnson³, Dmitri Artemov³, Andrew Cosgarea³, John Carrino³, Mei Wan⁶, William Lu⁷, Xu Cao⁴. ¹The Johns Hopkins Hospital, USA, ²Li Ka Shing Faculty of Medicine, University of Hong Kong, Hong Kong, ³Johns Hopkins University, USA, ⁴Johns Hopkins University, USA, ⁵Hong Kong University, China, ⁶Johns Hopkins University School of Medicine, USA, ⁷The University of Hong Kong, Hong Kong

Osteoarthritis (OA) is a highly prevalent and debilitating joint disorder. There is currently no effective therapy for OA due to limited understanding of its pathogenesis. Using OA anterior cruciate ligament transection (ACLT) animal model, we demonstrate structural and histological changes indicative of uncoupled bone formation. Continuously increased total subchondral bone tissue volume with significantly altered micro-architecture was observed by μ CT scanning in ACLT mice. Histological analysis revealed that phosphorylated pSmad2/3⁺ cell number increased in a similar pattern as TRAP⁺ osteoclasts, indicating activation of TGF β 1 during continuous osteoclastic bone resorption after ACLT. Parallel to osteoid distribution, nestin⁺ stem cells and osterix⁺ osteoprogenitors were clustered in bone marrow 30 days post surgery, suggesting osteoblastic differentiation in bone marrow cavities. This phenomenon was correlated with the occurrence of intense bone marrow lesions on MRI. Significant proteoglycan loss was observed 60 days post ACLT, which is much later than when the subchondral bone micro-architectural changes began. Injection of T β R1 inhibitor (1mg/kg for 1 month) improved subchondral bone

structure and attenuated articular cartilage degeneration. Furthermore, local administration of TGF β 1 antibody in the subchondral bone reduced articular cartilage degeneration in the rat ACLT model.

To further validate the role of nestin⁺ cells in the onset of OA in the microenvironment of high level TGF β , we knocked out TGF β type II receptor (T β RII) specifically in nestin⁺ stem cells by inducible nestin-CreER after ACLT. The microarchitecture of T β RII knockout mice was significantly improved relative to WT mice once nestin⁺ stem cells no longer respond to TGF β post ACLT. Importantly, proteoglycan loss, advances of calcified cartilage zone, MMP13 and type X collagen expression in chondrocytes were prevented in ACLT T β RII knockout mice. Interestingly, the thickness of calcified cartilage zone in sham-operated T β RII knockout mice increased, suggesting a critical role of nestin⁺ stem cells in maintenance of the osteochondral junction at regular concentration of TGF β 1. This study demonstrates that high levels of active TGF β 1 in the subchondral bone contribute to the pathological changes seen at the onset of mechanically-induced OA potentially by affecting nestin⁺ stem cells. Inhibition of TGF β 1 prevented OA progression and may be a target for therapy for early stages of OA.

Levels and Localization of Vitamin K2 in Subchondral Bone in Osteoarthritis Knee Joints. Yoshinori Ishii¹, Hideo Noguchi², Mitsuhiro Takeda³, Junko Sato², Noriaki Yamamoto⁴, Hirovuki Wakabayashi⁵, Junkichi Kanda⁶. ¹Ishii Orthopaedic & Rehabilitation Clinic, Japan, ²Ishii Orthopaedic & Rehabilitation Clinic, Japan, ³Ishii Orthopaedic & Rehabilitation Clinic, Japan, ⁴Niigata rehabilitation hospital, Japan, ⁵Niigata University of Pharmacy & Applied Life Sciences, Japan, ⁶Niigata University of Pharmacy & Applied Life Sciences, Japan

Objectives: The purpose of this study was to evaluate the distribution of vitamin K2 in harvested bones obtained during total knee arthroplasty in knee osteoarthritis (OA) patients. We also analyzed their characteristics of levels of vitamin K2. Our primary hypothesis was that the vitamin K2 localization would differ in subchondral bones showing different stages of OA. We also hypothesized that vitamin K2 might affect the turnover of subchondral bone in OA knees.

Methods: High-performance liquid chromatography was used to measure vitamin K2 in harvested bones obtained during 58 total knee arthroplasty procedures. Vitamin K2 levels were analyzed in the medial (FM) and lateral (FL) femoral condyles and in the medial (TM) and lateral (TL) tibial condyles. The vitamin K2 value is expressed using the median (25th percentile, 75th percentile).

Results: The median vitamin K2 values in the condyles were as follows (expressed as ng per gram of dry bone tissue): FL 87.1 (50.6, 136.4), FM 32.4 (19.8, 62.5), TM 22.7 (15.0, 52.6), and TL 50.1 (32.7, 87.7). There was significantly more vitamin K2 in the lateral femoral and tibial condyles than in the corresponding medial condyles (FL vs. FM, p<0.0001; TL vs. TM, p<0.0001). There was significantly more vitamin K2 in the FL than in the TL (p=0.003), and the FM vitamin K2 levels were higher than those of the TM, although this was not significant (p=0.212). There were no significant differences in vitamin K2 levels in men vs. women nor was there a significant correlation with age.

Conclusions: This study suggested that vitamin K2 might affect bone turnover since medial condyles showing advanced OA had lower vitamin K2 levels, while lateral condyles showing less advanced OA contained more vitamin K2. Gender and age were not correlated with vitamin K2 localization. All cases had Grade IV OA, and this study suggested that OA grade might be important in controlling the vitamin K2 levels in human bones. Animal experiments show that the vitamin K2 (MK-4) level in bone increases in a dose-dependent way, so future prospective studies should determine whether a diet rich in vitamin K or the optimal dose and preferred form vitamin K2 could be part of an effective OA treatment strategy.

Mineral Homeostasis and Body Composition Measures in Adults with Rotator Cuff Arthropathy. Lisa Gao¹, Julie Glowacki², Lawrence Higgins¹, Meryl Leboff². ¹Brigham & Women's Hospital, USA, ²Brigham & Women's Hospital, USA

Rotator cuff arthropathy (RCA) increases with age and is associated with rotator cuff tears, cuff muscle atrophy, radiographic osteopenia, and a "soft" quality of the bone noted at surgery. We recently found increased osteoid in subjects with RCA compared to those with shoulder osteoarthritis (OA), without differences in current 25-hydroxyvitamin D levels (Glowacki J et al. ASBMR 2012). To determine the skeletal factors that may contribute to RCA, we enrolled 18 subjects with RCA and 28 controls with shoulder OA scheduled for arthroplasty for non-inflammatory disorders. All subjects signed an IRB-approved consent form. Subjects were excluded if they took any medications or had medical conditions that affect skeletal homeostasis. Prior to surgery, we measured calcium, phosphate, 25-hydroxyvitamin D [25(OH)D], bone specific alkaline phosphatase (BSAP), estimated glomerular filtration (eGFR), body mass index (BMI), bone mineral density (BMD) and body composition [lean mass index (LMI), appendicular LMI, and fat mass index (FMI)] (Table 1). The 18 RCA subjects were older than the 28 shoulder OA subjects (73.6 \pm

8.0 vs 63.3 ± 9.8 years, respectively). The RCA subjects had higher BSAP levels and marginally higher phosphate levels than those with shoulder OA. There were no significant differences between the two groups in the levels of calcium, 25(OH)D, or eGFR. Subjects with RCA tended to have lower total hip T-score; they had lower LMI and appendicular LMI, although BMIs were similar. These data show that, despite higher BSAP levels in these RCA subjects, the lack of hypophosphatemia, low vitamin D levels, or renal insufficiency is not consistent with a disorder of mineral metabolism. Because there are important relationships between muscle and bone, the lower LMI in RCA subjects may potentially contribute to the pathophysiology of RCA.

| Table 1: Clinical Parameters and Body Composition Measures | | | |
|---|--------------------------|------------------------------|------------|
| Clinical Variables (Normal Range for test) | Osteoarthritis | Rotator Cuff Arthroplasty | P Value |

Tibial Response to Axial Compression in Aging C57BL/6 Mice. Nilsson Holguin^{*1}, Michael Brodt², Michelle Sanchez², Matthew Silva³.
¹Washington University Department of Orthopaedic Surgery, USA, ²Washington University Department of Orthopaedics, USA, ³Washington University in St. Louis School of Medicine, USA

Aging purportedly diminishes the ability of the skeleton to respond to mechanical loading, but recent data show that old age did not impair accrual of bone in BALB/c mice subjected to axial tibial compression. We sought to extend these findings to the commonly used C57BL/6 mice. We hypothesized that aging does not limit the response of the tibia to axial compression over a range of adult ages in C57BL/6. We subjected the right tibia of old (22 months, n=14), middle-age (12 months, n=15) and young-adult (5 months, n=15) female C57BL/6 mice to axial tibial compression (4 Hz, 1200 cycles/day, 5 days/week, 2 weeks) at 9, 10 and 10.5 N, which engendered similar peak periosteal strains of 3000 µε. The left tibia served as a contralateral control. Cortical bone measures from right and left tibias were assessed by in vivo micro-computed tomography (µCT) and by dynamic histomorphometry at 5 mm proximal of the distal tibio-fibular junction. Trabecular bone measures were determined by µCT at the proximal metaphysis, distal of the growth plate. In mice of every age, 2 weeks of tibial compression increased cortical bone volume (p<0.05, Figure 1) by increasing total volume (p<0.001) despite also increasing medullary volume (p<0.001). Compared to the increase in total and bone volume of the cortical midshaft of 5 months mice, increases were less in 12 and 22 months mice (p<0.01). Thus far, periosteal and endocortical MS/BS (n=2-3 per age) were increased in the loaded tibias of each age group compared to contralateral controls, of which 6 out of 8 of the highly strained tibias displayed some periosteal woven bone. Tibial loading increased trabecular BV/TV of 5 months mice from 0.085 to 0.010 mm³/mm³ (p<0.05) but BV/

TV did not change in 12 or 22 months mice, perhaps due to low initial values (0.032 and 0.038 mm³/mm³, respectively). By contrast, contralateral tibias from every age lost cortical bone volume and from 5 months mice lost trabecular BV/TV, suggesting a systemic effect from loading. In conclusion, these data show that while young-adult C57BL/6 mice had greater tibial bone accrual following loading than middle-age or old mice, aging did not eliminate the ability of the tibia to accrue cortical bone.

Juvenile Paget's Disease Without Mutation of *TNFRSF11B* (OPG) or *TNFRSF11A* (RANK). Steven Mumm^{*1}, Omayma El-Shafie², Xiafang Zhang³, Samir Hussein², Deborah Novack⁴, Nicholas Woodhouse², Michael Whyte⁵. ¹Washington University School of Medicine, USA, ²Sultan Qaboos University, Oman, ³Washington University School of Medicine, USA, ⁴Washington University in St. Louis School of Medicine, USA, ⁵Shriners Hospital for Children-Saint Louis, USA

Juvenile Paget's disease (JPD) is the extremely rare heritable disorder that features the greatest rates of skeletal turnover documented in humans. In 2002, homozygous loss-of-function mutations in the *TNFRSF11B* gene that encodes osteoprotegerin (OPG) were discovered in JPD. Most JPD patients have autosomal recessive JPD that reflects remote "founders" in different geographic locations worldwide. Additionally, in 2008, we reported the JPD phenotype in a preliminary report of a Bolivian girl with a sporadic, heterozygous, 15-bp tandem duplication in exon 1 of the *TNFRSF11A* gene that encodes RANK (JBMR 23:S134, 2008). The remaining JPD patients are not understood at the molecular level. Here, we describe this type of extremely rare patient.

A 16-year-old nonconsanguineous boy from Oman had progressive skeletal deformities first noted at age 3 years. Physical examination showed macrocranium, severe and painful bony deformities, and bilateral deafness. Retinal examination showed no angioid streaks. He had 8 unaffected siblings. Radiographs and bone scintigraphy were in keeping with JPD, and showed in his skull striking expansion and sclerosis of the diploic space, basilar impression, expanded maxilla, and deformed teeth (Fig). Ribs, scapulas, and clavicles were wide and sclerotic. Severe deformities affected the femur and pelvis with loss of cortical differentiation. Fractured ribs and flattened vertebrae were also in keeping with JPD. Serum alkaline phosphatase (ALP=3,900 U/L) and other bone turnover markers (BTMs) were markedly elevated. Despite serum 25OHD=12 nmol/L ("deficient"), serum parameters of mineral homeostasis were unremarkable. He also had hyperthyroidism. Iliac crest histology [after tetracycline (TCN) labeling] revealed an irregular arrangement of trabeculae, increased osteoid, hypocellular fibrotic stroma, numerous osteoclasts in some areas, large amounts of woven bone, diffuse TCN labeling, and a very high rate of bone turnover, but without the parallel trabecular pattern identified in the OPG deficiency form of JPD (JBMR 19:695, 2004). Despite 4 mg zolendronate i.v. every month x 40, BTMs did not achieve ~1/2 peak levels.

The coding exons and adjacent mRNA splice sites of *TNFRSF11B* (OPG) and *TNFRSF11A* (RANK) were sequenced without identification of a mutation that would explain his JPD. Similarly, *TNFSF11* (RANKL), *SQSTM1*, *TGFB1*, *SFRP1*, and exons 2-4 of *LRP5* were negative. Hence, there is additional genetic heterogeneity for JPD.

Lateral skull radiograph at age 17 years shows marked expansion of the diploic space, loss of definition of the inner and outer tables, a sclerotic appearance with scattered lucencies, and platybasia.

Responsiveness to Pamidronate Treatment is not Related to Genotype of Type 1 Collagen in Osteogenesis Imperfecta. Junko Kanno^{*1}, Akiko Hakoda¹, Ikuma Fujiwara². ¹Department of Pediatrics Tohoku University Hospital, Japan, ²Tohoku University School of Medicine, Japan

Objective: Osteogenesis imperfecta (OI) is a heritable disorder of connective tissue characterized by bone fragility, low bone mass and short stature. Other external clinical features of OI include dentinogenesis imperfecta and blue sclerae. The majority of patients with OI have a mutation in either *COL1A1* or *COL1A2* that encode type 1 collagen. Mutation analyses of the genes have been reported, but examination of genotype-phenotype correlation in the effect of the treatment have been rarely reported. In this study, we screened *COL1A1* and *COL1A2* in OI patients and compared the results of genotype analysis with clinical examination, including increase of BMD after pamidronate treatment, in the patients.

Subjects and Methods: 22 children (9 males and 13 females) with OI types I (6), III (11), and IV (5) were analyzed. They were treated with pamidronate infusion (1mg/kg, monthly). Lumbar BMD was measured using DXA (Hologic 4500A) before and during the treatment. All exons of the *COL1A1* and *COL1A2* genes were amplified by PCR and analyzed by direct sequencing. We compared the genotype with clinical characteristics including height, blue sclerae, dentinogenesis imperfecta, fractures at birth and the Z-score of the BMD (Z).

Results: Sequencing analysis of *COL1A1* and *COL1A2* in 22 patients revealed 14 mutations in heterozygous forms; 10 missense mutations, two nonsense mutations, and two frame-shift mutations. Three mutations were novel. Each of the 14 mutations was found only in a single family even though the patients were from the same region. Glycine to serine substitutions were the most common type of mutation in both genes. Patients with serine substitutions were shorter than those with other genotype. Most of the patients had blue sclerae and dentinogenesis imperfecta. Pamidronate significantly increased Z in all the patients, though no correlation was found between the mutated gene or mutation type and increment in Z. One of the patients affecting exon 44 of the *COL1A2* suffered intracranial hemorrhage.

Conclusions: *COL1A1* and *COL1A2* mutant alleles in OI are heterogeneous. Glycine to serine substitutions tend to lead to a more severe phenotype. The genotype does not seem to be related to the effect of treatment.

Vertebral Fracture Assessment by the GE Lunar iDXA™ versus Radiographic Assessment in Children. Nicola Crabtree^{*1}, Nicholas Shaw², Wolfgang Hogler³, Natalie Bebbington³, Deirdre Chapman³, Steve Chapman³. ¹Birmingham Children's Hospital, United Kingdom, ²Birmingham Children's Hospital, United Kingdom, ³Birmingham Children's Hospital, United Kingdom

Vertebral fracture assessment (VFA) by DXA is an accepted tool for use in adults. However, its use in children has not been validated. The iDXA is a high resolution

bone densitometer capable of producing good high images with minimal radiation exposure. The aim of this study was to validate VFA using iDXA against spinal radiographic assessment (RA) for the identification of vertebral fractures in children.

Spine radiographs and VFA (L5-T2) by iDXA were acquired on the same day in 25 children. An additional 24 children had VFA alone performed. Agreement between RA and VFA was assessed by an expert paediatric radiologist and two metabolic bone specialists; agreement between raters for VFA alone was additionally assessed by an expert, an experienced and a naive DXA operator. Vertebrae were ranked as normal, mild, moderate or severe if they had <10%, 11-25%, 26-50% and >50% deformity, respectively. Levels of agreement were calculated using the kappa statistic and consistency by the intra-class correlation coefficient (ICC).

Depending on rater, 84.0-90.5% of the visible vertebrae were analysable by RA. In contrast, 97.2% of the visible vertebrae were analysable by VFA. Moderate agreement was noted between raters for RA [kappa 0.523-0.588] and between RA and VFA [kappa 0.511-0.584], substantial agreements were observed between raters for VFA assessment [kappa 0.637-0.704]. Agreement improved if the vertebral deformities were dichotomised as normal or mild versus moderate or severe, with substantial agreement observed between raters for RA and between RA and VFA and almost perfect agreement observed between raters for VFA alone [ICC ranged from 0.802-0.895, $p < 0.0001$]. Similar patterns were observed between all 6 raters for VFA with no discernable difference detected for rater experience. Poorer agreement was seen between quantitative and visual assessment [kappa 0.302-0.408], however this did improve when the classifications were dichotomised.

VFA is accurate and consistent when identifying vertebral fractures, particularly moderate and severe fractures in chronically sick children. Moreover, its accuracy appeared to be independent of reader experience. Consequently, VFA should prove to be a useful tool in the assessment of bone health in children.

Age-related Genetic Influences on Bone Traits in the Metacarpals: Evidence for Genetic Independence across the Hand. Maja Seselj^{*1}, Richard Sherwood², Dana Duren³. ¹Lifespan Health Research Center, USA, ²Division of Morphological Sciences & Biostatistics Wright State University, USA, ³Wright State University, USA

Throughout childhood, gross properties of bone (length, width, cortical thickness) are highly phenotypically correlated across the metacarpals. Early in development, patterning of the autopod is regulated by posterior genes of the *Hoxa* and *Hoxd* clusters. In this early patterning, metacarpals two (MC2) and four (MC4) are contained in separate domains of gene expression (e.g., *Hoxd11-13*), with potential differential anatomical consequences of these expression patterns. It is unclear, however, whether there remain independent genetic effects on bone properties across the hand in any post-natal period. Using a longitudinal growth series consisting of related individuals, we examined additive genetic correlations between paired bone traits of MC2 and MC4, measured from hand-wrist radiographs at ages 3 (N=197), 7 (N=293), 14 (N=400) and 18 years (N=158). Narrow-sense heritability was estimated for each trait, and genetic correlations determined for each trait pair, at each age using a maximum likelihood variance components method implemented in SOLAR. Covariates included sex, skeletal age, weight, and height (or recumbent length).

All traits were heritable at all ages. Genetic correlations between paired bone traits in MC2 and MC4 each exhibited a distinct pattern with age. First, genetic correlations for bone length of MC2/MC4 indicated incomplete pleiotropy throughout childhood, ending with complete pleiotropy ($\rho_g=1$) by age 18. Second, a high genetic correlation was found between bone widths at age 3 ($\rho_g=0.88$), tapering to moderate correlations during mid-childhood. By age 18, the shared genetic influence between MC2/MC4 bone widths was lost ($\rho_g=0$). The third pattern involves cortical thickness, where MC2 and MC4 share genetic underpinnings at ages 3 and 18 ($\rho_g=1$), but show incomplete pleiotropy at mid-childhood ages ($\rho_g=0.85, 0.68$).

Our results suggest that, despite their morphological similarity and anatomical proximity, phenotypic correlations in bone properties between individual metacarpals are not due to uniform genetic control. These patterns of genetic correlation of bone traits in the hand serve as an indicator of the changing role of genes during childhood. It is unclear whether the genetic fields established during embryogenesis continue to exert differential influence across the developed autopod, or if changes in shared genetic underpinnings reflect variation in the timing of regulation of bone growth or mitigating environmental effects.

Early Onset Type 2 Diabetes Impairs Skeletal Acquisition in the Tallyho Mouse. Maureen Devlin^{*1}, Miranda Van Vliet², Christine Conlon², Leeann Louis², Lamya Karim¹, Mary Boudoux¹. ¹Beth Israel Deaconess Medical Center, USA, ²Beth Israel Deaconess Medical Center, USA

The incidence of Type 2 diabetes (T2D) in children and adolescents is rising, yet it is not known whether T2D onset during peak bone mass acquisition affects bone mass, geometry or strength. Here we test effects of early onset T2D on bone mass, microarchitecture and strength in the Tallyho mouse, which develops polygenic T2D at 2-3 months of age. Methods: We compared skeletal acquisition in male

TALLYHO/JngJ and SWR/J controls (N=5/grp) fed a normal (N, 10% kCal/fat) or high fat-sucrose (HFS, 20% kCal/fat) diet from 4-16 wks of age. Outcomes included body mass, % body fat, glucose tolerance, serum leptin, whole body bone mineral content per body mass (BMC/BM), cortical (Ct) and trabecular (Tb) microarchitecture via μ CT, femoral strength by 3-pt bending, and mechanical properties of cortical bone tissue by microindentation. Results: There were no significant differences between N and HFS diet in either strain, so diet groups were pooled for analysis. Tallyho were obese and glucose intolerant, developing T2D (fasting blood glucose >250 mg/dl) by 8 wks of age. Tallyho had ~2-fold higher leptin and % body fat, with 51-64% lower BMC/BM vs. SWR at all timepoints ($p < 0.03$ for all). Tallyho had severe deficits in distal femur Tb microarchitecture: lower Tb. bone volume fraction (BV/TV) (-54%), Tb number (-27%) and connectivity density (Conn.D) (-82%) ($p < 0.01$ for all). Tallyho also had worse Tb bone in the spine: lower Tb.BV/TV (-13%, $p < 0.07$), and Conn.D (-50%, $p < 0.05$) vs. SWR. Tallyho had higher midshaft femur Ct bone area fraction, Ct. thickness, total cross-sectional area, and polar moment of inertia ($p < 0.05$ for all) vs. SWR, but these differences disappeared after adjustment for higher Tallyho body mass. 3-pt bending of the diaphysis showed Tallyho had higher maximum force but lower post-yield displacement than SWR ($p < 0.01$ for both). Cortical bone tissue properties by microindentation were worse in Tallyho, with higher indentation distances ($p < 0.05$). Conclusion: The Tallyho mouse model of early onset T2D has pronounced deficits in bone mineral content, trabecular microarchitecture, and cortical bone material properties, while cortical geometry and whole bone strength are appropriate for body mass. Biomechanical properties are consistent with bone brittleness, perhaps due to accumulation of advanced glycation endproducts. These data suggest the Tallyho mouse is a useful model for studying skeletal effects of T2D onset in adolescence.

Increased Vascularity in Association with Elevated Osteoclast Precursors and Bone Resorption in the Brlm Mouse Model of Moderately Severe Osteogenesis Imperfecta. Patricia Collin-Osdoby^{*1}, Linda Rothe², Rajeev Aurora³, Joan Marini⁴, Philip Osdoby¹. ¹Washington University in St. Louis, USA, ²Washington University, USA, ³St. Louis University, USA, ⁴National Institute of Child Health & Human Development, USA

Brlm mice are a valuable model for moderately severe osteogenesis imperfecta (OI) that contain a glycine substitution (G349C) in half of their type I collagen $\alpha 1(I)$ chains, resulting in mice with a smaller body size, reduced cortical and trabecular bone volumes, abundant osteoclasts (OCs), matrix insufficiency, and brittle bones prone to fracture. Bone resorption in vivo is increased in Brlm mice and histological sections from Brlm vs. WT littermates exhibit greater numbers, sizes and TRAP stained intensities of bone-resorbing OCs. The bone vasculature is essential for normal bone development and remodeling, and it is often increased and contributes to skeletal diseases characterized by bone loss. Here, we investigated if the bone vascular network in Brlm OI mice was expanded in comparison to WT littermates (all 8 week old males). Immunostaining of bone sections showed a marked increase in PECAM-1+ stained blood vessels in Brlm vs. Wt bone, indicating greater vascularity in trabecular Brlm OI bone. Microfil injection was used to prepare bone vascular casts from Brlm and WT mice, and tibial casts were analyzed by microCT to quantify potential vascular differences. Brlm bone vascular casts demonstrated greater vessel numbers, vessel thickness, and overall vascular volumes (30% higher) compared to WT bone vascular casts, particularly in the metaphyseal region. This increased vascularity was associated with a 2-fold greater recruitment of RANK+CD11b+ OC precursors in Brlm bone marrow and the enhanced capacity of such precursors to form more bone-resorbing OCs. Increased vascularity also could provide additional potential stromal vascular niches conducive to OC stimulation, consistent with the 3-fold increase in RANKL+ mesenchymal stromal cells detected in Brlm bone marrow. We conclude that increased OC-mediated bone resorption exhibited by Brlm OI mice is associated with a notable increase in bone vascularity that may contribute to the skeletal pathology of this moderately severe OI disease through multiple mechanisms impacting on precursor cell recruitment and vascular stromal cell niches.

School Based Intervention Improves Fitness But Not Bone Accrual in 8-14 year old Girls. Danielle Ries^{*1}, Aaron Carrel², Sijan Wang³, Tamara Scerpella⁴. ¹University of Wisconsin School of Medicine & Public Health, USA, ²University of Wisconsin-Madison Department of Pediatrics, USA, ³University of Wisconsin-Madison Department of Biostatistics & Medical Informatics, USA, ⁴University of Wisconsin, USA

Introduction: Physical activity modulates bone growth during childhood and adolescence and may enhance lifelong bone health. However, an effective, broadly applicable activity has not been identified. Similarly, physical activity has been shown to enhance youth fitness, as assessed by body composition (BMI), V02 max testing and serologic indices of insulin sensitivity and inflammation. An ideal physical activity would improve fitness as well as skeletal health.

Purpose: To determine whether a school-based fitness-oriented curriculum known to improve V02 max, BMI, insulin sensitivity, and markers of inflammation also improves bone acquisition.

Study design: Data were evaluated from 17 elementary aged (ELEM) and 29 middle school aged (MID), non-obese girls who were enrolled in a school-based, general-fitness intervention (INT). This nine-month program consisted of 40 min of moderate to vigorous activity every other school day. All subjects underwent total body DXA scans (Norland XR-36, software version 3.7.4/2.1.0) before and after the intervention, providing total body subhead (SH) bone mineral content (BMC, g) and non-bone lean mass (LM, g). Percent change in SH BMC was calculated and compared to the same parameter in control subjects (CON) who were matched at baseline for gender, age, height and BMI. CON were enrolled in a different study and received total body scans using a Hologic Discovery A scanner (software v.12.7.3.2.3). Gynecologic age was calculated for MID as years subsequent to menarche at time of baseline scan. Multiple linear regressions were applied separately to ELEM and MID cohorts, exploring the intervention effect on SH BMC % change/month.

Results: The intervention was not a significant predictor of SH BMC % change in either age cohort, as evidenced by β coefficients: ELEM, 0.07 ± 1.83 , $p = 0.74$; MID, -0.25 ± 0.18 , $p = 0.18$. The only significant predictor was change in height for ELEM (1.62 ± 0.72 , $p = 0.033$) and gynecologic age (-0.24 ± 0.09 , $p = 0.008$) for MID.

Conclusion: Although this school-based, fitness-oriented curriculum has been shown to improve body comp, insulin sensitivity, fitness, and markers of inflammation, it did not increase the rate of bone accrual in either elementary or middle-school aged girls over a nine month period. This data demonstrates the need for alternative programs to improve fitness AND maximize bone acquisition in young females.

Subject Characteristics: Means and standard deviations for baseline characteristics and % gains

| | Age (yrs) | Gynecologic Age (yrs) | Height (cm) | Weight (kg) | BMI | SH BMC % Δ /mo | SH LM % Δ /mo |
|----------|-------------------|-----------------------|--------------------|-------------------|-------------------|-----------------------|----------------------|
| ELEM-INT | 8.8 ± 0.8 | - | 132.3 ± 9.2 | 30.1 ± 5.8 | 17.1 ± 2.1 | 1.35 ± 0.56 | 1.16 ± 0.77 |
| ELEM-CON | 9.0 ± 0.5 | - | 133.5 ± 6.6 | 31.7 ± 5.6 | 17.7 ± 2.1 | 1.35 ± 0.71 | 1.51 ± 0.62 |
| MID-INT | 12.9 ± 0.7 | 0.2 ± 1.3 | 159.6 ± 6.4 | 51.0 ± 8.4 | 19.9 ± 2.6 | 1.09 ± 0.52 | 0.79 ± 0.78 |

Reference Data for BMD in Children 2 – 10 Years of Age Assessed by DXL Calscan. Ann-Charlott Soderpalm^{*1}, Ragnar Kullenberg², Kerstin Albertsson Wikland³, Diana Swolin-Eide⁴. ¹Orthopedic Clinic, Sweden, ²Dept of Radiology, Sweden, ³Department of Pediatrics, Sweden, ⁴Queen Silvia Children's Hospital, Sweden

Aim: To collect normative data in order to generate pediatric reference values for calcaneal bone mineral density (BMD) in healthy 2 - 10-yr-old Swedish children.

Background: Site-specific information on bone mass development is important when investigating children with different disorders. The lower extremities e.g., are affected at an early stage in children with neuromuscular disorders such as Duchenne muscular dystrophy. Dual energy X-ray absorptiometry (DXA) in combination with a laser measurement of the heel thickness, DXL Calscan (Demetech AB), measures BMD in the heel bone and an apparent density (BMAD) is calculated. The DXL Calscan is portable, easy to use, has a short measurement time, gives a low absorbed radiation dose and the method is applicable in very young children and in individuals with disabilities.

Subjects and Method: Healthy, Swedish children were randomly included. The left foot was scanned in 117 2-yr-old, 110 4-yr-old and 107 7-yr-old children, 50% were boys, using the DXL Calscan technique. More than 35 % of the children from each age group were followed for another 2 years. A total of 645 measurements in children aged 2 – 10 yrs were performed. Height and weight were determined annually and questionnaires concerning general health were completed at every visit.

Results: The mean BMD in the 2-yr-olds was 0.17 ± 0.003 g/cm², in the 4-yr-olds 0.22 ± 0.003 g/cm² and in the 7-yr-olds 0.30 ± 0.005 g/cm². The 7-yr-old girls had a significantly higher BMD than the boys ($p=0.026$) but there were no significant gender differences in the calcaneal BMD in 2- and 4-yr-olds. BMD was significantly correlated with age ($p<0.001$, $r=0.78$). A weaker correlation was found between BMAD and age ($p<0.001$, $r=0.23$). Based on the data from the 2-yr follow-up; a total of 645 (328 girls/ 317 boys) measurements, reference curves (mean \pm 2 SD) were produced for calcaneal BMD in girls and boys aged 2 - 10 yrs according to age and height.

Conclusions: Gender differences are present in the heel bone BMD at an early age. This study presents gender specific reference curves for heel BMD for children 2-10 yrs of age. These data will be valuable in future research and for evaluating the bone health in children with different disorders and a useful complement when other bone mass measurement techniques are not possible to use, e.g. due to metallic implants. BMAD may reflect mineralization without the influence of bone size.

Effect of Cox2 on Hypoxia-induced VEGF Expression in Cartilage During Ischemia Femoral Head Osteonecrosis. Chi Zhang^{*1}, Yang Li², Reuel Cornelia², Harry Kim³. ¹Bone Research Laboratory, Texas Scottish Rite Hospital, USA, ²Texas Scottish Rite Hospital for Children, USA, ³Scottish Rite Hospital for Children, USA

Legg-Calve-Perthes disease (LCPD) is a juvenile form of ischemic osteonecrosis of femoral head caused by blood supply disruption to the femoral head which results in the hypoxic injury. Piglet model of ischemic osteonecrosis of the femoral head involves surgically disrupting the blood supply to the femoral head. The model has been shown to have radiographic and histopathologic changes resembling LCPD. Our histological studies showed increased vessel formation in cartilage in the ischemic group. Angiogenesis is an essential component for the healing of damaged head. VEGF is an important mediator of angiogenesis. To explore the mechanism underlying this response, porcine microarray was performed to compare gene profiles of cartilage from normal and ischemic femoral heads. In the ischemic side, the expression of VEGF was upregulated along with Cox2. Microarray results were confirmed by quantitative RT-PCR. Immunohistochemistry staining demonstrated that both VEGF and Cox2 were upregulated in chondrocytes in ischemic femoral heads. To examine the coordinate expression of VEGF and Cox2 in vitro under hypoxia, pig primary chondrocytes and RCS were cultured in hypoxia station with 1% or 20% of O₂. Expressions of Cox2 and VEGF were upregulated in both RNA and protein levels. To investigate if Cox2 is involved in VEGF regulation by hypoxia, we used siRNA directed against Cox2 to knockdown Cox2 expression. We observed that expression of VEGF was increased after Cox2 siRNA transfection. Furthermore, Cox2 specific inhibitor NS-398 treatment resulted in modest upregulation of VEGF during hypoxia. Taken together, our data indicated that Cox2 is involved in VEGF regulation by hypoxia. Mechanisms of effect of Cox2 on hypoxia-induced VEGF deserve further investigation.

Application of Vitamin D Status to Development of Normal Ranges for Serum Calcium Concentration in the Pediatric Population. Jeff Roizen^{*1}, Michael Levine², Dean Carlow³. ¹The Children's Hospital of Philadelphia, USA, ²Children's Hospital of Philadelphia, USA, ³The Children's Hospital of Philadelphia, USA

The recognition that vitamin D insufficiency is widespread in pediatric and adult populations raises doubts about the credibility of current reference values for serum calcium, which have been determined using uncharacterized "normal subjects." We therefore set out to determine age-adjusted normal ranges for serum calcium concentration in subjects with normal (20 – 80 ng/mL) levels of serum 25(OH)D. We reviewed clinical and laboratory data of inpatient and outpatient subjects (n = 5868) ranging from full term newborns to greater than 19 years who had a serum levels of total calcium and 25(OH)D measured in the CHOP clinical chemistry lab from 1/1/2011 to 2/16/2012. Serum calcium was measured using a colorimetric assay (VITROS 5, 1 FS automated chemistry system) and serum total 25(OH)D was determined by LS/MS/MS (analytical sensitivity of 4 ng/mL for 25(OH)D₂ and 25(OH)D₃). After excluding patients with renal or endocrine disease or who had been managed in the endocrine clinic or a critical care unit, we ascertained 4628 subjects who had serum

25(OH)D levels that were 20-80 ng/mL within 30 days of their serum calcium measurement. We used EPEvaluator v9 software (Data Innovations, Inc) in accordance with National Committee for Clinical Laboratory Standards (NCCLS) guidelines to analyze the data. We used parametric analysis to generate age-specific reference intervals for serum calcium: 0-90 day-old infants (7.2-11.1 mg/dL); 31-90 day-old infants (7.6-11.0 mg/dL); 91-180 day old infants (8.7-11.1 mg/dL), 181-365 day old children (8.4-11.1 mg/dL), 1-3 year old children (8.5-11.0 mg/dL), 4-11 year old children (8.5-10.6 mg/dL), 11-19 year old children (8.5-10.4 mg/dL) and patients greater than 19 years old (8.4-10.4 mg/dL). Non-parametric analyses yielded ranges that were within 5% of the values obtained by parametric analyses. Serum 25(OH)D levels were between 20-30 ng/mL in 27% of subjects; Wilcoxon matched-pairs signed-ranks test showed a significant (two-tailed $P < 0.03$) difference (0.35 mg/dL) between the lower limits of normal for these subjects compared to subjects with 25(OH)D levels > 30 ng/mL. In summary, we have generated normal calcium ranges for pediatric population that exclude subjects who are vitamin D-deficient. Moreover, our data indicate that many patients with serum 25(OH)D between 20-30 ng/dL have mildly depressed serum calcium levels. These new normal ranges refine previous normal ranges that likely included subjects with abnormal vitamin D status.

Long-Term Evolution of a Patient with Hereditary Vitamin D-Resistant Rickets Due to a R30X Mutation in the Vitamin D Receptor. Bruno Ferraz-de-Souza^{*1}, Regina M Martin², Ana Claudia Latronico², Pedro Henrique Correa². ¹Univ of Sao Paulo School of Medicine (FMUSP), Brazil, ²Univ of Sao Paulo School of Medicine, Brazil

Background: Hereditary vitamin D-resistant rickets (HVDRR) is a rare autosomal recessive disorder characterized by end-organ resistance to calcitriol, resulting in early-onset severe hypocalcemia, rickets and secondary hyperparathyroidism. Inactivating mutations in the vitamin D receptor (VDR) are the primary molecular defect determining resistance to calcitriol. Individuals bearing heterozygous VDR mutations, including relatives of patients with HVDRR, are considered to be phenotypically normal but a heterozygous VDR mutation leading to HVDRR has been recently described.

Clinical case: In 1997, we reported a prepubertal 12-yo boy bearing a R30X nonsense mutation in VDR with severe HVDRR and alopecia (Mechica et al., J Clin Endocrinol Metab 1997). He was born to consanguineous parents and developed total alopecia at 1 mo of life followed by rickets and convulsions at 6 mo of age. Clinical diagnosis of HVDRR was made and therapy initiated at 8 mo of age. Clinical, biochemical and radiological improvement were seen with daily oral doses of 3.0 g calcium, 600,000 IU ergocalciferol and 3.0 ug calcitriol. However, hypocalcemic crisis occurring during intercurrent infections were relatively frequent until he was 11 yo. At 12 y of age, Ca serum levels stabilized leading to regression of secondary hyperparathyroidism and reduction of alkaline phosphatase levels. He developed 2ary sexual characteristics at 13 y of age and normal pubertal growth spurt. Requirements of oral calcium and vitamin D decreased slowly and progressively so that at 18 y of age he required only 1.5 g Ca/d to maintain normocalcemia. Follow-up with DXA showed normal peak bone mass and BMD accretion from 15 y of age onwards. He is now 28 yo and maintains normocalcemia without therapy. Notably, his parents and a younger sister who are heterozygous carriers of the R30X mutation are healthy and normocalcemic with mildly elevated calcitriol levels.

Conclusion: Spontaneous clinical remission of HVDRR despite the permanent molecular defect has been previously reported, occurring more commonly around puberty. Reduced calcium demand after completion of linear growth has been postulated as a mechanism to explain this observation. Nevertheless, long-term follow-up of cases such as this one indicate that remission may start early in puberty, during a period of active growth and that, therefore, yet unknown mechanisms may contribute to increase intestinal Ca absorption in these patients.

Spontaneous Osteoclastogenesis in Turner Syndrome Patients with High FSH Serum Levels. Giacomina Brunetti^{*1}, Maria Felicia Faienza², Annamaria Ventura², Laura Piacente², Angela Oranger³, Flaviana Marzano², Maria Ciccarelli², Giorgio Mori¹, Luciano Cavallo², Silvia Colucci³, Maria Grano¹. ¹University of Bari, Italy, ²Interdisciplinary Department of Medicine, University of Bari, Italy, ³Department of Basic Medical Science, Section of Human Anatomy & Histology, University of Bari, Italy

Bone health is a major lifelong concern in caring for girls and women with Turner Syndrome (TS), a chromosomal aberration characterized by total or partial loss of one of the two X-chromosomes. In TS patients there is a decreased bone density and a selective reduction in cortical bone thickness that probably contributes to the

increased fracture risk. However, the mechanisms underlying the bone disease remain poorly understood. Thus, the aim of this study was to investigate the osteoclastogenic potential of unfractionated peripheral blood mononuclear cells (PBMCs) and T cell-depleted PBMC cultures from TS patients (mean age 10.44 ± 5.48 range 1.5-19 years) with high or normal FSH serum level as well as from age-matched controls. Spontaneous formation of active resorbing osteoclasts, without adding M-CSF and RANKL, occurred in PBMC cultures from TS patients with elevated FSH serum levels. Conversely, M-CSF and RANKL were essential to trigger and sustain osteoclastogenesis in PBMCs from controls as well as TS patients with normal FSH serum levels. T-cell depleted PBMC cultures from TS patients with high FSH serum level showed only a partial reduction of spontaneous osteoclast formation, suggesting that both monocytes and T cells have an important role supporting the elevated osteoclastogenesis. In fact, in these patients, monocytes express elevated c-fms, TNF α and RANK levels, whereas T cells showed high RANKL levels. Moreover, elevated amount of RANKL were also detected in PBMC culture media and sera from TS patients with high FSH circulating levels. In conclusion, the present study showed for the first time a high osteoclastogenic potential of PBMCs from young TS patients with high FSH circulating levels. This condition could contribute to the bone disease that become evident in the adult life.

Dietary Calcium Restriction in Idiopathic Infantile Hypercalcemia does not Adversely Affect Spinal & Distal Radial Bone Mineral Density: Report on Nine Patients. Anjali Daniel¹, Raja Padidela^{*1}, Judith Adams², M Zulf Mughal¹. ¹Royal Manchester Children's Hospital, Central Manchester University Hospitals NHS Foundation Trust, United Kingdom, ²The Manchester Royal Infirmary, Central Manchester University Hospitals NHS Foundation Trust, United Kingdom

Idiopathic infantile hypercalcemia (IIH) (OMIM 143880) is characterised by severe hypercalcemia, failure to thrive, vomiting, dehydration and nephrocalcinosis. Laboratory evaluation of infants affected with this condition reveals hypercalcemia, suppressed parathyroid hormone and hypercalciuria. Recently loss of function mutations in *CYP24A1* gene have been found to cause IIH (N Engl J Med. 2011;365:410-21). Short-term treatment for this condition includes intravenous rehydration, furosemide, glucocorticoids, and pamidronate. Low-calcium diet and is the mainstay for managing IIH until there is resolution of hypercalcemia with age.

The aim of this study was to determine if dietary calcium restriction during infancy and early childhood adversely affected bone mineral density (BMD) in patients with IIH, when they were between 5 to 15 year old. Nine patients with IIH who were treated with dietary calcium restriction for a period ranging from 1.7 to 4 years were studied. BMD of L1-L4 was measured using the dual energy absorptiometry and data was expressed as bone mineral apparent density (BMAD; g/cm³). The lumbar spine (LS) BMAD values transformed to Z scores using the normative data [ADC;2007;92(1):53-9]. A peripheral quantitative computed tomography total and trabecular volumetric bone density (vBMD [mg/mm³]) of the distal radial metaphysis, at 4% of the non-dominant forearm length. Distal radial (DR) total & trabecular vBMD values were transformed to Z scores using the normative data [Osteoporos Int. 2009;20(8):1337-46]. A one sample t-test was used to determine if measured bone parameters were significantly different to zero.

The mean (SD) Z score of BMAD [0.09 (0.97)], DR total vBMD [0.32 (0.87)] and DR trabecular vBMD [-0.04 (0.76)] were not significantly different from zero.

From these results, we conclude that dietary calcium restriction for management of IIH during infancy and early childhood does not appear to adversely affect the distal radial and spinal BMD, when the patients were between 5 to 15 year old.

"Distribution/Mass" and "Distribution/Quality" Relationships in Human Cortical Bone. Influence of Gender and Physical Activity. Ricardo Capozza¹, Paola Reina¹, Laura Nocciolino¹, Sara Feldman², Pablo Mortarino¹, Joern Rittweger³, Jose Ferretti^{*4}, Gustavo Cointry¹. ¹Center of P-Ca Metabolism Studies (CEMFoC), Natl Univ of Rosario (UNR), Argentina, ²LABOATEM, Faculty of Medicine, UNR, Argentina, ³Div Space Physiology, Institute of Aerospace Medicine, German Space Agency (DLR), Germany, ⁴National University of Rosario, Argentina

In a serial pQCT study (slices taken at every 5% of the tibia height throughout the bone, sites S5- S95) of sedentary and running-trained men and women aged 20-40 yr (n=10/group) we had shown that bone mass distribution along the tibia reflected a structural adaptation to the variable stress pattern imposed by the mechanical usage of the limb. Now we extend that analysis to describe the relationships between indicators of cortical bone distribution (bending and torsion cross-sectional moments

of inertia, MIs,y), mass (BMC,x₁), and "quality" (vBMD, proportional to bone tissue stiffness,x₂). Correlations between MIs and cortical BMC and between MIs and cortical vBMD were regarded as describing "distribution/mass" (d/m) and "distribution/quality" (d/q) relationships, respectively, at each studied site.

The d/m curves were all described by positive exponential functions, while the d/q curves, hyperbolically shaped, were always adjusted to negative exponential functions. All d/m and d/q correlations were significant at every site. The distributions of the r coefficients of both d/m and d/q curves, plotted by site, were described by quasi-symmetrical, bell-shaped curves, reaching a maximum toward the central region of the tibiae in every instance. Both men and trained individuals showed significantly higher MIs and BMC and lower vBMD values than women. The d/m relationships were described by unique curves for all groups, with increasing slopes from the heel to the knee. The d/q relationships were described by separate, parallel curves for men (higher ordinates, lower abscissae) and women, with little or no influence of the trained/untrained condition within sex.

Results offer original support to 4 important concepts in Bone Biology: 1. the architectural quality of diaphyseal design concerning bending and torsion strength is proportional to the relative influence of bending and torsion in the varying stress patterns along the bones (known to be maximal toward the central regions) with a significant trend to minimize bone mass; 2. there is a trade-off between cortical bone "quality" (intrinsic stiffness) and distribution, as if both variables were interrelated by a feedback control mechanism of structural diaphyseal stiffness/strength (in agreement with the mechanostat theory); 3. both d/m and d/q relationships are highly related to bone mechanical environment, and 4. the d/q relationships are also affected by sex.

Assessment of varying CT image resolution on Voxel-based, Subject-Specific High-throughput FEA models. David Mcerlain^{*1}, Kyle Nishiyama¹, Clara Sandino², Steven Boyd¹. ¹University of Calgary, Canada, ²Faculty of KinesiologyBone Imaging LabUniversity of Calgary, Canada

Introduction: Computed tomography (CT) is a 3D imaging modality with tremendous promise for advanced Osteoporosis diagnosis techniques. Moreover, CT data is an ideal input for creating biomechanical models using finite element (FE) analysis that simulate mechanical tests (CT-FE) to provide patient-specific estimates of bone strength. Traditional CT imaging protocols use varying voxel dimensions depending on the anatomical site and patient size, and it is likely to underestimate stress values within bone using CT-FE. Thus, the purpose of this project is to assess the optimal voxel dimensions required for subject-specific CT-FE analysis of bone strength.

Methods: Cadaveric distal tibia specimens (n=8 fresh-frozen; mean age 78) were scanned (GE Discovery CT750HD; 120 kVp, 60mA·s) and reconstructed with varied slice thicknesses (0.625mm - 2.50mm) typical in orthopaedic exams. After, all bones were scanned using micro-CT (Scanco Medical XtremeCT; 60kVp, 1.0mA; 0.082mm isotropic voxels), which acted as the over-resolved 'gold' standard. The endosteal bone surfaces were semi-automatically segmented using Stradwin (Cambridge, UK) and exported for FE model creation. In-house software converted the CT data into density units based on a phantom within the image (B-MAS200, Kyoto, Japan), which were converted to Young's modulus. Linear FE models were generated with hexahedral elements from isotropic voxels and solved using FAIM (Numerics88; Calgary, Canada). A 3-mm axial compression load was applied to each model along the articular surface.

Results: Each clinical CT-FE simulation was completed in less than 17 min (number of elements for clinical CT-FE models ranged from approximately 5800-370000). The distribution of stress appeared similar between models as the load transmitted evenly from the surface to the cortical bone, though the mean von Mises stress values decreased by 27% for the models with 2.5 mm elements versus 0.63 mm.

Discussion: This work investigates the utility and feasibility of whole bone, subjects-specific CT-FE for use in high-throughput analysis of osteoporotic patients. The bounds of solutions were determined for the resolutions tested, and these results suggest that a minimum 1mm, isotropic voxel size may be required for testing. Advanced, constitutive properties are currently under development for large-scale FE models. Future work will compare the CT-FE models to micro-CT derived FE models of the same bone.

Disclosures: *David Mcerlain, None.*

Biomechanical Bone Testing in Cynomolgus Monkeys: Neonate, Juvenile, Young Adult and Aged Animals. Aurore Varela^{*1}, Robert Guldberg², Susan Y. Smith¹. ¹Charles River Laboratories, Canada, ²Parker H. Petit Institute for Bioengineering & Bioscience, USA

Biomechanical strength testing of bones, considered the ultimate bone quality assessment, is a critical end-point in the evaluation of the safety and efficacy of test

compounds in postnatal, juvenile, young adult and aged animals in preclinical studies. The purpose of this study was to assess precision and validate procedures for the biomechanical testing of femurs (3-point bending) and vertebral body (compression) from Cynomolgus monkeys of different ages using an MTS Servohydraulic test system, Model 242.03, using TestWorks version 3.8A for TestStar® software version 4.0C, under GLP conditions.

Femurs and lumbar vertebrae were collected from six 1-day-old, twelve 6-month-old monkeys, twenty-one 2.5-3 year-old and seventeen monkeys greater than 9 years old, and stored frozen at -20°C until pQCT scanning and testing. pQCT was measured at the expected 3-point bending fracture site (distal diaphysis). Due to the specimen size, 1-day-old femurs (~5 cm) were tested with a small fixture (rounding of 3.2 mm), bottom span of 20 mm, and 6-month-old (~8 cm) with a bottom span of 30 mm. Femurs from older animals were tested with a larger fixture (rounding of 6.35 mm), bottom span of 50 mm. Femur tests were done at a rate of 1 mm/sec, load cell 2.5kN (1-day-old and 6-month-old femurs) or 15kN (older animals). Vertebral body compression was done at a rate of 20 mm/min, load cell 2.5kN (1-day-old) or 15kN (older animals). Load and displacement data were collected and biomechanics parameters derived.

The 3-point bending tests provided the following range of results: peak load 120 to 200N, stiffness 170 to 240N/mm and area under the curve at peak load (AUC) 330 to 700N-mm as well as respective corrected parameters for specimen size, ultimate stress 115 to 150 MPa, modulus 2500 to 4000 MPa and toughness 13 to 35 MPa. In addition, using linear regression analyses, a positive relationship between femur vBMC and peak load was obtained ($r=0.90$) regardless of age, supporting the reproducibility of the procedures. %CV of peak load and stiffness was approximately 19% for 3-point-bending and 25 % for vertebral body compression regardless of age.

With respect to precision, these results were similar for bones of different size, density and age and confirm the adequacy of procedures in neonate, juvenile and adult monkeys, which support the feasibility and utility of integrating these endpoints in neonate or juvenile preclinical studies to assess potential effects on bone.

Disclosures: *Aurore Varela, None.*

Bone Heterogeneity measured by DXA Complements aBMD for Prediction of Mechanical Behavior of Human Lumbar Vertebrae. François Duboeuf^{*1}, Jean-Paul Roux², Julien Wegrzyn³, Mary Bouxsein⁴, Roland Chapurlat⁵. ¹INSERM, UMR 1033, Université de Lyon, France, ²INSERM, UMR 1033, Université de Lyon, France, ³INSERM U1033 - Université de Lyon, France, ⁴Beth Israel Deaconess Medical Center, USA, ⁵E. Herriot Hospital, France

More than 50% of fragility fractures are not predicted by areal bone mineral density (aBMD). A previous study showed the contribution of microarchitecture heterogeneity to the mechanical behavior of human lumbar vertebrae (Wegrzyn et al. JBMR 2010: 2324-2331) in an ex-vivo study. Thus the aim of this study was to assess the contribution of bone heterogeneity measured simply by DXA to the mechanical behavior of human lumbar vertebrae.

Lumbar vertebrae (L3) were harvested fresh from 21 lumbar spines of human donors, including 11 men and 10 women, aged 54 to 93 years of age (75 ± 10 years for men and 76 ± 10 years for women). The lateral BMC (g) and aBMD (g/cm^2) of the vertebral body were measured using DXA (Delphi W, Hologic). Using subregion analysis, we measured separately anterior and posterior region from the lateral DXA view and computed the ratio of anterior to posterior DXA BMC and BMD measurements (i.e. BMC_{ratio} and BMD_{ratio}). Quasi-static uniaxial compressive testing was performed on L3 vertebral bodies under displacement control (0.5mm/min) to assess failure load (FL, N), stiffness (STF, N/mm) and Work to failure (WF, N. mm).

Anterior BMC and BMD measurements were significantly lower than posterior measures ($p<0.0001$) but no significant difference was found between the anterior and posterior areas. BMC_{ratio} was significantly correlated to FL and WF ($r=0.49$ and 0.45 ; $p=0.02$ and 0.04 respectively), but not with BMD or BMC. In addition, these correlations remained significant after adjustment with BMC or aBMD (partial correlation, $r=0.47$ and 0.46 ; $p<0.045$ for all). In multiple regression analysis the combination of aBMD and BMC_{ratio} was strongly associated with FL (multiple $R=0.75$, $p<0.001$).

In conclusion, the anteroposterior heterogeneity expressed by the BMC_{ratio} improves the prediction of bone mechanical behavior in association with aBMD in this ex vivo study, with the combination explaining up to 56% of the variability of the failure load, compared with 44% for aBMD alone. These results provide rationale for testing DXA-based heterogeneity measures as predictors of vertebral fracture in clinical studies.

Bivariate regressions

| | Failure Load (FL, N) | Work to failure (WF, N. mm) | stiffness (STF, N/mm) |
|----------------------|-------------------------|--------------------------------|--------------------------|

Development of Functional Interactions Among Cortical and Trabecular Traits During Growth of the Lumbar Vertebral Body. Melissa Ramcharan^{*1}, Meghan Faillace¹, Zoe Guengerich², Valerie Williams², Karl Jepsen³. ¹Mount Sinai School of Medicine, USA, ²Mount Sinai School of Medicine, USA, ³University of Michigan, USA

Because variation in bone traits in the elderly is largely established by adulthood, understanding how bone function is established during growth will benefit efforts to reduce fracture risk later in life. Although skeletal structures like the vertebral body depend on both cortical and trabecular traits for whole bone function, little is known about how these traits co-develop during growth. In adults, cortical and trabecular traits are functionally related, but whether early variation in one trait is followed by adaptive changes in the other remains unclear. To study this, we examined the temporal sequence of trait maturation during growth in the vertebral body among three inbred mouse strains expressing widely varying adult vertebral traits. A/J (AJ), C57BL/6J (B6) and C3H/HeJ (C3H) mice are genetically distinct where AJ exhibits a slender (narrow relative to length) bone, B6 a robust (wide relative to length) bone, and C3H has an intermediate vertebral body size with a thick cortex and low trabecular bone mass.

Female mice from each strain were sacrificed at 7, 14, 28, and 112 days of age ($n=10$ /age/strain). The L3 and L4 lumbar vertebrae were harvested, prepared for plastic embedding, sectioned along the mid-transverse and mid-coronal plane, respectively, and then imaged using fluorescence microscopy. Morphological traits were quantified in the transverse plane by measuring relative cortical area (RCA) and, in the coronal plane by calculating trabecular bone volume/ total volume (BV/TV). Differences in traits relative to age and genotype were determined using a two-way ANOVA and Student's t-test. Overall significance was set as $p<0.05$.

At 7 days of age, BV/TV varied significantly among strains and was consistent with differences seen in adulthood (112days). For each strain, an increase in BV/TV during growth was later followed by an increase in RCA. The data suggested that early variation in trabecular BV/TV lead to an adaptive response in the cortical shell traits.

In this study, we gained a better understanding of the biological processes between cortical and trabecular bone that are essential for developing a mechanically functional vertebral body. Also, along with early established variation in trabecular traits, there was a large amount of bone resorption in the marrow space as well as an increase in anisotropy. This suggested that an increase in osteoclastic activity may regulate the initial development of genetic variation in bone traits.

Femur Strength Indices and Trabecular Bone Score (TBS) in Postmenopausal Patients With Primary Hyperparathyroidism. Elisabetta Romagnoli¹, Cristiana Cipriani¹, Claudia Castro¹, Vincenzo Carnevale², Daniele Diacinti³, Sara Piemonte¹, Jessica Pepe¹, Luigina Ostuni¹, Maurizio Angelozzi¹, Addolorata Scarpiello¹, Salvatore Minisola^{*1}. ¹Dpt of Internal Medicine & Medical Specialties, University "Sapienza", Rome, Italy, ²Dpt of Internal Medicine, "Casa Sollievo della Sofferenza" Hospital, S. G. Rotondo, Italy, ³Dpt of Radiology, University "Sapienza", Rome, Italy

Purpose: We investigated new parameters of bone strength and quality obtained from DXA-derived indices in 46 postmenopausal patients with primary hyperparathyroidism (PHPT)(mean age 64.4±11.3 yrs;BMI 24.5±4.6) and in 68 age-and BMI matched postmenopausal healthy controls (C)(61.1±6.7 yrs;BMI 24.3±3.5).

Methods: Bone mineral density (BMD) of the left hip was measured by DXA (Lunar iDXA with enCORE software version 13).Structural variables were determined using the advanced Hip Strength Analysis (HAS) program, including hip axis length (HAL,mm), cross-sectional area (CSA,mm²-an indicator of axial strength), cross-sectional moment of inertia (CSMI,mm⁴-a measure of the distribution of material around the neck axis), and femoral strength index (FSI,that indicates the risk of fracture for forces generated during a fall on the greater trochanter).In 31 patients (65±12.1 yrs;BMI 25±4.5) and 41 age-and BMI matched controls (61.2±6.8 yrs;BMI 24.7±3.7) trabecular bone score (TBS)(TBS iNspight,Med-Imaps,France) was also obtained from DXA images of the lumbar spine (LS)(Hologic QDR 4500).

Results: Table 1 reports the correlation matrix between the structural parameters studied and femoral neck BMD.In PHPT and C, both CSA and CSMI significantly correlated with HAL and BMD.No correlation was found between FSI and BMD in PHPT patients, contrary to what observed in C.Mean femoral BMD values were significantly lower in PHPT compared to C (740.7±103.2 vs 790.6±98.2 mg/cm²,p<0.02).Mean HAL,CSMI, CSA and FSI values were not significantly different between PHPT and C (Table 2). The results did not change also after adjustment for age, height, weight, HAL and femoral BMD, as appropriate.BMD at LS did not differ between groups, while mean TBS values in PHPT (1.22±0.09) were significantly lower than in C (1.26±0.08).TBS values were highly correlated with BMD at LS in both PHPT (r=0.666,p<0.0001) and C (r=0.728,p<0.0001).

Conclusion: The hip structural properties of PHPT patients, despite the lower femoral BMD, did not differ from those of C, while trabecular bone microarchitecture estimated by TBS, appeared to be compromised in PHPT patients. However, the technical limitations of these DXA-derived indices of bone strength and quality should be taken into account when interpreting the clinical significance of these results for fracture risk evaluation in patients with PHPT.

Table 1. Correlation matrix between structural parameters of femoral strength and femoral neck BMD

| | PHPT (n=46) | | Controls (n=68) | |

IGF-1, PINP, CTX, Osteocalcin and 25-OH Vitamin D Stability in Human Serum under Variable Storage Conditions. Ellen McMonagle^{*1}, Elizabeth McMenamin², Anne Breggia¹, Susan Durham³, Clifford Rosen¹. ¹Maine Medical Center, USA, ²Maine Medical Center Research Institute, USA, ³Immunodiagnostic Systems, Incorporated, USA

Background: Preservation of biomarker integrity is essential for consistent and reproducible data. In this study we investigated the effects of variable storage

conditions on markers of bone metabolism including IGF-1, PINP, CTX, osteocalcin, and 25-OH Vitamin D.

Methods: Serum was separated from whole blood collected from 5 healthy volunteers, aliquoted and stored at room temperature (RT), 4°C, -20°C or -70°C. Testing time points for each storage condition included 1) immediate assay as baseline (BL) for all storage conditions; 2) storage at RT or 4°C for 4,8,24,48, or 72 hours; 3) storage at -70°C with 1 thru 6 freeze/thaw (FT) cycles; and 4) storage at -20°C until tested at 1,4,7,9, and 13 months. All immunoassays were performed using the iSYS analyzer (Immunodiagnostic Systems, Inc. Scottsdale, AZ). All statistical comparisons to BL were made using paired t tests, with two-tailed analysis and are reported as mean ± SEM.

Results: Units for all analytes are in ng/mL. CTX concentration decreased from 0.268 at BL to 0.249 (p=0.032) at RT for 4 hours; 0.217 (p=0.014) at 4°C for 24 hrs; 0.239 (p=0.018) at -70°C with 1 FT cycle and 0.222 (p=0.04) at -20°C for 1 month. Osteocalcin concentration also decreased from 17.2 at BL to 16.5 (p=0.011) at RT for 8 hrs but was not significantly affected by storage at 4°C for up to 72 hours, 6 FT cycles, or 1 year at -20°C. Conversely, the concentration of IGF-1 increased from 177 at BL to 181 (p=0.031) at RT for 4 hrs; 184 (p=0.007) at 4°C for 4 hrs; 184 (p=0.044) at -70°C with 1 FT and 216 (p=0.011) at -20°C for 1 month. 25-OH Vitamin D was stable at all time points at both RT and 4°C up to 72 hrs and also after 6 FT cycles, but increased from 22.8 at BL to 31.3 (p=0.03) after 4 months at -20°C. PINP concentration also increased from 34.3 at BL to 39.2 (p=0.003) at RT for 24 hrs; 39.2 (p=0.009) at 4°C for 4 hrs; 39.3 (p=0.0002) at -70°C with 1 FT and 39.1 (p=0.002) at -20°C for 7 months.

Conclusions: Of the 5 biomarkers tested, CTX was the most sensitive to variable storage conditions while 25-OH Vitamin D and osteocalcin appeared to be the most stable. Storage at -20°C was the most detrimental to analyte stability. This data supports the need for prompt storage of serum samples at ultralow temperatures (≤-70°C) and limited freeze-thaw cycles. An additional study of long-term storage at -70°C is currently being conducted.

Linear and Nonlinear High-Resolution Finite-Element Analysis of the Distal Tibia and Radius from in Vivo MRI. Ning Zhang^{*1}, Jeremy Magland¹, Chamith Rajapakse², Yusuf Bhagat¹, ShingChun Lam¹, Felix Werner Wehrli³. ¹University of Pennsylvania, USA, ²University of Pennsylvania School of Medicine, USA, ³University of Pennsylvania Medical Center, USA

High-resolution image-based micro-finite-element (μFE) modeling is a valuable tool for characterizing bone mechanics. Linear μFE analysis is widely utilized but can only estimate elastic moduli. Nonlinear μFE analysis is capable of predicting bone's failure strength, but is computationally far more demanding. In this study, we investigate the associations of trabecular bone yield stress and toughness with axial stiffness derived respectively from nonlinear and linear μFE modelings. In-vivo μMR images of distal tibiae of 21 women (ages 58-84) with osteoporosis and distal radii of 20 women (ages 50-75) were used as study subjects. Tibia images were previously acquired at 3T field strength and radius images at 1.5T, both with a voxel size of 137 x 137 x 410 μm³. All images were subjected to linear and nonlinear μFE simulations yielding axial stiffness and stress-strain curves. The yield stress and strain were then determined by the 0.2% offset rule (Niebur, 2000) and toughness was calculated as the area under the stress-strain curve up to the ultimate point. Sixty strain levels with a step size of 0.05% were applied to obtain each stress-strain curve (e.g., Figs. 1: radius, 2: tibia). Simulated strain maps in sagittal view (Figs. 1&2 a-c) reflecting different amounts of strain (corresponding to points on the stress-strain curve before, at and after the yield point) highlight locations where trabeculae were gradually loaded until simulated failure occurred. Figs. 3 and 4 compare yield stress (5.34 ± 0.83 MPa for tibia, 3.55 ± 0.92 MPa for radius) and toughness (45.31 ± 6.83 kPa for tibia, 38.56 ± 8.03 kPa for radius) with axial stiffness (0.81 ± 0.11 GPa for tibia, 0.57 ± 0.13 GPa for radius), respectively. Strong correlations (R²>0.97, p<0.0001) between yield stress and axial stiffness were found for both tibia and radius with similar slopes and intercepts, suggesting that (1) the axial stiffness may be able to predict trabecular bone's yield stress and (2) slopes and intercepts in the correlation may not vary much for distal tibia and radius of elderly women. Further, axial stiffness was found to explain 74% (p<0.0001) of the variation in toughness of the tibia but only 38% (p<0.005) of the radius, suggesting that nonlinear μFE analysis may provide extra information compared to linear analysis, such as fracture toughness, e.g. from the shape and trend (brittle versus ductile) of the simulated stress-strain curve.

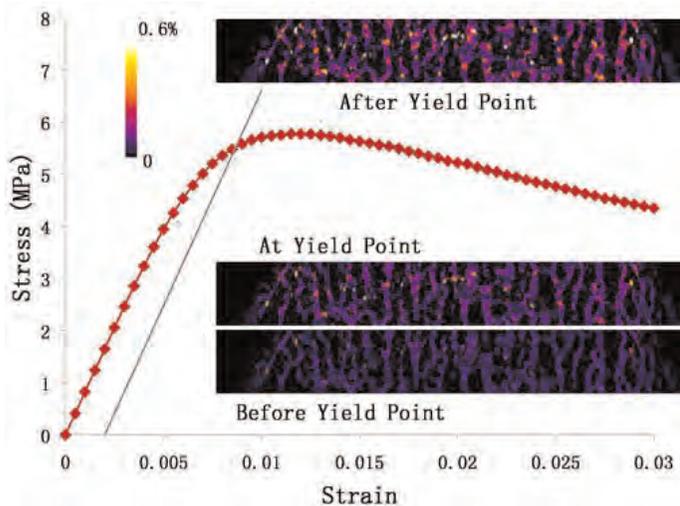

Fig. 1. Simulated stress-strain curve and strain maps based on an in vivo MR image of distal tibia.

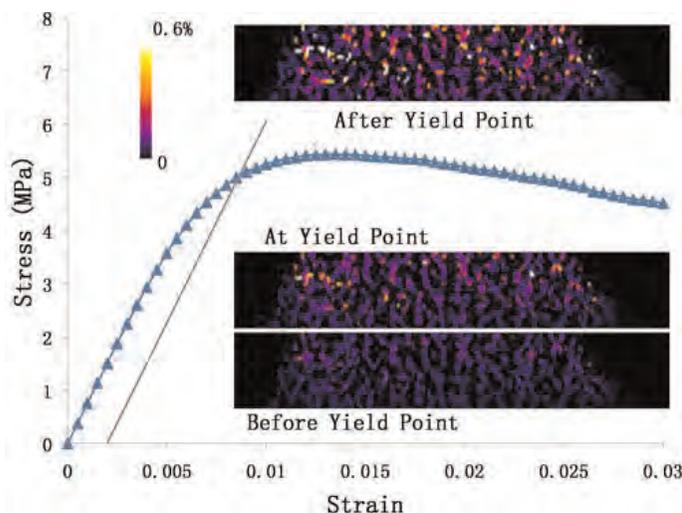

Fig. 2. Simulated stress-strain curve and strain maps based on an in vivo MR image of distal radius.

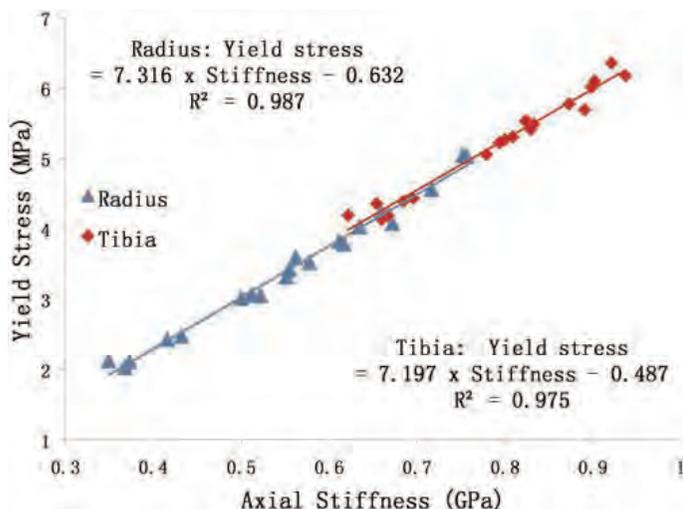

Fig. 3. Nonlinear μ FE-predicted yield stress versus linear μ FE-estimated axial stiffness.

Longitudinal Analysis of Cortical Pore Structure using HR-pQCT. Willy Tjong, Jasmine Nirody, Julio Carballido-Gamio, Andrew Burghardt, Janina Patsch, Sharmila Majumdar, Galateia Kazakia*. University of California, San Francisco, USA

Elevated levels of cortical porosity (Ct.Po) have been shown to adversely affect bone strength. Though previous cross-sectional studies have observed increased Ct.Po as a function of age, little is known on the mechanism of pore development. The purpose of this study was to characterize longitudinal changes in the cortical pore network with the goal of elucidating possible mechanisms of increased porosity. Ct.Po and pore diameter were calculated using an extended CRTX analysis previously developed in our lab. Additionally, a novel skeletonization algorithm was implemented to perform a topological analysis of the pore network. Each voxel was assigned a topological label (ie, surface, curve, junction), allowing for the classification of pores as either plate-like or rod-like. Finally, a laminar analysis was performed which quantified pore number and size in the periosteal, intracortical, and endosteal regions. Early postmenopausal women ($n = 21$, age = 57 ± 4 years) were imaged at the distal tibia at baseline and after 24 months. Ct.Po significantly increased after 24 months (+10.6%, $p < 0.001$), with both the number of plate-like canals (+14.6%, $p < 0.001$) and rod-like canals (+14.8%, $p < 0.001$) increasing. Though there was no change in the ratio of plate-like canals to rod-like canals, there was an increase in the ratio of total plate volume to rod volume (+13.8%, $p < 0.05$). This tendency toward a more plate-like pore network is confirmed by an increase in mean plate volume (+9.1%, $p < 0.05$). A corresponding decrease in mean rod volume (-3.7%, $p = 0.07$) trended towards significance. The cortical pore network also showed greater connectivity, as evidenced by an increase in the number of junctions (+25.3%, $p < 0.01$). Regional analysis indicated that increased Ct.Po was confined to the endosteal aspect of the cortex (+29.0%, $p = 0.05$; no significant changes in the other regions), and that Ct.Po increase occurred through a mechanism of increased pore size (+40.0% in the endosteal region, $p < 0.001$) rather than pore number. Based on these data, we hypothesize that age-related changes in the cortical pore network result in the preferential expansion of plate-like canals at the endosteal aspect of the cortex through a mechanism of pore merging. As cortical microstructure is linked to bone strength, the correlation between the morphological parameters presented here and the biomechanical properties of bone warrants further investigation.

Male Obese Adolescents Have Stronger and Bigger Bones than their Normal-weighted Peers. Sara Vandewalle¹, Stefan Goemaere^{2*}, Inge Roggen³, Hans Zmierzczak⁴, Kaatje Tovey⁴, Patrick Debode⁵, Maria Van Helvoirt⁵, Youri Taes⁶, Jean-Marc Kaufman⁷, Jean De Schepper³. ¹University Hospital Ghent, Belgium, ²University Hospital, Belgium, ³University Hospital Brussels, Belgium, ⁴University Hospital Ghent, Belgium, ⁵Zeepreventorium, Belgium, ⁶Dept. Endocrinology Ghent University Hospital GhentDe Pintelaan 1859000 Gent, Belgium, ⁷University Hospital of Ghent, Belgium

Background: Recent studies have shown that obesity is associated with an increased risk of fracture. Whereas some studies report higher bone mineral density (BMD) (measured by DXA) in overweight children, other studies conclude that obesity is linked to a lower BMD. However, there are few data on bone geometry and true volumetric bone mineral density (vBMD) in obese adolescents.

Objective: To determine bone strength, bone geometry and vBMD in obese male adolescents by peripheral quantitative computed tomography (pQCT) and the relationship between muscle force and bone characteristics at the tibia in adolescents.

Methods: 51 male obese (mean BMI sds : 2.55) adolescents, aged 10-19y, recruited at the start of a residential obesity treatment program in De Haan (Belgium), and 51 healthy male controls matched for age and height (mean BMI sds: -0.17) were included in this cross-sectional study. Trabecular (4% site from distal end) and mid shaft cortical (38 % site from distal end) vBMD and bone geometry were assessed at the non-dominant leg using the Stratec XCT 2000 device. Maximal muscle force (F max) was evaluated by two leg jumping mechanography using a ground force reaction plate (Leonardo, Novotec Medical GmbH).

Results: The trabecular vBMD and area measured at the distal end of the tibia were higher in the obese group. At mid shaft, tibial cortical area, periosteal circumference and endosteal circumference were larger in the obese group. There was no significant difference in cortical vBMD between the two groups. The stress-strain index (SSI) was significantly higher in the obese group. Obese adolescents developed a significantly higher maximal force (2.1 (range: 2.8) vs 1.2 (range: 1.3) kN; p<0.001) compared to the control group. In the merged study groups significant positive associations were observed between F max and cortical bone area (β : 0.60; p<0.001), periosteal circumference (β : 0.59; p<0.001), endosteal circumference (β : 0.41;p<0.01), trabecular bone area (β :0.50; p<0.001), and trabecular vBMD (β :0.34; p=0.01), but not cortical vBMD (β :0.13; p=NS).

Conclusions: Obese adolescents have a bigger bone size and higher bone strength at the tibia compared to normal-weighted controls. They develop higher ground reaction forces and apply higher mechanical load to the skeleton.

Measuring the Fracture Toughness of Mouse Bone. Alexander Makowski^{1*}, Sasidhar Uppuganti², Jeffrey Nyman³. ¹Vanderbilt University, USA, ²Vanderbilt University, USA, ³Vanderbilt University Medical Center, USA

The age-related increase in fracture risk may not be solely due to a loss in bone strength since bone matrix undergoes multiple changes independent of bone mineral density with aging and disease onset. To identify novel factors contributing to bone fracture resistance, a method was refined to quantify fracture toughness of rodent bone. This method involves generating a micro-notch in the cortex of the femur mid-shaft and loading the bone in three point bending to drive a crack from the notch through the matrix to failure. Quantifying this resistance to crack propagation as a material property known as the stress intensity factor (K_c) requires that the bone structure and the notch size be properly incorporated in the measurement. Given that the equations to do so were derived for a circular pipe and that the geometry of the mid-shaft is irregular varying across genotypes and strains, we investigated whether micro-notching the anterior vs. posterior side affects K_c using mouse strains with varying bone geometry. Femurs were harvested from nineteen 17 wk old male mice (FVB). To increase the variance in bone structure, femurs were also harvested from sixteen 11-12 wk old male, transgenic mice (on a mixed background), namely liver-specific insulin receptor knock-out (LIRKO) and cre-negative floxed mice (WT). Using a thin wafer saw and then a razor blade with μ -diamond solution, we obtained

15 anterior and 19 posterior notched bones meeting the geometry criteria. Notch angles and bone geometry were quantified from μ CT scans acquired at 6 μ m voxel size. Femurs were loaded at a rate of 0.06 mm/min to determine peak force and video was recorded (~14 μ m²/pixel; 30 fps) to track failure mode. The COV of the notch angle was lower for the posterior than for the anterior group (12.4% vs. 21.1%). Video and μ CT identified 2 specimens with deep notches and little cracking and 1 specimen with a partial notch and poor orientation. For the FVB mice, K_c is different between ant. and post. notched bones (Fig. 1). Also, K_c for post. notches differed between older FVB and younger LIRKO. Therefore, regressions to analyze independence of geometry were done separately (Fig. 1). For the ant. group, the y-intercept was not zero (95% CI: -3.97 to -0.93) suggesting a lack of independence. For the post. groups, this was not the case (FVB+WT 95% CI: -10.1 to 3.54). Further refinement of structure and notch angle analyses may help K_c become entirely independent of geometry.

Proximal Femoral Cortical Thickness in Postmenopausal Women Shows Highly Localised Significant Asymmetry. Tom Turmezei^{1*}, Graham Treece², Andrew Gee², Carol Tonkin², Madhavi Vindlacheruvu³, Karen Blesic², Kenneth Poole¹. ¹University of Cambridge, United Kingdom, ²University of Cambridge, United Kingdom, ³Cambridge University Hospitals NHS Foundation Trust, United Kingdom

Background: Establishing focal skeletal left-right difference is important for anthropological study, understanding adaptation to strain and the clinical investigation of bone. Asymmetry is not only well established in the human skeleton but, given that bone exhibits functional adaptation, is also to be expected. Differences in the lower limb are reported to be of smaller magnitude than in the upper limb, with the lower limb also mirroring the usual pattern of upper limb right-sided dominance. Until now, only selective focal or summative regions have been analysed. Dual energy X-ray absorptiometry of the proximal femora has shown either a left bias or no difference in areal bone mineral density, however individual left-right differences of up to 26% have been reported.

Method: Cortical thickness maps were created of the proximal femora from clinical CT data of 197 postmenopausal women aged 73 ± 7 yrs (mean ± sd) combined from 3 cohorts: 48 from the FEMCO study (75 ± 8 yrs), 80 from the FREEDOM study (74 ± 5 yrs) and 69 from the EUROFORS study (70 ± 7 yrs). All data were taken

from the study baseline prior to any intervention. After registration of each bone to an average (right) femur shape, statistical parametric mapping was used to determine sites of significant differences in mean cortical thickness between sides.

Results: We identified highly focal differences between left and right, including a vertical band of significantly thicker cortex along the load-bearing anteromedial aspect of the right proximal femoral shaft. Several smaller patches of cortex at the inferomedial femoral neck and the greater trochanter were also significantly different between sides, some thicker on the left (fig. 1). Results were validated across each of the study subgroups.

Discussion: Highly localised and significant left-right differences were detected in the cortical thickness of the proximal femora of postmenopausal women. The vertical band of increased thickness on the right correlates with the point of maximal stress in the early and mid-gait cycle, suggesting that side differences may be related to gait asymmetry. There is also a high thickness gradient in this region, and so findings could represent widening of thicker regions around the cortex from mineral redistribution in response to load-bearing. These results reinforce the importance of cortical thickness measurement location since dimensions derived from planar imaging can hide significant local fluctuations.

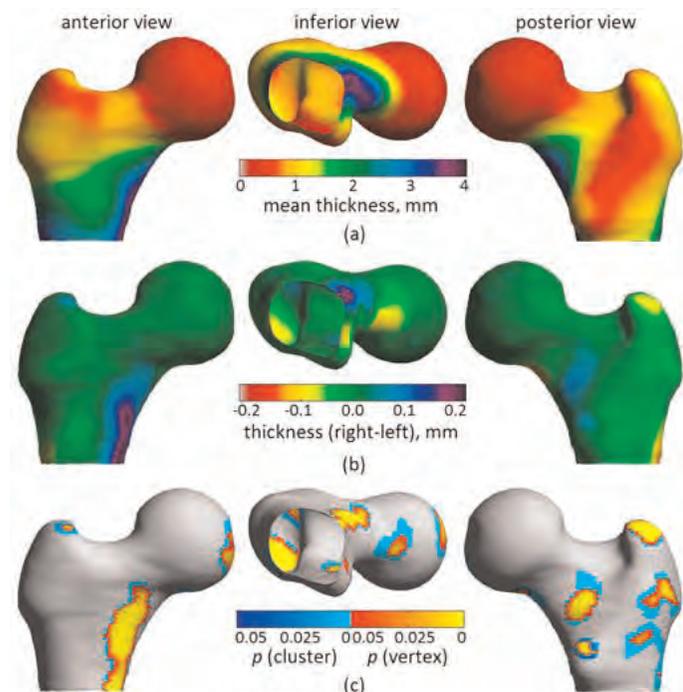

Figure 1 (a) Mean cortical thickness, (b) mean difference between left and right sides, (c) significance ($p < 0.05$) of regional (cluster) or individual (vertex) measured thickness changes. All results shown mapped to the right femur

Solid State NMR Investigation of Bone Quality in Osteoporotic Bone: Citrate/GAGs Are Present at the Mineral-Organic Interface. Ondrej Níkel^{1*}, Deepak Vashishth¹, Danielle Laurencin², Grazyna Sroga¹. ¹Rensselaer Polytechnic Institute, USA, ²Institut Charles Gerhardt de Montpellier, UMR 5253, CNRS-UM2-ENSCM-UM1, Université? Montpellier 2, France

The Solid State Magic Angle Spinning Nuclear Magnetic Resonance (SS MAS NMR) has long been appreciated for ability to inform on mineralization¹. The SS NMR was recently shown to be useful for assessing the matrix-hydroxyapatite (HA) interface. The rotational echo double resonance (REDOR) uses dipolar interaction between ³¹P (found in HA) and ¹³C (found in the organic matrix) to probe mineral-organic interface at the scale of atoms².

To use the REDOR NMR technique on a bone, it is necessary to spin the sample at rapid rate (here 750 000RPM). This rapid rotation poses a problem for inhomogeneous material, particularly the osteoporotic tissue which has a porosity (and thus density) gradient. Most of published work to date overcomes this problem by powdering and drying, which alters the tissues³.

Instead of powdering, here, for the first time, we show the use of the ¹³C-³¹P REDOR NMR to investigate intact human osteoporotic bone. Cortical bone from mid-diaphyseal femurs of 23yr healthy and 77yr old osteoporotic donors were machined to 2x2mm cylinders. The intact bone cylinders were probed in NMR in presence of saline and ¹H, ³¹P, ¹³C Cross Polarization (CP) and ¹³C-³¹P REDOR NMR spectra were recorded at MAS.

We found that citrate⁴ and/or glucosaminoglycans⁵ (GAG) are present as the most-intimately HA-adsorbed organic species in human bone, regardless of donor's age. This finding suggests that citrate/GAG anchors the HA platelets to the organic matrix. Furthermore, the analysis of ¹³C {³¹P} REDOR NMR spectra in bone tissues with different levels of non-enzymatic glycation suggests that hydroxyproline (the outermost amino acid in the collagen triple helix) and alanine proximity to HA changed with elevated glycation level. The ¹³C and ³¹P spectra were in agreement with published literature¹⁻³ and showed no significant difference with donor age. Crystallographic environment of phosphate is thus maintained in osteoporotic bone.

Trabecular Bone Score – TBS – a Novel Method to Evaluate Bone Microarchitecture in Primary Hyperparathyroidism. Barbara Silva^{1*}, Stephanie Boutroy¹, Didier Hans², Chiyuan Zhang³, Julia Udesky⁴, Donald McMahon⁵, Marcella Walker³, John Bilezikian⁵. ¹Columbia University Medical Center, USA, ²Lausanne University Hospital, Switzerland, ³Columbia University, USA, ⁴Columbia University Medical Center, USA, ⁵Columbia University College of Physicians & Surgeons, USA

Primary hyperparathyroidism (PHPT), a common endocrine disorder, is characterized primarily by biochemical and densitometric abnormalities. Typically, bone density by DXA is reduced at the predominantly cortical 1/3 radius while cancellous bone (e.g., lumbar spine) is generally preserved. These findings have been confirmed by bone biopsies. Since DXA does not directly assess bone microarchitecture, and bone biopsies are not routinely performed, a non-invasive approach to the evaluation of skeletal microstructure would be helpful. Trabecular Bone Score (TBS) is a novel gray-scale textural analysis to estimate trabecular microarchitecture from the AP Spine DXA. TBS correlates well with more direct measures of bone microarchitecture independent of BMD (Hans et al. 2011. *J Clin Densitom* 14:302-312). In this study, we compared TBS with High Resolution peripheral Quantitative Computed Tomography (HRpQCT, Scanco Medical AG, Switzerland), an established but not readily available approach to measuring microstructure of bone.

Materials & Method: 22 women (66.9 ± 8.6 yr) with well-characterized PHPT (elevated serum calcium and PTH levels) were studied. AP spine and hip BMD were assessed by DXA (QDR 4500, Hologic Inc, USA), and site-matched spine TBS parameters were extracted from the DXA image using TBS iNsign software (v1.9, Medimaps SA, France). Bone microarchitecture of the distal radius and tibia was

assessed by HRpQCT. Correlations between BMD, HRpQCT parameters and TBS were calculated.

Results: The mean (SD) TBS was 1.288 ± 0.123 (~ partially degraded microstructure). Correlations between TBS and BMD were positive at the lumbar spine ($r=0.39$), femoral neck ($r=0.36$) and total hip ($r=0.28$) but not significant. However, the relationships between TBS and HRpQCT parameters (Table) were positive and significant in terms of total, cortical, and trabecular volumetric BMD at both radius and tibia. After adjusting for weight, all HRpQCT parameters, except trabecular thickness, correlated significantly with TBS.

Conclusion: These data demonstrate that TBS has the potential to provide microstructure information in PHPT. The value of this approach rests with the facile availability of DXA and its routine use in PHPT. With significant correlations between TBS and microstructural indices by HRpQCT, a method that has greater resolving power but is not generally available, TBS could become a very helpful clinical tool in the assessment of skeletal involvement in PHPT.

Correlation between TBS and HRpQCT parameters:

| HRpQCT parameters | Relationship with TBS (correlation coefficient) | | |

Viscoelastic Mapping of Transmenopausal Bone Biopsies. Sara Campbell¹, Philip Yuya², Ben Polly³, Donna Hurley¹, Joseph Turner⁴, Joan Lappe⁵, Robert Recker⁵, Mohammed Akhter⁵. ¹National Institute of Standard & Technology, USA, ²Clarkson University, USA, ³National Renewable Energy Laboratory, USA, ⁴University of Nebraska, USA, ⁵Creighton University Osteoporosis Research Center, USA

Trabecular bone architecture has been shown to deteriorate in postmenopausal, osteoporotic women, yet the changes in the intrinsic material properties of bone during the transmenopausal period are uncertain. The general hypothesis for this work is that material properties of trabecular bone are affected by change in hormonal status at menopause soon after final menses. Here, we used atomic force microscopy (AFM) methods to measure viscoelastic properties (storage and loss modulus E' and E'' , respectively) at the nanoscale. The nanoscale spatial resolution of AFM enables measurement of material properties without the contribution of voids and pore spaces. In a previously reported study (Recker *et al.*, 2004), we obtained transilial bone biopsies from women on entry (pre-menopausal and >age 46) and at 12 months past the last menstrual period. In this preliminary work, we applied contact resonance force microscopy (CR-FM), a dynamic contact mode of AFM, on a pair of specimens from the previous study. The specimens were prepared with a flat surface (~155 nm roughness) by grinding with 600, 800, and 1200 grit sand papers and then polishing with 1 mm and 0.25 mm diamond slurry. A total of 14 point maps were acquired, each consisting of a 10 mm x 10 mm region (32 x 32 = 1024 pixels, 0.32 mm/pixel width). Absolute values of E' and E'' for the CR-FM data were obtained with use of dynamic nanoindentation values on the pre-menopausal sample as reference. Nanoindentation and CR-FM values for both E' and E'' declined in the postmenopausal bone biopsies in this pair (Table), consistent with nanoindentation results in 15 biopsy pairs (Polly *et al.*, 2012). The difference in test frequency between the two techniques (~1 MHz for CR-FM and 200 Hz for nanoindentation) likely contributes to measurement variations. Increased remodeling rates have been reported in postmenopausal women (Recker *et al.*, 2004), suggesting greater heterogeneity with respect to gradation in mineralization. Although no fractures were reported in women from the original study, the greater variation in mineralization may be responsible for lower values of E' and E'' in postmenopausal women. These results demonstrate how viscoelastic CR-FM mapping enables nanoscale characterization of material properties that may be affected by increased remodeling rates in postmenopausal women.

| sample | NI E' (GPa) | NI E'' (GPa) | CR-FM E' (GPa) | CR-FM E'' (GPa) |

Bone Mineral and Material Properties in a Patient with Alendronate-Associated Atypical Femur Fracture Before and After Two Years Treatment with Teriparatide. Steven Ing^{*1}, Hartmut Malluche², Marie-Claude Faugere², Daniel Porter³, David Pienkowski³. ¹The Ohio State University, USA, ²University of Kentucky Medical Center, USA, ³University of Kentucky, USA

Atypical femur fractures have been reported as a potential complication of long-term alendronate treatment. We performed bone biopsies in a 62-year old white female patient after 12 continuous years of alendronate treatment, 1) at time of spontaneous atypical left femur fracture (bone pain in the left femur starting 2 years before fracture) and stress fracture of the right femur diagnosed by technetium bone scanning, and 2) 22 months after switching from alendronate to daily treatment with teriparatide.

Bone samples were processed undecalcified for bone histology and assessment of bone quality by Fourier transformed infrared spectroscopy (FTIR). Results were compared with age and gender matched controls.

The first bone biopsy showed: low cancellous bone volume, reduced trabecular thickness, low osteoblast bone interface, mildly elevated osteoclast bone interface and dystrophic osteoclasts. The second biopsy showed: high cortical porosity, a mild increase in osteoblast and osteoclast bone interface, and normal osteoclasts. Bone mineral and material properties are shown in the Table.

In conclusion, this patient with bilateral fractures after long-term alendronate treatment, had: abnormally high mineral-to-matrix ratio, abnormally low carbonate-to-phosphate ratio associated with suppressed bone turnover, and dysmorphic osteoclasts. Teriparatide treatment results in: decrease in mineral-to-matrix ratio to normal levels, increase in carbonate-to-phosphate ratio to the normal range, and decrease in collagen crosslinking within the normal range. These findings might result from: 1) cessation of alendronate use, 2) use of teriparatide, 3) changes in bone turnover, or 4) a combination of any of these.

| Table | Baseline after 12 yrs. alendronate | After 22 months teriparatide | Controls (n=12) |
|-------------------------------------|------------------------------------|------------------------------|-----------------|
| Mineral-to-Matrix Ratio | 4.54 ± 0.51* | 3.90 ± 0.41* | 3.68 ± 0.23 |

Histomorphometry and Loss Tangent Changes in OVX Rat Cortical Bone with Combination Treatment. Xiao Yang^{*}, Taeyong Lee, PADMALOSINI MUTHUKUMARAN. National University of Singapore, Singapore

Loss tangent ($\tan \delta$) has been demonstrated as an important surrogate to characterize bone strength. However, change of $\tan \delta$ in rat bone associated with ovariectomy was never studied in literature. As an effective animal model in evaluating osteoporotic drug efficacy, standardization of $\tan \delta$ measurement in SD rat is of great value. Hence, we conducted a study on the ovariectomized rat femur cortical bone to investigate the $\tan \delta$, BMD and bone area changes response to ovariectomy.

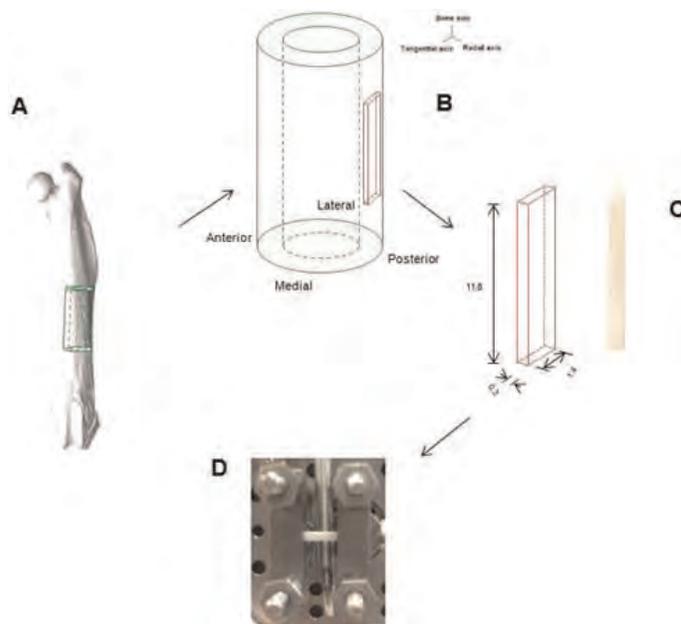

SD rats were divided into 5 groups: SHM, OVX, PTH, IBN and COM group. The rats from OVX group received ovariectomy surgery, whilst rats in SHM group received sham surgery without removing ovary organ. PTH group receive 10 µg/kg weekly PTH administrations. IBN group received 7 µg/kg ibandronate administrations. COM group received both. Rats were euthanized, 30 femurs were harvested after 3 months. $\tan \delta$ was obtained using the Dynamic Mechanical Analyzer (DMA), which produces an oscillating stress on the bone specimen so that the resultant strain can be measured. Specimens were subjected to a single cantilever bending stress (frequency range: 0.01 Hz – 15Hz) at physiological temperature (37 °C). Cortical BMD (Ct. BMD), cortical area, periosteal perimeter, endocortical perimeter, medullary area, Y-axial stress-strength indices (SSIy) was measured by pQCT.

Although there is no significant change occurred in Ct. BMD between SHM and OVX, the measured $\tan \delta$ of OVX bones was significantly lower than SHM ($p<0.001$). It worth noticing that the cortical area of OVX ($6.5 \pm 0.5 \text{ mm}^2$) was different from SHM ($7.4 \pm 0.4 \text{ mm}^2$) significantly. OVX has both larger periosteal perimeter ($14.9 \pm 0.3 \text{ mm}^2$) and endocortical perimeter ($11.8 \pm 0.6 \text{ mm}^2$) than SHM ($14.0 \pm 0.4 \text{ mm}^2$ and $10.1 \pm 0.6 \text{ mm}^2$). Among treatment groups, PTH and COM has the largest periosteal perimeter, while IBN and COM has the largest endocortical perimeter. Thus the resultant cortical area showed an additive effect in COM group. Furthermore, $\tan \delta$ of COM was significantly higher than mono treatments.

Our results suggest that, periosteal formation and endosteal resorption induced by ovariectomy surgery may cause the thinning of cortical shell in OVX rats, while the treatment can alter the configuration. In dependent of area, $\tan \delta$ of different groups varied, which suggests that there is a change in load bearing capacity between the groups.

Testosterone Treatment Has Differential Effects on Trabecular and Cortical Bone Strength in Men with Hypopituitarism. Mona Al Mukaddam^{*1}, Chamith Rajapakse², Yusuf Bhagat¹, Wensheng Guo³, Jeremy Magland¹, Felix Werner Wehrli⁴, Peter Snyder¹. ¹University of Pennsylvania, USA, ²University of Pennsylvania School of Medicine, USA, ³University of Pennsylvania, USA, ⁴University of Pennsylvania Medical Center, USA

Deficiencies of testosterone (T) and growth hormone (GH) result in bone loss. Replacement of T in hypogonadal men leads to improvement in BMD, trabecular structure and bone strength. Replacement of GH in men with GH deficiency leads to improvement in BMD. The aim of this study was to determine the effects of T and GH on bone strength assessed by microMRI-based finite element analysis.

Thirty two men (age 50 ± 15 yr) with severe deficiencies of T and GH due to hypopituitarism but no prior treatment for those deficiencies were randomized to receive T alone (n=15) or T+GH (n=17) for two years. The doses of T and GH were adjusted to keep the serum concentrations of T and IGF-1 in their mid-normal ranges. MicroMRI of the distal tibia was performed at baseline and after 12 and 24 months of treatment. MicroMRI at 1.5 Tesla field strength yielded $137 \times 137 \times 410 \mu\text{m}^3$ voxels that were converted to hexahedral finite elements. Micro-finite element (μFE) models for cortical and trabecular bone were generated using an operator-guided segmentation program that delineated endosteal and periosteal boundaries. Uniaxial-simulated compression yielded axial stiffness, a marker of bone strength.

The mean serum T concentration increased from severely low before treatment to normal during months 3-24 of treatment in both the T only (67.9 to 616 ng/dL) and T+GH (91.6 to 627 ng/dL) groups. The mean serum IGF-1 concentration increased

from low before treatment to normal during months 3-24 of treatment (59.6 to 151 ng/mL) in the T + GH group and remained low in the T only group (41.7 to 47.1 ng/mL).

Both T alone and T+GH increased trabecular bone axial stiffness from 0 to 24 months (Table 1, Fig. 1a), but the increase with T+GH (10.9%; $P < 0.01$) was not significantly greater than that with T alone (8.5%; $P < 0.05$). In contrast, cortical bone axial stiffness decreased significantly in both treatment arms from 0 to 12 months (T alone, -7.3%, $P < 0.05$; T+GH, -10.2%, $P < 0.01$) and from 12 to 24 months tended to decrease further in the T only group (-1.0%, NS) but increased in the T+GH group (7.2%, $P < 0.05$) (Table 1, Fig. 1b).

We conclude that in men with hypopituitarism, testosterone treatment for two years, with or without growth hormone, significantly increased trabecular bone strength but, during the first year, significantly decreased cortical bone strength.

Table 1. Effect of testosterone and growth hormone treatment on μFE -derived stiffness in the distal tibia

| Duration of treatment | Axial Stiffness (GPa, mean \pm SE) | | | |
|-------------------------------|--------------------------------------|-----------------|-----------------|-----------------|
| | Baseline | 12 months | 24 months | |
| Testosterone | Trabecular Bone | 1.34 \pm 0.13 | 1.43 \pm 0.16 | 1.48 \pm 0.16 |
| | Cortical Bone | 0.64 \pm 0.07 | 0.60 \pm 0.07 | 0.58 \pm 0.07 |
| Testosterone + Growth Hormone | Trabecular Bone | 1.31 \pm 0.10 | 1.39 \pm 0.10 | 1.43 \pm 0.12 |
| | Cortical Bone | 0.59 \pm 0.04 | 0.53 \pm 0.05 | 0.55 \pm 0.04 |

Effects of Spaceflight and a Sclerostin Antibody Countermeasure on the Mechanical Properties of Bone in Mice. Anthony Lau^{*1}, Alicia Ortega², Mary Bouxsein³, Ted Bateman⁴, Andrea Hanson⁵, Travis Pruitt⁶, Eric Livingston⁷, Colin Smith⁸, Angelica de Rosa⁷, Eric Lai⁷, Laura Bowman¹, Louis Stodieck⁹, Rachel Ellman³, Jordan Spatz¹⁰, Kelly Warmington¹¹, HL Tan¹¹, Dave Hill¹¹, Shweta Maurva², Andy Cureton², Sutada Lotinun¹², Chris Paszty¹³, Virginia Ferguson⁹. ¹University of North Carolina at Chapel Hill, USA, ²University of Colorado, USA, ³Beth Israel Deaconess Medical Center, USA, ⁴University of North Carolina, USA, ⁵University of Washington, USA, ⁶Clemson University, USA, ⁷University of North Carolina- Chapel Hill, USA, ⁸North Carolina State University, USA, ⁹University of Colorado, USA, ¹⁰Harvard-MIT Division of Health Sciences & Technology (HST), USA, ¹¹Amgen, USA, ¹²Harvard School of Dental Medicine, USA, ¹³Amgen, Inc., USA

Skeletal unloading from spaceflight reduces bone volume and mineral density; how this loss translates to functional change in strength and stiffness is not well known. To study this, 30 mice were flown on Space Shuttle flight STS-135 for 13-days (FL) with half treated with each vehicle (VEH, n=15) and a sclerostin antibody countermeasure (SclAb, n=15). Corresponding ground control (GC) groups were similarly treated. Bone strength was assessed through computational finite element modeling (FEM) at the proximal tibia, and mechanical testing of the femur diaphysis. FEM was created from microCT images (10 μm resolution) for a 1.0 mm thick tibial cross section just inferior to the proximal growth plate. Axial compression to 50 μm (5% deflection) of the proximal tibia was performed to determine the effective stiffness. Three-point bending the femur was performed, assessing yield and maximum forces (Pe and Pm) at the femur mid-diaphysis. Spaceflight Effects: Tibia FEA showed FL-VEH treated mice experienced declines in bone volume (BV) and bone stiffness of -17% and -35%, respectively, compared to GC-VEH mice. FEM allowed separation of trabecular and cortical compartment contributions to overall bone stiffness; FL-VEH mice had a -32% decrease in trabecular BV, which corresponded to a -45% decrease in stiffness of

the trabecular region. Three-point bending of the femur resulted in -9% and -11% declines in Pe and Pm, respectively, compared to GC-VEH. Sclerostin Antibody Effects: SclAb countermeasure increased proximal tibia BV +42% (GC), +39% (FL) and FEM stiffness +61% (GC) and +62% (FL). FEM analysis of tibial trabecular compartment shows greater effects of SclAb on BV for both GC (+88%) and FL (+96%) mice; and trabecular stiffness contribution increased +107% (GC) and +133% (FL). In femur three-point bending, SclAb treatment resulted in Pe increases of +18% (GC) and +23% (FL); while Pm increased +20% and +24% for GC and FL, respectively, with SclAb. Conclusion: The unloading environment caused a significant loss in BV, strength and stiffness in both the tibia and femur, with greater effects in trabecular bone. The SclAb largely reversed the spaceflight-mediated deterioration, with generally similar effects in GC and FL mice. Tibial FEM correlated well with femur bending strength, providing a useful, non destructive analysis technique.

Local Changes Due to Bone Remodelling are Triggered by Mechanical Loading. Patrik Christen^{*1}, Rafaa Ellouz², Stephanie Boutroy³, Roland Chapurlat⁴, Keita Ito⁵, Bert Rietbergen⁶. ¹Eindhoven University of Technology, The Netherlands, ²Université de Lyon, France, ³Columbia University Medical Center, USA, ⁴E. Herriot Hospital, France, ⁵Eindhoven University of Technology, Netherlands, ⁶Eindhoven University of Technology, The Netherlands

Bone has the remarkable ability to adapt to its mechanical environment in order to withstand external forces. It is generally assumed that bone achieves this in an on-going process of bone remodelling where bone cells add bone at high-load locations and remove bone at low-load locations (Wolff's law). In a recent animal experiment it was found that, indeed, a stochastic relationship between local loading conditions and bone resorption or formation at the microscopic level exists for bone adapting to higher loading (Schulte F.A., PhD Thesis ETH Zurich, 2011). With the development of high-resolution peripheral quantitative CT (HR-pQCT) imaging techniques and micro-finite element (micro-FE) analyses, it is now possible to also quantify bone microstructure and tissue loading in human bone *in vivo*. The goal of the present study was to investigate if a relationship between bone tissue loading and bone formation or resorption can be found as well for human bone during normal bone turnover.

Five postmenopausal women were measured by HR-pQCT at the distal tibia at baseline and after 6 years. Using 3D registration of baseline and follow-up images, voxels at the bone surfaces were classified as belonging either to a resorption site, a formation site, or an unchanged site. Resorption and formation were defined as a change in density exceeding 200 mg HA/cm³. Micro-FE models were created from the baseline images, and a previously developed bone loading estimation method was used to determine a realistic bone loading history for each subject (Christen *et al.*, BMMB, 2011). The bone tissue strain energy density (SED) was calculated for this loading history and histograms were made for the voxels classified as bone loss and bone gain.

The histograms showed that both bone loss and bone gain were strongly correlated with tissue loading, with bone loss decreasing and bone gain increasing with increasing tissue loading (Fig. 1). Resorption dominated over bone gain, which is in agreement with the net loss of bone found during aging in these women.

This study is the first to report such relationships for human bone. In *in vivo* human case, the resolution of the images (~82 microns) is not high enough to identify individual resorption cavities, but resulting microstructural changes could be well recognized. In conclusion: our results suggest that load-adaptive remodelling at the bone micro-level may play an important role also in humans during normal bone turnover with aging.

PTH Enhances Mechanical Stress-induced Osteoblast Proliferation in Calvarial Derived Osteoblasts via Up-regulation of CyclinD1 Expression. Shirakawa Jumpei^{*1}, Yoichi Ezura², Takuya Notomi³, Tadavoshi Hayata⁴, Tetsuya Nakamoto¹, Shuichi Moriya⁵, Ken Omura⁶, Masaki Noda¹. ¹Tokyo medical & dental university, Japan, ²Tokyo Medical & Dental University, Medical Research Institute, Japan, ³GCOE, Tokyo Medical & Dental University, Japan, ⁴Medical Research Institute, Tokyo Medical & Dental University, Japan, ⁵Department of Orthopaedics, Juntendo University School of Medicine, Japan, ⁶Oraland Maxillofacial Surgery of Tokyo Medical & Dental University, Japan

Mechanical stimulation regulates bone homeostasis, and increases osteoblast activity, through gene expression, protein synthesis, cell proliferation and differentiation. Exposure to mechanical forces promotes osteoblast proliferation and bone remodeling. Parathyroid hormone (PTH), a systemic factor regulating bone metabolism also stimulates osteoblast activity via intermittent administration. A positive role of PTH in the cell cycle has been observed in osteoblasts to induce a cyclin D1 expression. Relationship between PTH and mechanical stimulation has been postulated, but the molecular link between mechanical stimulation and PTH in osteoblast proliferation and osteogenesis remains unclear. We hypothesized that certain factors could affect osteoblast proliferation interactively upon mechanical and PTH stimulation. *In vitro* experiments, indicated the proliferative effects of PTH and flow-induced mechanical stress in the calvaria derived osteoblastic cell line (MC3T3E1). A trend of enhancement was observed by both treatments. To examine *in vivo* effects, we subcutaneously injected PTH(1-34) daily (40µg/kg/day) to the mice subjected to calvarial suture expansion by dental wire. The initial force was around 2 N. PTH injection tended to enhance cyclin D1 expression induced by mechanical expansion. These data indicate that mechanical stress and PTH synergistically enhance bone formation via stimulation of osteoblasts proliferation.

Vibration Induced Mechanical Signals that Increase Proliferation and Osteogenic Commitment of Mesenchymal Stem Cells. Gunes Uzer^{*}, Sarah Manske, Stefan Judex, Stony Brook University, USA

Human, animal and cell studies indicate that the application of vibrations can be anabolic and/or anti-catabolic to bone. The specific mechanical signal to which cells respond has not been identified, in part because the generated fluid shear is coupled with the magnitude of the applied acceleration in most *in vivo* and *in vitro* studies. We recently developed an *in vitro* model in which acceleration magnitude and fluid shear can be controlled independently. We hypothesized that vibrations in the presence of very low fluid shear conditions will enhance mesenchymal stem cell (MSC) proliferation and promote osteogenic commitment. Cells were vibrated at 100Hz, 1g acceleration magnitude for 30 minutes every day. These vibration parameters exposed cells to peak fluid shear of 0.28Pa, a level that is substantially below the threshold typically required to elicit a response in MSCs. Cells were maintained in standard culture medium or supplemented for adipogenic and osteogenic differentiation. When vibrated in standard culture medium, MSC proliferation increased by 56% ($p < 0.001$) at day three. When the differentiation mediums were used on confluent cultures, the phenotypes were not evident at the molecular level until day five. At this time point, the application of vibrations promoted transcriptional regulation towards osteogenesis. Compared to non-vibrated controls, RUNX2 expression in osteogenic cultures was 24% greater ($p < 0.01$) and PPRG expression in adipogenic cultures was 10% smaller ($p < 0.05$). Without any differentiation medium, vibrations did not induce phenotypic changes. Vibrations significantly increased the expression of c-Fos, an immediate early transcription factor, in all mediums, demonstrating that the vibration-induced accelerations were sensed by MSCs. Together, the data show that oscillatory accelerations, applied without generating significant fluid shear stresses can play a role in enhancing MSC proliferation and their osteogenic commitment at the transcriptional level. We are currently investigating whether fluid shear can contribute to this response in an additive or synergistic manner by increasing the range of fluid shear (0.05-2Pa) and acceleration (0.1-2g) magnitudes. Ultimately a better

understanding of the interactions between fluid shear and accelerations is critical for identifying and optimizing vibration regimes.

Influence of Time and Dosing of Indomethacin on Mechanically Induced Bone Formation. Cheryl Druchok^{*1}, Kyle Eastwood², Gregory Wohl¹. ¹McMaster University, Canada, ²Department of Mechanical Engineering, McMaster University, Canada

Introduction: Prostaglandins (PGs) are important signaling factors for bone mechanotransduction. The inhibition of cyclooxygenase, responsible for the synthesis of PGs, with non-steroidal anti-inflammatory drugs (NSAIDs) has been shown to hinder bone formation induced by mechanical stimulation. However, NSAID dosing after exercise was recently shown to enhance bone formation in human subjects (Kohrt, JBMR 2010). The purpose of this pilot study was to examine the effects of Indomethacin dose and timing on bone formation in response to mechanical stimulation in a rat model of mechanical loading.

Methods: Male Sprague Dawley rats (n=20), aged four months were randomly assigned to five groups (n=4/grp) 1) low dose (0.2 mg/kg Indomethacin) administered 2 hours before loading, 2) low dose immediately after loading, 3) high dose (2.0 mg/kg) 2 hours before loading, 4) high dose immediately after loading, or 5) vehicle control. Indomethacin was delivered via a Jello® vehicle. A four-week (11 loading days) forelimb loading protocol, with recovery periods, was used. Right forelimbs were loaded to 21 N for 15 sets of 20 cycles with 20-second rest periods between each set. Left forelimbs served as non-loaded controls. To measure bone formation, fluorochrome labels were administered on day 6 (calcein green) and day 24 (alizarin complexone). Animals were sacrificed on day 27. Following dissection, right and left forelimbs were plastic embedded. Transverse forelimb sections were taken 1 mm distal to the mid-diaphysis. Images were captured by fluorescent microscope. Mineral apposition rate (MAR) was calculated for each of the medial and lateral aspects as total area of new bone encompassed between labels divided by cortical perimeter.

Results: On the lateral aspect of the ulna the group with high dose Indomethacin administered after loading had significantly greater MAR compared to all groups (p<0.05) except vehicle control (p=0.051) (Fig 1). There were no significant differences in MAR on the medial aspect (p>0.05).

Conclusions: Though NSAIDs have been shown to impair mechanically-induced bone formation, our current data in the rat model confirm recent findings in humans, that NSAID dosing after mechanical loading can enhance bone formation. These data suggest that the anti-inflammatory effects of NSAIDs after loading may be beneficial for bone formation.

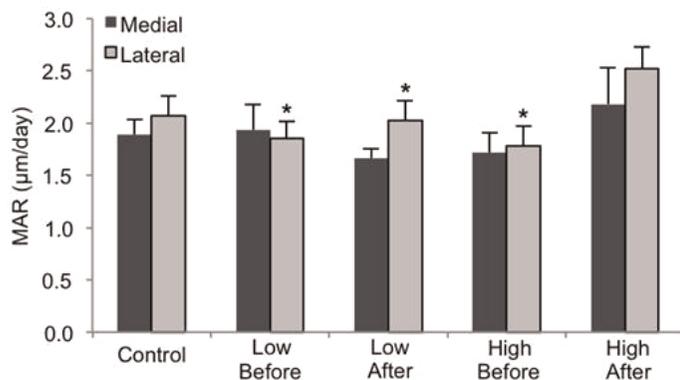

Figure 1. Average MAR on the medial and lateral aspects of the rat ulna. There were no differences in MAR between groups on the medial aspect (p>0.05). The High After group had significantly greater MAR on the lateral aspect compared to the Low Before, Low After and High Before groups. (*p<0.05 compared to High After)

Stepping Out: Developmental Changes in Tibial Trabecular Bone Microarchitecture and Kinematics of Early Human Walking. James Gosman¹, David Raichlen², Zachariah Hubbell^{*3}, Simone Sukhdeo⁴, Leah Souza⁴, Timothy Ryan⁴. ¹The Ohio State University, USA, ²University of Arizona, USA, ³The Ohio State University, USA, ⁴Pennsylvania State University, USA

The objective of this research is to examine how human locomotor development contributes to changes in tibial trabecular microarchitecture from homogeneous, high density morphology to one with high spatial differentiation. Of special concern is linking the kinematics of the initiation and maturation of human walking to ontogenetic changes in trabecular bone morphology. The degree of anisotropy (DA) is used as a morphological corollary to the variability of joint kinematics, representing the quality of loading as opposed to the quantity of loading. The hypothesis tested predicts that the pattern of ontogenetic within-tibial variability in the degree of anisotropy of trabecular bone in the proximal and distal tibia is associated with the age-related variability in gait kinematics. High-resolution x-ray CT scans were collected for the tibia of 70 individuals from the Norris Farms #36 skeletal collection ranging in age from neonate to adult. The entire bone was scanned with voxel dimensions less than 0.05 mm. 3D trabecular bone fabric structure was quantified for multiple cubic volumes of interest from the proximal and distal tibial metaphyses using the BoneJ plugin within ImageJ. Resolution-corrected morphometric structural analysis included bone volume fraction, trabecular number, trabecular thickness, and the degree of anisotropy (DA) from neonate to age 12. The DA was calculated using the mean intercept length (MIL) method. In addition, DA data were visualized by 3D rose diagrams generated by the Quant3D software. Gait analyses were undertaken on 16 age-grouped children between the ages of 1 and 9 years to establish new data for joint kinematics/kinetics coefficients of variation (CV) across age classes. The results of this work demonstrate that individual CVs versus age for joint angles are significant in the medial/lateral axis at the knee and ankle with the greatest variability in the youngest. Scatterplots of DA vs. age support the hypothesis of increased trabecular bone microarchitectural variability in the younger ages at the proximal, but not the distal tibia. Our conclusions from these data support the concept that the kinematic characteristics associated with the initiation of human gait contribute to intra-tibial trabecular bone microarchitectural heterogeneity and differentiation.

In-vivo Evaluation of the Progress of Bone Fracture Healing in a Rat Model: a Non-Invasive Raman Spectroscopy technique. Paul Okagbare^{*1}, Dana Begun², Francis Esmonde-Whilte³, Steven Goldstein⁴, Michael Morris².
¹Department of Chemistry, University of Michigan, USA, ²University of Michigan, USA, ³University of Michigan, USA, ⁴University of Michigan Orthopaedic Research Lab, USA

Introduction: Bone regeneration is a complex biological process. Although, the biochemical pathway of fracture healing has been intensively investigated, the mechanism of impaired healing of bone tissues remains unclear. Approximately 5 – 15% of “fractures at risk” have delayed healing, non-union and require repeated operative intervention. Where allografts are used for repair of large defects, failure rates approach 25%. Consequently there is a need for new techniques to assess and monitor progress of bone regeneration and allograft incorporation. Raman spectroscopy can complement existing techniques because it provides detailed information about the mineral and matrix composition of bone tissue. In this study, we report non-invasive Raman spectroscopy for in-vivo assessment of the progress of bone fracture healing in a rat model. The same technique can be used to study implant integration and to report on the progress of therapeutic interventions.

Methods: In an experiment approved by our institutional animal use committee, a 1.5 mm defect was created in the mid-diaphysis of a rat tibia. The defect was stabilized using a unique internal fixation plate. Following the surgery, the rats were monitored by Raman spectroscopy at two week intervals for eight weeks. Spectroscopy was performed with a fiber optic probe comprising a single laser delivery fiber and an array of signal collection fibers in contact with the skin of the rat. The fibers were mounted in a Delrin holder surrounding the tibia to allow reproducible fiber positioning.

Results: We followed the time course of fracture healing using well-established correlations between Raman spectral features for bone mineral phosphate and carbonate and for matrix collagen content. We observed callus formation during the first two weeks, followed by deposition of bone mineral and increasing mineralization with time. Mineral maturity (decreasing monohydrogen phosphate content) and increasing mineral crystallinity also increased with time.

Conclusions: This new spectroscopic methodology enables non-invasive *in-vivo* assessment of the progress of bone fracture healing and bone-graft incorporation in rodent models and is extendable to other *in-vivo* animal measurements. With current technology the technique may also be scalable for use in human subjects at anatomical sites where the periosteal surface of the bone is within about 1 cm of the skin.

Studies on the Distribution of Mineral Elements in the Tooth of Zinc - deficient Rats. Yoshimi Teraki^{*}, Sagami Matsugae clinic, Japan

Abstract:Element analysis of plaque-like black deposits noted on the surface of teeth in zinc-deficient rats at necropsy was performed. Rats deficient in zinc show signs of abnormality in iron metabolism and increase of accumulation of iron in plasma and tissues.

This study was designed, therefore, to examine the plasma and salivary levels of iron and other elements and to determine the distribution of mineral elements in the dental substances of zinc-deficient rats by contact microradiography, electron probe micro-analysis (EPMA) and X-ray fluorescent element mapping spectrometry (XEMS) on ground sections of teeth. Rat tooth specimens were analyzed also for zinc, iron, copper and manganese using colorimetry and Inductively Coupled Plasma, ICP.

EPMA and XEMS analysis revealed the presence of iron on the enamel surfaces of maxillary molars teeth of zinc-deficient rats showed higher iron concentration in mixed saliva and in plasma, compared with the controls.

Thus, the sign of abnormality in iron metabolism noted in oral cavity of zinc-deficient rats was investigated by EPMA and XEMS analysis, with discussion on the origin of supradental iron deposits.

Comparative Study of the Effects of Milk and Dairy Products on Bone Metabolism in Ovariectomized Rats. Rieko Tanabe^{*1}, Mayu Haraikawa², NATSUKO SOGABE³, Aoi Sugimoto², Yuka Kawamura², Satoshi Takasugi⁴, Masashi Nagata⁵, Akira Yamaguchi⁶, Tadahiro Iimura⁷, Masae Goseki-Sone⁸. ¹Department of Food & Nutrition, Faculty of Human Sciences & Design, Japan Women's University, Japan, ²Department of Food & Nutrition, Faculty of Human Sciences & Design, Japan Women's University, Japan, ³KOMAZAWA WOMEN'S UNIVERSITY, Japan, ⁴Meiji Co., Ltd., Japan, ⁵Meiji Co., Ltd., Japan, ⁶Tokyo Medical & Dental University, Japan, ⁷Tokyo Medical & Dental University, Global Center of Excellence Program, Japan, ⁸Japan Women's University, Japan

Calcium is one of the important nutrients for bone health, and the best source of calcium is food such as milk and dairy products. In this study, we compared the effect of milk, yogurt, or whey on the bone strength, body composition, and serum biomarkers using ovariectomized rats. Forty 12-week-old female Sprague-Dawley rats were ovariectomized (OVX), and another nine rats received a sham operation (Sham-Cont). After a one-week recovery period, the OVX rats were divided into 4 dietary groups: OVX-control group (OVX-Cont), 17% skimmed milk powder diet group (OVX-Milk), 17% powdered fermented milk diet group (OVX-Yogurt), and 12% whey powder and 6% whey protein extract diet group (OVX-Whey) (n=10 in each group). The calcium content was 0.5% in all 5 groups. Eighty-four days after the beginning of the experimental diet, the total bone mineral density of lumbar vertebrae was significantly higher in the OVX-Milk and OVX-Yogurt group than in the OVX-Cont group (p<0.01, respectively). Bone mineral contents of lumbar vertebrae were significantly higher in the OVX-Milk and OVX-Whey group than in the OVX-Cont group (p<0.05 and p<0.01, respectively). Interestingly, the level of serum 1 α , 25-dihydroxyvitamin D3 was significantly higher in the OVX-Cont group than in the Sham-Cont group, and significantly lower in the OVX-Milk, OVX-Yogurt, and OVX-Whey groups than in the OVX-Cont group (p<0.001, respectively). The level of serum fibroblast growth factor 23 was significantly lower in the OVX-Cont group than in the Sham-Cont group (p<0.001), and significantly higher in the OVX-Milk, OVX-Yogurt, and OVX-Whey groups than in the OVX-Cont group (p<0.05, respectively). These findings were confirmed by histological sections of the proximal tibial metaphysis. Further studies on the effects of dietary milk or dairy products on the regulation of bone metabolism would provide valuable data for the prevention of lifestyle-related disorders, including osteoporosis.

Circumferential Periosteal Division of Diaphysis of Rat Femur Stimulates Endochondral Ossification of Growth Plate. Shinjiro Takata^{*}. Institute of Health Biosciences, University of Tokushima Graduate School, Japan

Circumferential periosteal division (CPD) of diaphysis of femur of developing rat produces longitudinal overgrowth. Endochondral ossification of growth plate stimulates longitudinal overgrowth of tubular bone. Here we report the mechanisms of longitudinal CPD-induced overgrowth of femur.

Seventy-two Wistar rats aged 8 weeks were used for this study. Periosteum of diaphysis of the right femur was divided circumferentially (CPD group), and the left femur was control (Control group). Longitudinal length of CPD and Control groups 6 weeks after CPD were 41.0 \pm 0.9 and 39.4 \pm 0.7 mm (p=0.0052, n=6), respectively, indicating that overgrowth of longitudinal length reached to approximately 4.1% of Control group. Distal growth plate is responsible for approximately 91.5% of longitudinal overgrowth (n=6).

Bone histomorphometry showed that CPD increased longitudinal growth rate, mineral apposition rate, bone volume, osteoid volume, trabecular number and thickness of femur (n=6). Histological findings showed that the width of distal growth plate and the number of hypertrophic chondrocytes of CPD group were greater than those of Control group 4 weeks after CPD.

These results showed that CPD stimulates endochondral ossification of growth plate to produce longitudinal overgrowth of femur of developing rat. These facts suggest that periosteum plays an important role to regulate endochondral ossification of growth plate, and that CPD might become promising treatment to lengthen tubular bone of pediatric patients with leg length discrepancy.

IFT80 Promotes Chondrogenic Differentiation by Regulating Hedgehog and Wnt Signal Pathways. Xue Yuan^{*1}, changdong wang², Shuying Yang³.

¹University At Buffalo, USA, ²University at Buffalo, USA, ³State University of New York At Buffalo, USA

Partial mutation of intraflagellar transport 80 (IFT80) in humans causes Jeune asphyxiating thoracic dystrophy (JATD) and short-rib polydactyly syndrome type III. These disorders have severe bone development abnormalities. However, the role and mechanism of IFT80 function in chondrogenic proliferation and differentiation remain largely unknown. We hypothesize that IFT80 is required for the formation, maintenance, and function of cilia and plays a critical role in the proliferation and differentiation of bone marrow-derived stromal cells (BMSCs) by regulating the Hedgehog (Hh) and Wnt signaling pathways. To test this hypothesis, we first analyzed the IFT80 expression pattern and found that IFT80 was predominantly expressed in bone tissue and mouse BMSCs. Silencing IFT80 caused a loss of cilia in mouse BMSCs and the promotion of cell proliferation by increased expression of Cyclin D1, Cyclin E and Cyclin-dependent kinase 1 (CDK1). Silencing IFT80 also promoted the transition of BMSCs from the G0/G1 stage to the S and G2/M stages. Moreover, silencing IFT80 in BMSCs resulted in impaired chondrogenic differentiation accompanied by the decreased expression of collagen II, aggrecan, and Gli2 and increased β -catenin expression. The overexpression of Gli2 as well as treatment with smoothed agonist (SAG), an agonist of the Hedgehog signaling pathway, in IFT80-silenced cells could rescue the chondrogenic differentiation deficiency, indicating that IFT80 regulates chondrogenic proliferation and differentiation by down-regulating the Hedgehog pathway and up-regulating the Wnt/ β -catenin signaling pathway. Overall, IFT80 functions as an inhibitor of proliferation and an activator of differentiation during the chondrogenic progress.

Limb- and Sternum-Specific Inactivation of Dullard Gene Causes Severe Defects in Skeletal Development via Alteration of TGF- β Signaling.

Tadayoshi Hayata^{*1}, Yoichi Ezura², Makoto Asashima³, Ryuichi Nishinakamura⁴, Masaki Noda⁵. ¹Medical Research Institute, Tokyo Medical & Dental University, Japan, ²Tokyo Medical & Dental University, Medical Research Institute, Japan, ³National Institute of Advanced Industrial Sciences & Technology (AIST), Japan, ⁴Kumamoto University, Japan, ⁵Tokyo Medical & Dental University, Japan

The transforming growth factor (TGF- β) and bone morphogenetic protein (BMP) signaling pathways play important roles in endochondral bone formation, an essential process for skeletal growth. However, it has also been shown in mouse models that limit of TGF- β signaling by E-selectin-ligand-1, an inhibitor of TGF- β maturation in Golgi apparatus is of importance in endochondral bone formation as well as limit of BMP signaling by BMP inhibitors including Noggin and Smad6. Although our previous in vitro studies revealed that an intracellular factor Dullard acts as an inhibitor of both TGF- β and BMP signaling in bone cells, physiological relevance of Dullard in endochondral bone formation is unknown. In this study, we report that mice lacking Dullard in early limb and sternum mesenchyme with Prx1-Cre system exhibit retardation of ossification. Analysis of Dullard expression using Dullard LacZ knock-in mice revealed its prominent expression in the resting and proliferating chondrocytes, but not in hypertrophic chondrocytes. Although Dullard (Prx1) mutant mice were born according to Mendelian ratio, approximately 70% of the mice died 1 day after birth presumably due to defects in suckling milk, and the rest of them displayed dwarfism and defects in locomotion and died before weaning. Body weight of the Dullard (Prx1) mutant mice was reduced at birth. Soft X-ray and skeletal preparation analyses revealed that Dullard (Prx1) mice showed reduction in length of limb long bones and retardation of ossification in metatarsal and metacarpal bones as well as in sternum. Histological analysis showed occupation of hypertrophic chondrocytes in sternum of the Dullard (Prx1) mice. Luciferase reporter assay using immature murine articular chondrocytes (iMACs) isolated from P0 mice revealed that TGF- β signaling, but not BMP signaling was augmented in Dullard-deficient iMACs after 24-hour treatment. Dullard-deficient iMACs also responded to TGF- β strongly to change cell shape from round to fibroblastic. These results suggest that Dullard regulates endochondral bone formation via suppression of TGF- β signaling in chondrocytes.

Egr-1 Mediates the Suppressive Effect of IL-1 on PPAR γ Expression in Human OA Chondrocytes. Sarah Nebbaki*¹, Fatima Ezzahra El Mansouri², Hassan Fahmi³. ¹Research Center-Hospital Center of Montreal University, Canada, ²Research Center-CHUM, Canada, ³Research Center-CHUM, Canada

Background: Peroxisome proliferator-activated receptor gamma (PPAR γ) is a ligand activated transcription factor and member the nuclear hormone receptor superfamily. Several lines of evidence indicate that PPAR γ have protective effects in osteoarthritis (OA). Indeed, PPAR γ has been shown to down-regulate several inflammatory and catabolic responses in articular cartilage and chondrocytes and to be protective in animal models of OA. We have previously shown that IL-1 down-regulated PPAR γ expression in OA chondrocytes. In the present study we will investigate the mechanisms underlying this effect of IL-1.

Methods: Chondrocytes were stimulated with IL-1, and the level of PPAR γ and Egr-1 protein and mRNA were evaluated using Western blotting and real-time reverse-transcription polymerase chain reaction, respectively. The PPAR γ promoter activity was analyzed in transient transfection experiments. Egr-1 recruitment to the PPAR γ promoter was evaluated using chromatin immunoprecipitation (ChIP) assays. Small interfering RNA (siRNA) approaches were used to silence Egr-1 expression.

Results: We demonstrated that the suppressive effect of IL-1 on PPAR γ expression requires de novo protein synthesis and was concomitant with the induction of the transcription factor Egr-1. CHIP analyses revealed that IL-1 induced Egr-1 recruitment at the PPAR γ promoter. IL-1 inhibited the activity of PPAR γ promoter and overexpression of Egr-1 potentiated the inhibitory effect of IL-1, suggesting that Egr-1 may mediate the suppressive effect of IL-1. Finally, Egr-1 silencing with small interfering RNA blocked IL-1-mediated down-regulation of PPAR γ expression.

Conclusion: These results indicate that Egr-1 contributes to IL-1-mediated down-regulation of PPAR γ expression in OA chondrocytes and suggest that this pathway could be a potential target for pharmacologic intervention in the treatment of OA and possibly other arthritic diseases.

GSN: A Novel Susceptibility Gene for Osteoporosis in Humans. Fei Yan Deng*¹, Wei Zhu², Yong Zeng³, Shu-Feng Lei³, Yao-Zhong Liu², Hong-Wen Deng². ¹Tulane University, USA, ²Tulane University, USA, ³Hunan Normal University, China

Osteoporosis is a public health problem, especially in the females. Low BMD is a risk factor of osteoporosis and has strong genetic determination. Genes influencing the majority of variation of BMD are largely unknown yet. Peripheral blood monocytes (PBM) can serve as progenitors of bone-resorbing osteoclasts and are involved in bone metabolism. Herein, we attempted to identify osteoporosis susceptibility gene(s), through initial proteome profiling of PBM in vivo, and using a strategy of multi-disciplinary and integrative studies.

We recruited 3 independent case-control samples (N=37, 29, 40, respectively) including premenopausal women with extremely low vs. high hip BMD from bottom 20% vs. top 20% of distribution in Caucasian population, and two population samples including 2,286 unrelated Caucasians and 1,627 unrelated Chinese, respectively. We utilized quantitative proteomics methodology to profile PBM proteomes in the 1st case-control sample to discover proteins, thus gene(s), functionally relevant to low BMD. Differentially expressed protein(s) identified were verified by western blotting (WB). Then, comparative analyses at mRNA expression level in PBM were conducted in the 2nd and 3rd case-control samples. For gene(s) also differentially expressed at mRNA level, we further tested association of gene SNPs with hip BMD in the population samples.

Among 2,117 proteins identified in PBM, gelsolin (GSN) was down-regulated 1.7-fold in subjects with low BMD in the 1st sample (p<0.05). Down-regulation of GSN gene expression in low BMD subjects were verified by WB, and further replicated at mRNA level in the 2nd and 3rd samples (p<0.05), respectively. Furthermore, seven SNPs (rs10739594, rs4837827, rs7857673, rs4837832, rs4837835, rs306761, and rs306772) within GSN locus were associated with hip BMD in the Caucasian population (p<0.05). Three of them (rs306761, rs4837827 and rs4837832) were also associated with hip BMD in the Chinese population (p<0.05), suggesting ethnic-general effect of these SNPs on hip BMD.

Based on the above integrative evidence at protein, mRNA, and DNA levels, we conclude that GSN is a significant susceptibility gene involved in the pathogenesis of osteoporosis in humans.

The Thyroid Hormone Transporters Monocarboxylate Transporter 8 and 10 (MCT8, MCT10) Are Expressed Reciprocally in Growth Plate Chondrocytes. Noriyuki Namba*¹, Makoto Abe², Sanae Abe³, Makoto Fujiwara³, Tomonao Aikawa⁴, Mikihiro Kogo⁵, Keiichi Ozono⁶. ¹Osaka University Graduate School of Medicine, Japan, ²Osaka University Graduate School of Dentistry, Japan, ³Osaka University Graduate School of Medicine, Japan, ⁴Osaka University Graduate School of Dentistry, Japan, ⁵Osaka University Graduate School of Dentistry, Japan, ⁶Osaka University Graduate School of Medicine, Japan

Thyroid hormone transporters mediate thyroid hormone transport into the cytoplasm. Among the identified transporters, monocarboxylate transporter 8 (MCT8) has been shown to exclusively transport thyroid hormone. Since thyroid hormone is essential for the normal development of the neurons and the growth plate, untreated congenital hypothyroidism results in severe mental retardation and short stature. The Allan-Herndon-Dudley syndrome, caused by MCT8 mutations, is characterized by severe psychomotor retardation and elevated T₃ levels. Interestingly, growth is not severely retarded in these patients. This led us to hypothesize that chondrocytes utilize transporters other than MCT8 for thyroid hormone uptake. At the 2010 meeting, we reported abundant expression of monocarboxylate transporter 10 (Mct10), a transporter most homologous to Mct8 within the MCT family, in murine chondrogenic ATDC5 cells. Silencing Mct10 mRNA abrogated the effects of thyroid hormone on proliferation and differentiation in these cells. However, to date, the expression of these two transporters in the growth plate has not been clarified.

We thus utilized *in situ* hybridization to localize Mct8 and 10 *in vivo*. Pregnant C57/BL6 mice were humanely killed on embryonic day (E) 18 and humeri including the growth plate were obtained. Digoxigenin-labeled riboprobes were hybridized overnight to 14 μ m sections. Mct10 mRNA was most abundant in the resting zone (RZ) chondrocytes while the signal was weaker in chondrocytes differentiating into the secondary ossification center, the proliferating zone (PZ), as well as the hypertrophic zone (HZ) chondrocytes. In a reciprocal manner, levels of Mct8 mRNA increased with differentiation with the strongest signal observed in the HZ chondrocytes. These results were consistent with the changes in Mct8 and Mct10 mRNA levels during ATDC5 differentiation evaluated by quantitative real-time (qRT)-PCR.

The major thyroid hormone receptor in the growth plate, thyroid hormone receptor alpha 1 (TR α 1), is expressed in the RZ and PZ chondrocytes but not in HZ chondrocytes. This, in combination with the above results, indicates that Mct10 is expressed in early stage chondrocytes concomitantly with TR α 1, thus suggesting that Mct10 plays a significant role in thyroid hormone signaling in the growth plate.

Defining a Visual Marker of Progenitor Cells within the Periodontium. Hrvoje Roguljic*¹, Brya Matthews², Melissa Lacombe¹, Ivo Kalajic². ¹University of Connecticut Health Center, USA, ²University of Connecticut Health Center, USA

The periodontium is the tissue supporting the teeth including cementum, periodontal ligament (PDL) and alveolar bone. In periodontal disease, which is a major cause of tooth loss in adults, the periodontium is inflamed and cementoblasts, PDL fibroblasts and osteoblasts are affected. We have previously identified a periodontal tissue progenitor cell that resides in perivascular areas and expresses GFP under the control of the smooth muscle alpha actin (α SMA) promoter (SMA-GFP). The aim of this study is to identify and trace periodontal progenitor cells in vivo. We have generated an α SMA promoter-driven and tamoxifen inducible Cre mouse (α SMA-CreERT2) that in combination with a Rosa-tomato reporter (SMACre/Tomato) labels a defined cell population. We aimed to examine expansion and localization of these progenitor cells during normal growth and after periodontal

injury. To trace these progenitors during normal growth, tamoxifen was administered to 3-week-old SMACre/ Tomato mice on two consecutive days to label cells, and histology was performed on the second molar in mandibles after 2 and 17 days. At day 2 a small population of cells in the PDL were labeled. This population expanded by day 17, particularly in the apical region and the tension side of the root. To detect transition of SMACre/tomato labeled cells into mature phenotype we utilized a Col2.3GFP transgene. Following treatment with tamoxifen we detected a small number of SMACre/ Tomato/Col2.3GFP-expressing cells by day 17. Using a cell ablation model (Col2.3TK mice) we have established an *in vivo* injury model. Administration of ganciclovir (GCV) results in the death of cells that express the TK gene and undergo division. SMACre/ Tomato/Col2.3TK mice were treated with GCV for 16 days then SMACre-expressing cells were labeled with tamoxifen. 21 days later mice treated with GCV showed remodeling of the apical root and adjacent alveolar bone. We observed an expansion of tomato-labeled cells in the apical root region of the PDL in the GCV-treated mice compared to the untreated controls. In summary, the SMACre transgene labels a small population of cells in the PDL. These cells show expansion and differentiation into mature cells during growth, and increased expansion following cell ablation. This population of cells may represent the source of progenitors that give rise to a number of mature lineages within the periodontium that could assist tissue regeneration in periodontal disease.

PTH in the Treatment of Non Healing Long Bones. Hans-Christof Schober^{*1}, Dirk Ganzer², Thomas Westphal³, Thomas Mittlmeier⁴, Reimer Andresen⁵, Sebastian Manzelmann⁶. ¹Klinikum Südost RostockKlinik Für Innere Medizin I, Germany, ²Orthopaedic surgery, Germany, ³orthopaedic surgery, Germany, ⁴university rostock, trauma surgery, Germany, ⁵Westküstenklinikum Heide, Germany, ⁶klinikum Suedstadt Rostock, Germany

Introduction: Teriparatide (rh PTH 1-34) a bone anabolic drug approved for the treatment of osteoporosis, has been shown to induce fracture healing in animals. Parathyroid hormone (Preotact[®]) is able to create fracture healing in patients. Non healing fractures of long bones remain a challenge to clinical practice. In desperate cases of non healing fractures, we aimed to induce fracture healing and to improve the clinical situation by short term treatment with rh PTH 1-34. So far no data are available whom to treat, how long to treat and which dosage to use. The aim of our study was to find a useful treatment period and fractures which respond to this kind of treatment.

Material and Methods: 23 patients (12 female and 11 male, age 50.4 ± 14.2yr), with non healing (average 13 ± 11months) fractures, 15 fractures of the lower leg, 6 femoral fractures, 2 fractures of the ankle joint, 2 olecranon fractures, non union for more than 3 months after repeated (in average 3,4) surgical interventions were treated. Drug administration schedule: 4 patients 60µg teriparatide daily s.c. for 6 weeks, 19 patients 20 µg daily s.c. for 8 weeks. Blood was analyzed for calcium, phosphorus, creatinine, bone specific alkaline phosphatase, alkaline phosphatase, TRAP 5b, and 25-hydroxyvitamin D. Vitamin D deficiency was treated. The callus development was evaluated by an independent radiologist.

Results: So far results are available for 20 cases. Healing took place in 17 cases (all 4 with 60µg and 13 with 20µg). All Pilon-tibial- and periprotetic fractures did heal. A functional improvement was seen in 15 cases. There were no significant differences in the calcium levels (2,4 ± 0,1 before vs. 2,5 ± 0,1 mmol/l). The increase in bone specific alkaline phosphatase and TRAP 5b reflected the action of the PTH but did not reach significance.

Conclusion: In desperate cases of non healing fractures rh PTH (1-34) Forsteo[®] may be useful. A dosage of 20µg for 8 weeks in the so called "anabolic window" seems to be adequate. Especially Pilon-tibial and periprotetic fractures might be considered. These promising results have to be evaluated in randomized controlled trials.

Suberoylanilide Hydroxamic Acid Enhances Odontoblast Differentiation. Arang Kwon^{*1}, Kyunghwa Baek², Hye-Lim Lee¹, Joo-Cheol Park³, Jung-Wook Kim⁴, Kyung Mi Woo⁵, Hyun-Mo Ryoo⁵, Jeong-Hwa Baek².

¹Department of Molecular Genetics, School of Dentistry, Seoul National University, South Korea, ²Seoul national university, School of dentistry, South Korea, ³Departments of Oral Histology-Developmental Biology, School of Dentistry, Seoul National University, South Korea, ⁴Seoul National University, South Korea, ⁵Seoul National University School of Dentistry, South Korea

Previous studies have shown that histone deacetylase (HDAC) inhibitors stimulate osteoblast differentiation *in vitro* and bone formation *in vivo*. However, the effect of HDAC inhibitors on odontoblasts has not been elucidated. Therefore, in this study, we examined the effect of suberoylanilide hydroxamic acid (SAHA), an HDAC inhibitor, on odontoblast differentiation using a MDPC23 odontoblast-like cell line. SAHA significantly enhanced matrix mineralization and the expression levels of odontoblast marker genes. SAHA increased the expression levels of nuclear factor I/C (Nfic) and dentin sialophosphoprotein (Dspp). Nfic bound directly to the Dspp promoter and stimulated Dspp transcription. SAHA increased both basal and Nfic-induced Dspp promoter activity. SAHA-induced Dspp promoter activity disappeared when mutations were introduced within the Nfic binding element of the Dspp promoter. Nfic knockdown by siRNA blocked SAHA stimulation of Dspp expression. These results indicate that SAHA enhances odontoblast differentiation and that SAHA increases Dspp expression, at least in part, by increasing the expression level of Nfic.

Calvaria Cells from Bone Sialoprotein Knockout Mice Contain Less Osteoprogenitors and Display a Cell Density-dependent Impairment of Bone Formation and Mineralization *in vitro*. Guénaëlle Bouët^{*1}, David Marchat², Blandine Merle³, Marie-Thérèse Linossier¹, Mireille Thomas¹, Wafa Boulefour¹, Laurence Vico⁴, Luc Malaval⁵. ¹INSERM U1059-Université de Lyon-Université Jean Monnet, France, ²Ecole Nationale Supérieure des Mines de Saint-Etienne, Center for Health Engineering, France, ³INSERM U1033-Université de Lyon-UCLB, France, ⁴University of St-Etienne, France, ⁵INSERM U1059-Université de Lyon-Université Jean Monnet, Saint-Etienne, France

Bone sialoprotein (BSP) is highly expressed in bone. In BSP KO (-/-) bone marrow stromal cell cultures¹, the pool of osteoprogenitor (OP) cells (CFU-F) is not reduced, nor is their early differentiation (same numbers of alkaline phosphatase positive colonies [=CFU-ALP], although they are smaller). However, the number of osteoblastic, mineralized colonies (CFU-OB) is dramatically lower¹. Because of delayed ossification of newborn BSP-/- mouse calvaria, we analysed the impact of BSP KO on *in vitro* osteogenesis in cultures of mouse calvaria cells (MCC), isolated from 6 days old mice by collagenase digestions.

In contrast to the marrow, CFU-F and CFU-ALP numbers were lower in BSP-/- MCC cultures, along with less CFU-OB. Consistent with the lack of OP, early BSP-/- cultures displayed lower proliferation and delayed population growth. Expression of osteoblast genes was analysed between day (D)3 and D17 of MCC cultures seeded at 5,000 cells/cm². Levels of most markers did not differ between BSP+/+ and -/- at D3 and D6. Periostin, however, presented a transient peak at D6 in BSP+/+ cultures, but not in the BSP-/. Starting at D14 (first CFU-OBs) expression of ALP, Col11, OSX, Runx2 as well as markers of terminal differentiation, OCN, PHEX, DMP1 and MEPE was dramatically lower in BSP-/- MCC cultures, with no mineralization. In contrast, osteopontin (OPN) and CathepsinB (CatB) were over-expressed. In high density cultures (≥25,000 cells/cm²), marker levels were similar for both genotypes, and BSP-/- cultures mineralized. PHEX binds to DMP1, MEPE or OPN, preventing cleavage by CatB and generation of free ASARM ("Acidic Serine and Aspartate Rich Motif"), a potent inhibitor of mineralization. In high density BSP-/- cultures, PHEX expression increased while CatB decreased, suggesting reduced ASARM peptide production, favoring matrix mineralization. We recently developed a long term culture system in perfused HAP/TCP cubic macroporous bone substitutes. Preliminary results in this 3D model confirm our 2D observations on BSP+/+ and -/- MCC cultures, in particular the over-expression of OPN mRNA by BSP-/- cells.

In conclusion, BSP regulates mouse calvaria osteoblast cell clonogenicity, differentiation and activity *in vitro*, consistent with low levels of bone formation *in vivo*. The BSP KO bone microenvironment may alter the proliferation/cell fate of early OP, as suggested by the smaller CFU-PAL observed in marrow cultures.

Differential Contributions of Leprel1 to Collagen Processing. Erica Homan*¹, Caressa Lietman¹, Ingo Grafe², Roy Morello³, Dobrawa Napierala⁴, Ming Ming Jiang⁵, Elda Munivez⁵, Brian Dawson⁵, Olivier Lichtarge⁵, MarvAnn Weis⁶, David Eyre⁷, Brendan Lee⁸. ¹Baylor College of Medicine, USA, ²Department of Molecular & Human Genetics, Baylor College of Medicine, USA, ³University of Arkansas for Medical Sciences, USA, ⁴University of Alabama At Birmingham School of Dentistry, USA, ⁵Baylor College of Medicine, USA, ⁶University of Washington, USA, ⁷University of Washington Orthopaedic Research Labs, USA, ⁸Baylor College of Medicine & Howard Hughes Medical Institute, USA

Mutations in Cartilage Associated Protein (CRTAP), prolyl 3-hydroxylase 1 (P3H1), and Cyclophilin B (CypB) have been identified as causative of recessive osteogenesis imperfecta (OI). These proteins form a complex that functions to 3-hydroxylate a single proline residue on the alpha 1 chain of type I collagen as well as having cis/trans isomerase (PPIase) activity, a function essential for proper collagen folding. Recent data suggests that this 3-prolyl hydroxylation is not integral to the structural integrity of collagen; however, its absence may disrupt protein-protein interactions integral for proper collagen folding. P3H1 and CRTAP stabilize each other and when one is absent, the other is degraded. Therefore, mutations in this complex result in hypomorphic or complete loss of function alleles. It is thus unclear what roles the 3-hydroxylation function and/or the PPIase activity play in the pathogenesis of recessive OI. This project studies the contribution of P3H1 hydroxylase activity and how it pertains to the pathogenesis of recessive OI by inactivating the hydroxylase domain while maintaining the protein and complex structure.

Through evolutionary tracing we identified a residue that is considered critical for the hydroxylase function and generated a mutant P3H1 cDNA construct containing an alanine substitution at this residue. We demonstrated by immunofluorescence and Western blot that we rescued the stability of CRTAP in the loss of function cells transduced with WT or mutant P3H1 cDNA. Analysis of prolyl 3-hydroxylation by collagen mass spectrometry indicates that the enzymatic activity of P3H1 is abolished. These data suggest that the mutant can maintain the stability of the P3H1 complex, thus maintaining the PPIase function, while abolishing enzymatic activity.

To understand how the 3-hydroxylation function pertains to the pathogenesis of recessive OI, a recombinering strategy was utilized to introduce the alanine substitution into the murine P3H1 locus. Compared to control mice, the mutant mice are normal in appearance and growth. Analysis of the trabecular bone shows a reduction in BMD along with a decrease in Tb Th, an increase in Tb Sp, and a decrease in BV/TV, whereas cortical bone parameters are normal.

We have established a novel mouse model that recapitulates the bone phenotype of OI but not the cartilage phenotype of recessive OI. These observations can be attributable to the differential contributions of P3H1 to collagen processing.

Hox Genes are Re-deployed after Development to Play Critical Roles in Adult Fracture Healing. Ilea Swinehart¹, Aleesa Schlientz², Christopher Quintanilla², Kenneth Kozloff³, Steven Goldstein⁴, Deneen Wellik*⁵. ¹University of Michigan, USA, ²University of Michigan, USA, ³University of Michigan Department of Orthopaedic Surgery, USA, ⁴University of Michigan Orthopaedic Research Lab, USA, ⁵University of Michigan Medical Center, USA

Hox genes are critical regulators of skeletal development. Loss of *Hox* function leads to regionally restricted malformations along the anteroposterior axis of the axial skeleton and the proximodistal axis of the limb. Three *Hox* genes, *Hoxa11*, *Hoxc11*, and *Hoxd11*, demonstrate functional redundancy, and loss of *Hox11* gene function leads to dramatic mispatterning of the sacrum and limb zeugopod elements (radius/ulna, tibia/fibula). Developmental expression is restricted to the perichondrium and connective tissue and expression is maintained at low levels in the periosteum through adulthood. To investigate whether *Hox11* is reactivated during bone repair, a mid-ulnar fracture was performed in adult mice. Following fracture, *Hox11* expression is highly upregulated at the site of injury as early as 3 days post-fracture. Upregulation of expression is observed during callus formation in the periphery of the callus, but is excluded from *Sox9*-expressing cells and osteoblasts. Osteoclasts in the fracture callus express high levels of *Hox11*. *Hox11* compound mutants display reduced cartilage formation after ulnar fracture and a drastically reduced ability to remodel after injury compared to controls. These data clearly highlight a post-developmental role for *Hox11* genes in skeletal repair. The mechanism of *Hox* function in fracture repair is the focus of current work in the laboratory.

Disclosures: Deneen Wellik, None.

RhoA Is Differentially Regulated by Moderate and High Intensities of Shear Stress in Chondrocytes. Qiaoqiao Wan*¹, Hiroki Yokota², Sungsoo Na³. ¹Indiana University-Purdue University Indianapolis, USA, ²Indiana University Purdue University Indianapolis, USA, ³Indiana University-Purdue University Indianapolis, USA

Physical force environment is a major factor that influences homeostasis and remodeling of bone and joint tissues. It is not well understood, however, a potential role of differential intensities of shear stress in cellular mechanotransduction, in particular, shear stress-driven GTPase signaling in chondrocytes. Using a fluorescence resonance energy transfer (FRET)-based approach, we raised a question whether activities of GTPase RhoA in chondrocytes are differentially regulated depending on intensities of shear stress. RhoA is a member of the Rho GTPase, which is known to be involved in cellular migration as well as regulation of matrix metalloproteinases. We hypothesized that RhoA activities can be either elevated and/or reduced by shear stress at 2 – 20 dyn/cm².

The results revealed that C28/I2 chondrocytes exhibited an increase in RhoA activities in response to high shear stress (10 or 20 dyn/cm²), while they showed a decrease in their RhoA activities to moderate shear stress at 5 dyn/cm². No changes were observed under low shear stress (2 dyn/cm²). Shear-induced activities were closely linked to the alterations in actin cytoskeleton. In response to shear stress at 5 dyn/cm², actin stress fibers gradually disappeared but shear stress at 20 dyn/cm² resulted in the increase in their fiber formation.

To further examine the relationship of actin cytoskeleton to RhoA activity, cells were pretreated with drugs that disrupted actin filaments or inhibited pre-stress. Treatment with these drugs prevented shear-driven RhoA inhibition or activation. Shear stress of 5 dyn/cm² decreased tractions (~30%) in 20 min, while shear stress of 20 dyn/cm² substantially increased them (~70%) in 60 min. These results suggest that magnitude-dependent RhoA activities are required to achieve stress-driven strengthening and weakening of actin stress fibers. In the presence of constitutively active RhoA (RhoA-V14), intermediate shear stress was able to suppress RhoA activities, while high shear stress failed to further elevate RhoA activities.

Collectively, these results support the notion that moderate and high intensities of shear stress differentially regulate RhoA activities as well as the formation of actin stress fibers in chondrocytes.

RhoA activity and actin cytoskeleton organization are shear stress-magnitude dependent.

SA0109

Role of Plasminogen in Bone Repair and Heterotopic Ossification. Naoyuki Kawao^{*1}, Yukinori Tamura², Katsumi Okumoto³, Masato Yano⁴, Kiyotaka Okada⁴, Osamu Matsuo⁴, Hiroshi Kajii¹. ¹Kinki University Faculty of Medicine, Japan, ²Kinki University Faculty of Medicine, Japan, ³Life Science Research Institute, Kinki University, Japan, ⁴Kinki University Faculty of Medicine, Japan

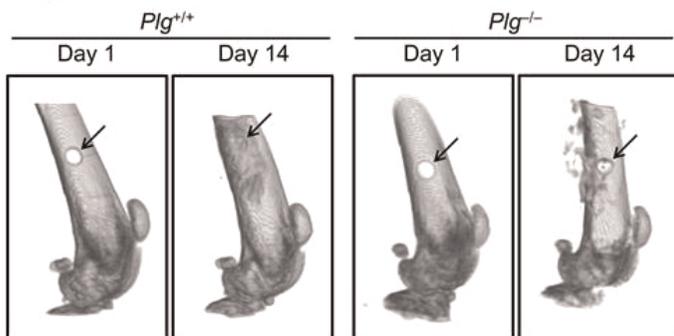

The clarification of the details in mechanism of bone regeneration is necessary to meet the clinical demand of bone generation for the treatment of bone defects. Plasminogen, a critical component of the tissue fibrinolytic system, activates tissue proteolytic system, including matrix metalloproteinases, and several reports indicate that it mediates tissue repair in skin and liver. However, the roles of fibrinolytic system in bone repair and ossification reactions still remain unknown. We therefore investigated the processes of bone repair and heterotopic ossification in mice with gene deficiency of plasminogen (*Plg*^{-/-}) and their wild-type littermates (*Plg*^{+/+}).

A hole was drilled in the femur of the 7-9 weeks old mice for the bone repair model. Heterotopic ossification was induced by the implantation of bone morphogenetic protein (BMP)-2-filled collagen sponge into the muscle. The processes of bone repair and ossification were analyzed by quantitative computed tomography (qCT) and immunohistochemistry.

The bone defect was repaired on day 14 in *Plg*^{+/+} mice, but still remained in *Plg*^{-/-} mice, as assessed by qCT (Fig. 1). In *Plg*^{+/+} mice, but not *Plg*^{-/-} mice, blood vessels were observed at the damaged site from day 4, which was associated with the expression of vascular endothelial growth factor (VEGF). The area of cartilage matrix was reduced on day 7 in *Plg*^{-/-} mice, compared with *Plg*^{+/+} mice in alcian and toluidine blue stains. Alkaline phosphatase (ALP)-positive cells as well as tartrate-resistant acid phosphatase-positive multinucleated cells were localized surrounding the bone tissue at the damaged site on day 7 in *Plg*^{+/+} mice. However, ALP-positive cells were not observed at the damaged site on day 7 in *Plg*^{-/-} mice. In contrast, the BMP-2-induced heterotopic ossification was similarly induced in both *Plg*^{+/+} and *Plg*^{-/-} mice, as assessed by qCT. Furthermore, angiogenesis and expression of VEGF were comparable between *Plg*^{+/+} and *Plg*^{-/-} mice in the heterotopic bone on day 14. These findings suggest that the presence of bone marrow is essential for the role of plasminogen in bone repair.

In conclusion, the present study indicates that plasminogen plays a key role in the processes of bone repair presumably through the expression of VEGF, but not heterotopic ossification. The modulation of the tissue fibrinolytic system might be a new strategy for the enhancement of fracture healing and the development of bone regeneration.

Fig. 1

CT images of the site of bone defect on days 1 and 14 in plasminogen gene deficient (*Plg*^{-/-}) and their wild-type (*Plg*^{+/+}) mice. The arrows indicate the site of bone defect.

A Comparison of Receptor Binding, Receptor Activation and β -arrestin Recruitment by Salmon and Human Calcitonin. Kim Andreassen^{*1}, Sara Toftegaard Petersen², Mette Grøndahl Sørensen², Morten Asser Karsdal², Kim Henriksen³. ¹Nordic Bioscience A/S, Denmark, ²Nordic Bioscience A/S, Denmark, ³Nordic Bioscience A/S, Denmark

Introduction and Aim: Salmon calcitonin (sCT) and human calcitonin (hCT) are very different pharmacologically. However, the cause of the observed difference in potency or what implications it has for future pharmacological findings remains to be elucidated. The aim of this study was to investigate whether the differences in sCT and hCT potency could be translated into differences in functional output in terms of binding kinetics and downstream signaling mediated through the calcitonin receptor (CTR).

Methods: This study was conducted on the human U2OS CALCR (U2OS) cell line over-expressing the human CTR. CTR downstream signaling was investigated with dose response profiles for cAMP induction and β -arrestin recruitment for sCT and

hCT during short term (< 2 hours) and prolonged (up to 72 hours) stimulation. CTR receptor kinetics was investigated using 125I-sCT and 125I-hCT ligands to study receptor association (up to 160 min), receptor dissociation (up to 72 hours) and competitive binding on cultured cells or isolated membranes.

Results: Short term stimulation resulted in similar cAMP and β -arrestin dose response profiles. However, hCT binding on live cells declined after 20 min, whereas sCT association on live cells continued to increase for 160 min, indicating potential differences in receptor activation. Prolonged stimulation resulted in distinct sCT and hCT dose response profiles. After 24 hours, sCT dose dependently induced a 50-200% ($P < 0.001$) and a 5-13 fold ($P < 0.001$) increase in cAMP and β -arrestin levels, respectively, compared to hCT. After 48 hours, sCT continued to induce a cAMP and β -arrestin response, whereas the hCT mediated signal ceased. Interestingly, neither sCT nor hCT dissociated appreciably from isolated membranes during 72 hours. In contrast, prolonged ligand dissociation experiments using live U2OS cells demonstrated a more than 90% release of 125I-hCT ligand after 2 hours, whereas 50% and 90% of the 125I-sCT ligand was released after 4 and 24 hours, respectively.

Conclusion: sCT promotes a prolonged activation of the CTR downstream signaling (cAMP induction and β -arrestin recruitment) compared to hCT. Our results indicate that the activity of calcitonins is linked to ligand specific differences in cellular CTR signaling and processing rather than receptor binding kinetics, which could have implications for the understanding and use of sCT in therapy of osteoporosis.

Acute Exposure to Fibroblast Growth Factor 23 Increases Cardiac Contractility. Michael Wacker^{*1}, Chad Touchberry¹, Troy Green², Vladimir Tchirikov³, Lori Wetmore², Lynda Bonewald⁴. ¹University of Missouri-Kansas City School of Medicine, USA, ²William Jewell College, USA, ³University of Missouri-Kansas City, USA, ⁴University of Missouri - Kansas City, USA

Fibroblast growth factor 23 (FGF23) is a hormone secreted by bone that regulates vitamin D and phosphate metabolism. Recent clinical data shows a correlation between chronically elevated levels of serum FGF23 in patients with chronic kidney disease (CKD) and a decline in cardiac function. Our laboratory has been studying the effects of chronic FGF23 exposure in the development of cardiac hypertrophy. However, it is currently unclear if acute exposure to FGF23 contributes to changes in cardiac function. To elucidate the acute effects of FGF23 on cardiac contractility, we exposed electrically paced left ventricular muscle strips from wild-type mice (C57BL/6; n=6-9) to pathophysiological concentrations of FGF23 (90, 900, 9000 pg/ml). Treatment with FGF23 increased the magnitude of isometric force in a concentration dependent manner when compared to vehicle treatment ($p < 0.01$). Isometric force nearly doubled within 20 minutes of exposure to 9000 pg/ml with corresponding increases in the rate of force development (slope) and the area (the integral) ($p < 0.01$) associated with the contractile waveforms. However, the rate of relaxation (τ) of the left ventricular muscle strips was not affected ($p > 0.05$). Increased cardiac contractility is tightly coupled to increases in calcium-induced calcium release (CICR). Our data showing increased isometric tension and rate of force development following acute FGF23 exposure suggest that FGF23 may alter CICR mechanisms in cardiac muscle. Since calcium is involved in the induction of pathological hypertrophy, disruption of calcium homeostasis may be a common mechanism by which FGF23 increases contractility acutely and pathological hypertrophy over time. Further studies are needed to confirm this hypothesis and elucidate the specific receptor mediated mechanism for these changes in cardiac performance.

Disclosures: Michael Wacker, None.

SA0112

FGF-23 Gene Expression Increases while Bone Quality Parameters Decrease with Age in D2B6F1 Mice. Marco Loayza^{*1}, Andrew Cureton², Xiaoxin Wang¹, Ted Bateman³, Virginia Ferguson⁴, Moshe Levi⁵, Karen King⁶. ¹University of Colorado School of Medicine, USA, ²University of Colorado, Boulder, USA, ³University of North Carolina, USA, ⁴University of Colorado, USA, ⁵University of Colorado Denver, USA, ⁶University of Colorado School of Medicine, USA

Mice of the D2B6F1 strain were purchased and housed under an IACUC-approved protocol. Mice received no special treatment. Six mice per age group (12, 80 and 108 weeks) were euthanized and femurs were obtained immediately and cleaned of soft tissues and marrow. One femur was used to examine age-related alterations in bone gene expression analysis using SYBR green method. The other femur was used to examine age-related alterations bone mass, microarchitecture and strength via micro-computed tomography of the proximal tibia and three-point bending of the femur diaphysis.

Aging from 12 and 80 wks of age in D2B6F1 mice negatively influenced proximal tibia tissue density by -71.7% ($p = 0.001$) and BV/TV by -68.4% ($p < 0.01$), with no additional changes beyond 80 weeks. Reduced bone volume paralleled loss of trabecular number (Tb.N) and spacing (Tb.Sp), -65.1% and -202%, respectively ($p < 0.001$), and connectivity density by -92.6% ($p < 0.01$). Trabecular anisotropy increased by 14.4% from 12 to 80 weeks and +25% ($p < 0.001$) from 12 to 104 weeks.

There was also diminished strength in the cortical bone at the femur diaphysis in three-point bending.

The mechanism behind these age-related alterations in bone quality may be due to alterations in the gene expressions of osteoprotegerin (OPG) and RANKL. OPG expression decreased about 2-fold between 12 and 108 weeks (no change between 12 and 80 weeks), while RANKL increased about 1.5-fold between 12 and 80 weeks and 2-fold between 12 and 108 weeks. The change in the relationship between OPG and RANKL imply osteoclast activation and subsequent bone resorption.

In light of recent hypotheses that a decrease in FGF-23 may lead to a pre-mature aging-like phenotype in multiple tissues including bone (Razzaque, 2006) we measured the gene expression levels in the bone of these mice. Contrary to low FGF-23 being associated with aging hypothesis, we found a 10-fold increase in FGF-23 expression between 12 and 80 weeks (no difference between 80 and 108 weeks) that correlated significantly ($p < 0.01$) with altered bone microarchitectural metrics. FGF-23 expression appears to increase with aging and is associated with impaired bone microarchitecture.

Disclosures: Marco Loayza, None.

Induction of the Intact and C-terminal FGF23 Levels and Its Gene Expression in Lipopolysaccharide-Induced Acute Inflammation. Shoko Ikeda^{*1}, Hironori Yamamoto², Otoki Nakahashi³, Mina Kozai⁴, Yutaka Taketani², Eiji Takeda⁵. ¹Institute of Health Biosciences, University of Tokushima Graduate School, Japan, ²University of Tokushima, Japan, ³University of Tokushima, Japan, ⁴University of Tokushima, Japan, ⁵University of Tokushima School of Medicine, Japan

Parathyroid hormone (PTH) and Fibroblast growth factor 23 (FGF23) are key regulators of inorganic phosphate (Pi) and vitamin D homeostasis. Sepsis is the systemic inflammatory response syndrome (SIRS) that occurs during severe infection and it often associated with electrolyte disorder. It has been reported that endotoxin increased plasma levels of PTH and hyperphosphaturia. However, the alteration of FGF23 during acute inflammation is still unclear. In this study, we investigated the regulation of plasma FGF23 status and its gene expression under the acute systemic inflammation using lipopolysaccharide (LPS). C57BL/6J mice were treated with LPS (E. coli 055:B5, 2-20 mg/kg, i.p.) and sacrificed at different time. Analysis of plasma parameters showed that LPS dose- and time-dependently increased the levels of plasma Pi and PTH. However, plasma intact FGF23 levels were only increased at 3hr after LPS treatment. Surprisingly, plasma levels of C-terminal FGF23 fragment were markedly increased from 1.5 to 9hr by LPS. In addition, TNF- α also increased its C-terminal levels but not intact levels in plasma. Furthermore, we revealed that the femur FGF23 mRNA expression was increased by LPS as well as FGF23 C-terminal levels. Interestingly, its increase was observed in other tissue, such as kidney, liver, lung and spleen. *In vitro* study also demonstrated that LPS directly induced FGF23 mRNA in primary osteoblast-like cells. These results suggest that acute systemic inflammation up-regulates the FGF23 gene expression in bone and other organs and increases both intact and C-terminal fragments of FGF23 in plasma. The measurement of C-terminal FGF23 may be useful as a biomarker for systemic infection like sepsis.

MEPE ASARM Motif and Age-Dependent Regulation of Fat Mass, Renal Phosphate and Bone Mass. Lesya Zelenchuk¹, Anne-Marie Hedge¹, Peter Rowe^{*2}. ¹University of Kansas Medical Center, USA, ²University of Kansas Medical Center, USA

Matrix extracellular phosphoglycoprotein (MEPE) belongs to the SIBLING protein family that includes Dentin Matrix Protein-1 (DMP1). Both proteins contain C-terminal ASARM motifs. The DMP1 ASARM-motif is capped by an additional short minifostin-motif sequence. Mutations in DMP1 cause autosomal recessive hypophosphatemic rickets with increased active FGF23. In contrast, the MEPE null mouse (Mn) has an age related increased bone mass phenotype. To determine if the free ASARM-peptide plays a role we engineered and used a murine model that expresses free ASARM-peptide on a MEPE null background (MnAt).

Wild type (WT), Mn and MnAt male mice (5 wks; N=6) were fed a normal phosphate diet to 22 wks of age. Every two weeks fat mass and aBMD were measured by DEXA and serum samples were taken for analysis. Mice were sacrificed at 22 wks after overnight metabolic-cage housing. The overnight serum plus urine was collected for further analysis. Femurs and kidneys were removed at necropsy for static and dynamic histology, micro computed tomography (μ CT) and RNA analysis. Bone dynamic histomorphometric analyses were carried following routine triple fluorescent dye labeling prior to sacrifice.

Mn mice displayed an age-dependent increase in bone mineral density (BMD), BV/TV, mineral apposition rates, osteoblast activity and trabecular number. This was accompanied by a major decrease in fat mass. In contrast the MnAt mice showed a reversed Mn phenotype and were strikingly obese (Fig 1A, B). Mn mice developed an age-dependent hyperphosphatemia whereas the MnAt mice remained hypophosphatemic (Fig 1B). Serum PTH and FGF23 levels were increased in MnAt mice relative to WT and Mn mice. No differences in PTH levels occurred between Mn and

WT mice. In contrast, Mn mice serum FGF23 levels were significantly lower than WT and MnAt mice. Serum 1,25-Vit D3 levels were increased in Mn mice relative to WT and significantly reduced in MnAt mice relative to WT and Mn mice. FGF23, Sclerostin and cystatin c expressions were increased in MnAt mice relative to WT mice. In contrast, bone mRNA expression of FGF23 and sclerostin were significantly reduced in Mn mice relative to WT mice.

In conclusion, transgenic overexpression of ASARM-peptide over corrected and reversed the age-dependent phenotypic bone, renal and fat abnormalities in MEPE null mice. This confirms processing of MEPE ASARM peptide plays a functional role in maintaining a dynamic age-dependent balance between energy metabolism and bone mass.

A Clinically Useful Paradigm for Optimal Interpretation of Serum 25-hydroxyvitamin D (25-OHD) Levels with Simultaneously Measured PTH Levels. Nayana Parikh^{*1}, Shijing Qiu¹, TarLisha Eskridge², Leila Idi², Sudhaker Rao¹. ¹Henry Ford Hospital, USA, ²Henry Ford Hospital, USA

A single 25-OHD level does not provide information either about the duration of vitamin D depletion or appropriate vitamin D replacement strategy in patients with low 25-OHD. Four years ago we presented a preliminary paradigm for interpretation of serum 25-OHD, the best available index of vitamin D nutrition, with concurrent PTH level in patients seeking advice for osteoporosis. We now present more detailed analysis of simultaneously measured 25-OHD and PTH levels in unselected patients seen over 5 years. We excluded patients with hypercalcemia, renal dysfunction (serum Cr >1.5 mg/dl) or with known causes of vitamin D depletion.

There were 10,310 patients, 7682 women and 6511 whites; mean age 61 \pm 14y. The mean serum 25-OHD was 24.7 \pm 12.6 ng/ml and PTH 77.2 \pm 57.3 pg/ml with the expected inverse relationship between the two. In addition, 25-OHD correlated inversely with Cr and AP, and directly with Ca and age (data not shown).

When patients were classified based on 25-OHD level (< or > 30 ng/ml), with or without high PTH (< or > 75pg/ml), 4 groups emerged that suggested different pathophysiologic basis. Group-1 (referent) had 25-OHD >30 ng/ml and PTH <75 pg/ml. Group-2 had normal 25-OHD but high PTH (>75 pg/ml) with weak relationship between the two variables. However, in the 2 groups with low 25-OHD (<30 ng/ml) with either normal (Group-3) or high (Group-4) PTH levels, there was a stronger inverse relationship between the 2 variables. Furthermore, the slope of regression was significantly steeper in Group-4 with high PTH compared to Group-3 with normal PTH (slopes: -1.76 Vs. -0.24; $p < 0.001$). This suggests that vitamin D depletion is of longer duration in Group-4 than Group-3 and thus may require aggressive pharmacologic therapy. Group-3 patients with low 25-OHD and normal PTH may represent seasonal variation, short duration vitamin D depletion or abnormal PTH response. Finally, Group-2 with normal 25-OHD and high PTH may represent patients with low calcium intake or incipient primary hyperparathyroidism and thus require further evaluation.

Conclusion: Simultaneously measured 25-OHD and PTH optimizes proper interpretation of vitamin D nutrition. The strategy offers a clinically useful tool to look for causes of high PTH in those with normal 25-OHD and reasons for lack of PTH response in those with low 25-OHD and normal PTH. We have now validated our initial proposal in a larger unselected population.

Parathyroid Hormone Stimulates Tob1 Expression in Osteoblastic Cells *in vitro* and *in vivo*. Shuichi Moriya^{*1}, Tadayoshi Hayata², Jumpei Shirakawa³, Tetsuya Nakamoto⁴, Takuya Notomi⁵, Yoichi Ezura⁶, Kazuo Kaneko¹, Masaki Noda⁴. ¹Department of Orthopaedics, Juntendo University School of Medicine, Japan, ²Medical Research Institute, Tokyo Medical & Dental University, Japan, ³Medical Research Institute, Tokyo Medical & Dental University, Japan, ⁴Tokyo Medical & Dental University, Japan, ⁵GCOE, Tokyo Medical & Dental University, Japan, ⁶Tokyo Medical & Dental University, Medical Research Institute, Japan

In the treatment of osteoporosis, PTH is an important hormone to increase bone mass by intermittent administration. Previous studies have found that there were several early gene expressions after PTH stimulation, such as c-fos and Fra-2. Tob (transducer of erbB2) is a member of antiproliferative family proteins and acts as a bone morphogenic protein inhibitor. However, the role of Tob1 by the action of PTH in osteoblast has not fully understood. The purpose of this study was to identify the effect of PTH on gene expression of Tob1 in bone *in vitro* and *in vivo*. PTH induction of Tob1 messenger RNA (mRNA) levels in MC3T3-E1 osteoblastic cells was maximal with 100 nM human PTH (1-34). The expression of Tob1 mRNA levels *in vitro* was maximal 1 h after human PTH (1-34) addition and returned to baseline within 3 h. Time response expression of Tob1 mRNA resembled that of c-fos. The gene expression of CyclinD1, the cell cycle regulated gene, decreased after 6h of PTH treatment. Up-regulation of Tob1 mRNA expression was also noted *in vivo*, where injection of human PTH (1-34) to 4 weeks old C57/BL6 male mice resulted in about 50% increase in Tob1 mRNA expression in metaphysis of distal femur at 10 µg/kg of PTH and about 90% increase at 20 µg/kg in comparison to the injection of vehicle, after 1h of treatment. Although the expression of Tob1 mRNA increased 1h after injection, by 6h, 12h and 24h levels returned to baseline values. The expression of Tob1 mRNA *in vivo* followed a pattern similar to that of *in vitro*. Intriguingly, after daily injection of PTH for seven days, the expression of Tob1 mRNA caused about 50% increase. These results indicate that Tob1 is one of the early target genes after stimulation by PTH and PTH might regulate cell cycle via Tob1.

Teriparatide (PTH 1-34) Treatment Increases Peripheral Hematopoietic Stem Cells in Postmenopausal Women with Osteoporosis. Elaine Yu^{*1}, Ruchit Kumbhani², Erica Siwila-Sackman², Fred Preffer², Michelle DeLelvs², Benjamin Leder³, Joy Wu¹. ¹Massachusetts General Hospital, USA, ²Massachusetts General Hospital, USA, ³Massachusetts General Hospital Harvard Medical School, USA

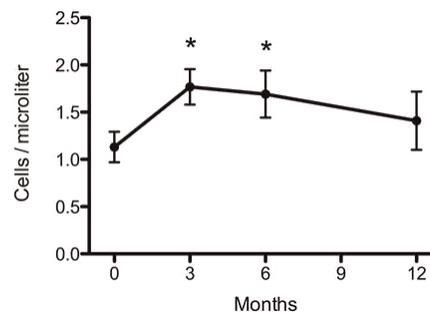

Background: Cells of the osteoblast lineage play an important role in regulating the hematopoietic stem cell (HSC) niche and early B cell development in animal models, perhaps via parathyroid hormone (PTH) dependent mechanisms. The impact of long-term daily teriparatide (PTH 1-34) treatment on cells of the hematopoietic lineage has not been investigated in human clinical studies.

Methods: We studied a subset of postmenopausal women with low bone density who were participating in the the Denosumab And Teriparatide Administration (DATA) study. Of the 36 subjects randomized to teriparatide 20 mcg SC daily, 23 women had peripheral blood leukocyte measurements at baseline, 3, 6, and 12 months, as well as DXA bone density measurements of spine and hip. Flow cytometry was performed to identify early transitional B cells (CD19+, CD27-, IgD+, CD24[hi], CD38[hi]) and HSCs (CD34+, CD45dim+; ISHAGE protocol). Data are presented as mean ± SEM.

Results: Average age of study subjects was 64 ± 5. There was an early increase in circulating HSC number of 40% ± 14% by month 3 (1.1 ± 0.2 cells/uL vs. 1.8 ± 0.2 cells/uL; p=0.004), which persisted through month 6 (1.1 ± 0.2 cells/uL vs. 1.7 ± 0.2 cells/uL; p=0.010) before declining towards baseline at month 12 (see Figure). There were no significant changes in transitional B cells or total B cells over the course of the study period. Other leukocyte lineages were also unchanged. There was no correlation between change in HSC number and changes in spine or hip bone density.

Conclusions: Daily teriparatide treatment for osteoporosis increases circulating HSCs by 3 to 6 months in postmenopausal women. This may represent a proliferation

of marrow HSCs or increased peripheral HSC mobilization. This clinical study establishes the importance of PTH in the regulation of the HSC niche within humans.

Hematopoietic stem cells during teriparatide treatment

Association of Serum Fibroblast Growth Factor 23 and Incident Fractures in Elderly men. Nancy Lane^{*1}, Neeta Parimi², Maripat Corr³, Jane Cauley⁴, Carrie Nielson⁵, Joachim Ix³, Gail Laughlin⁶, Eric Orwoll⁵. ¹University of California at Davis, USA, ²California Pacific Medical Center, USA, ³UCSD, USA, ⁴University of Pittsburgh Graduate School of Public Health, USA, ⁵Oregon Health & Science University, USA, ⁶University of California, San Diego, USA

Normal mineral metabolism is critical for skeletal integrity. Fibroblast derived growth factor-23 (FGF-23) is a bone derived circulating protein that is produced mainly by osteocytes and its production is stimulated by serum inorganic phosphorus and 1,25 vitamin D. Recently, serum levels of FGF-23 levels were found to be directly related to overall fracture risk in elderly Swedish Men (Mirza et al JBMR 2011). To study this association, we performed a prospective case-cohort study to understand the relation of FGF-23 and fracture risk in older Caucasian men enrolled in the MrOS study. Methods. In the cohort of 5994 men attending the baseline MrOS examination, we evaluated a subgroup of 387 men with incident non-vertebral fracture including 112 hip fractures and a sample of 1385 men randomly selected from the cohort with baseline mineral and calcium hormone measurements. FGF-23 was measured in baseline serum samples by ELISA (Millipore, Billerica, MA). All men who experienced any non-vertebral fracture from baseline until February 2007(average follow-up 4.7 years) were included in the analysis. Incident fractures were confirmed with x-ray reports. Modified proportional hazards models that account for case cohort study design were used to estimate the relative hazards (RH) of fracture in men across quartiles of FGF-23 (cutpoints 12.1, 16.6, 22.4 pg/mL). Estimates for regression models using Log transformed FGF23 were back transformed and reported as a 50% increase in FGF23. Results. Subjects with incident non-spine fractures were older, had lower total hip BMD, and higher serum phosphorus. Cases were more likely to report a history of falls and to be frail (all p<0.01). Overall, there was no difference in risk of nonspine or hip fracture by baseline FGF-23. However, in stratified analysis by subjects with eGFR < 60ml/min/1.73m² (n=54/290 non-spine fractures p for interaction=0.0047), the RH per 50% increase in FGF-23 was 1.35 (95% CI: 1.07-1.67) vs. 0.97 (95% CI: 0.87-1.08) in men with eGFR ≥60ml/min/1.73m² (324/1370 fractures) after adjustment for age, clinic site, BMI, race, total hip BMD, vitamin D and PTH. Summary. Overall, serum FGF-23 levels are not associated with incident fractures. However, higher levels of serum FGF23 are associated with fracture risk in those with GFR < 60 ml/min/1.73m².

Direct *in vivo* Effects of Vitamin D Sterol Therapy on Osteocyte Viability and Wnt Signaling. Renata Pereira^{*1}, Harald Juppner², Navdeep tumber³, Barbara Gales³, Isidro Salusky⁴, Katherine Wesseling-Perry⁵. ¹UCLA, USA, ²Harvard Medical School, USA, ³UCLA, USA, ⁴University of California, Los Angeles School of Medicine, USA, ⁵UCLA Medical Center, USA

Wnt signaling is suppressed in early CKD resulting in decreased bone turnover, a phenomenon that is overcome by 2°HPT in late CKD (Sabbagh et al JBMR in press), possibly through the inhibitory actions of PTH on osteoblast/osteocyte apoptosis (Jilka et al JCI 1999). Skeletal resistance to the actions of PTH characterizes advanced CKD and is exacerbated by vitamin D sterol therapy. However, the underlying mechanisms are poorly defined and it is unknown whether impaired Wnt-signaling in osteocytes contributes to these findings in CKD. Thus, osteocyte apoptosis and Wnt signaling were evaluated in primary cultures of bone cells derived from the iliac crest of 13 dialysis patients (7M, 6F), age 16 + 1 years before and after 8 months of therapy with vitamin D sterols and phosphate binders. Apoptosis was determined by TUNEL

staining pre- and post-therapy and skeletal expression of sclerostin (SOST), a known inhibitor of Wnt signaling, was determined by immunohistochemistry; both parameters were quantified on a 3 point scale (0=none, 1=some, 2=significant amount). Table 1 displays the biochemical and bone histomorphometric data as well as the percentage of biopsies with positive staining for apoptosis and SOST before and after treatment. Both cortical and trabecular bone apoptosis were markedly decreased at baseline compared to normal controls; this abnormality was much improved after 8 months of vitamin D sterol therapy. Although biochemical values, including PTH, did not change, cortical sclerostin (but not trabecular sclerostin) expression increased significantly ($p < 0.01$) with vitamin D sterol therapy. These data demonstrate that a decrease in normal osteocyte apoptosis characterizes advanced CKD and 2^oHPT. Vitamin D sterol therapy worsens this PTH-resistance in both cortical and trabecular bone of pediatric dialysis patients while increasing suppression of Wnt signaling in cortical, but not trabecular osteocytes, independent of any changes in circulating PTH. These changes may explain, in part, differences in cortical and trabecular bone response to PTH and in the exacerbation of skeletal resistance to PTH that occurs as a result of vitamin D sterol therapy in pediatric patients treated with maintenance dialysis (Wesseling-Perry et al KI 2010).

Does the Activation of the FGF-23 Pathway after Living Donor Nephrectomy Increase Bone Turnover? [Anthony Hodsmann](#)¹, [Ann Young](#)², [David Goltzman](#)³, [Amit Garg](#)², [Donor Nephrectomy Outcomes Research Network](#)². ¹Western University, Canada, ²Western University, Canada, ³McGill University, Canada

Living kidney donation offers a unique setting to study changes in skeletal homeostasis attributable to mild, isolated decrements in glomerular filtration rate (eGFR). Although Living Kidney Donors (LKD) are not at short-term risk of fragility fractures (Am.J.Kid.Dis. ePub 2012), serum FGF-23 levels increase by 3.2 pg/ml per 10 ml/min/1.73 m² decline in eGFR in LKD (Am.J.Kid.Dis. ePub 2011). If bone turnover is increased after LKD, these individuals might be at long-term risk for fracture.

Methods: We performed a retrospective cohort study evaluating 2 serum biochemical markers of bone turnover (C-Telopeptide, CTX, and PINP) and other markers of the mineralizing bone disorder of chronic kidney disease (MBD-CKD) in 157 LKD and 66 Non-Donor Controls (NDC). Participants were recruited from 1140 eligible LKD and 421 potential donor-identified NDC from 9 transplant centres. Median follow-up time after donation was 5 yrs. (interquartile range: 4-8). Estimated GFR (eGFR, ml/min/1.73 m²) was calculated using the CKD-EPI formula.

Results: As expected, LKD had a lower eGFR than NDC (73 ± 15 vs. 96 ± 15 , $p < 0.0001$); they were slightly older (45 vs. 41 yr, $p < 0.01$). Within the LKD group, 68%

had eGFR levels classified as Stage II CKD, and 18% as Stage III CKD; comparable data within the NDC group were 28% and 0%, respectively. Mean serum iPTH levels remained within normal limits between groups (ns). However, serum FGF-23 ($p < 0.0001$) levels were significantly higher, whilst serum calcitriol ($p < 0.001$) levels were lower than those in NDC. Mean serum calcitriol levels were > 70 nmol/L in both groups (ns). Serum CTX ($p < 0.01$), but not PINP levels were significantly higher in LKD (Table 1) Serum CTX and PINP were strongly correlated ($r^2 = 0.74$, $p < 0.0001$) suggesting coupled bone turnover. Only serum CTX was correlated to serum PTH ($r^2 = 0.14$, $p = 0.05$) and with eGFR ($r^2 = -0.17$, $p = 0.01$). There were no significant relationships between either marker and serum FGF-23.

Conclusion: The FGF-23 pathway is activated in LKD with mild renal failure. While serum iPTH remained within normal limits, serum calcitriol was significantly lower. These early changes of MBD-CKD may have contributed to increased bone turnover and thus higher serum CTX levels in this relatively young cohort.

| Serum | FGF-23 pg/ml | iPTH pmol/L | Calcitriol pmol/L | CTX ng/L | PINP µg/L |

Teriparatide Treatment in a Cardiac Transplant Patient with Adynamic Bone Disease and Renal Failure – Improvement of Bone Histomorphometric Indices and Bone mineral Density. [Astrid Fahrleitner-Pammer](#)¹, [Doris Wagner](#)², [Thomas Pieber](#)³, [Alexander Rosenkranz](#)⁴, [Harald Dobnig](#)⁵. ¹Medical University Graz, Austria, ²Medical University of Graz, Austria, ³Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University of Graz, Austria, ⁴Department of Internal Medicine, Division of Nephrology, Medical University of Graz, Austria, ⁵Diagnostikinstitut Univ.Prof.Dr.H.Dobnig GmbH & Medical University Graz, Austria

Introduction: Cardiac transplantation (CTX) has a negative impact on bone metabolism. Low dose ibandronate (IBN) has been proven to prevent bone loss and fractures; however immunosuppressive therapy and decreasing kidney function may lead to Chronic Kidney Disease-Mineralizing Bone Disorders (CKD-MBD) in the long term. Adynamic bone disease and increased fracture risk are possible complications.

Case: We report a case of a CTX recipient who has received a cardiac transplant 1993 at the age of 58. He received IBN for 4 years and presented with acute back pain at the osteoporosis outpatient clinic in 2010. The patient was still on triple immunosuppressive therapy, had an impaired kidney function (CKD 4). Standardized spinal X ray showed 10 vertebral fractures. Laboratory analysis revealed elevated levels of PTH, sCTX, osteocalcin and normal 25(OH)vitamin D and bALP concentrations. Prior to initiation of osteoprotective therapy we performed an iliac crest biopsy following tetracycline double labeling which demonstrated adynamic bone disease: BV/TV 26.7% (17.8-27.4), BS/BV 17.2mm³/mm³, OS/BS 8.7% (11.5-19.1), ES/BS 2.3% (2.9-5.3), QuS/BS 89%, Tb.N 2.29 1/mm (1.3-2.1), Tb.Th 116.4 µm (127-165), Tb.Sp 319.6 µm (406-604), MS/BS 1.42%. The patient received treatment with 20 µg teriparatide daily (TPT) in combination with 500 mg calcium and 1200 IU vitamin D over 12 months. After one year a second biopsy showed high bone turnover with improved trabecular structure: BV/TV 29.9% (17.8-27.4), BS/BV 19.7mm³/mm³, OS/BS 28.7% (11.5-19.1), ES/BS 7.9% (2.9-5.3), QuS/BS 65%, Tb.N 1.98 1/mm (1.3-2.1), Tb.Th 137 µm (127-165), Tb.Sp 309.6 µm (406-604), MS/BS 1.92%. Treatment was well tolerated, the kidney function stable, PTH and 25(OH)vitamin D were within the normal range, bone turnover markers including osteocalcin, bALP and sCTX were clearly elevated, serum calcium was within the normal range and the patient felt clinically better without occurrence of new fractures.

Conclusion: Adynamic bone disease is a complex entity. Teriparatide therapy was well-tolerated and proved an very effective treatment even in a patient on triple immunosuppressive therapy and CKD 4. Controlled prospective studies are urgently needed to establish teriparatide as a treatment option in adynamic bone disease.

The Role of the Skeleton in the Early Chronic Kidney Disease - Mineral Bone Disorder. Yifu Fang¹, Toshifumi Sugatani², Keith Hruska^{*2}. ¹Washington University School of Medicine, USA, ²Washington University in St. Louis School of Medicine, USA

By stage 2 CKD, the CKD-MBD has been induced and the associated increase in mortality stimulated. Vascular calcification (VC) is a strong cardiovascular risk factor in CKD. The CKD-MBD in stage 2 CKD consists of stimulation of VC, the onset of osteodystrophy, and a stimulation of osteocyte secretion. While Ca, Pi and PTH levels remain normal, FGF23 and sclerostin from the osteocyte are increased. The increase in FGF23 and sclerostin serve as biomarkers of the CKD effect on the skeleton. We have linked the skeleton in CKD to stimulation of VC. The pathogenesis of the initial stimulus for osteocytic secretion of FGF23 is unclear. Early changes in phosphate homeostasis, changes in bone remodeling, and PTH are the candidate factors under investigation. We examined the actions of either modifying Pi balance through intestinal Pi binding or a skeletal anabolic factor (a neutralizing monoclonal antibody to a Wnt inhibitor, DKK1 produced by renal injury) on the early CKD-MBD.

Methods: *ldlr* deficient mice fed high fat diets were subjected to partial kidney ablation at 14 weeks of age to create an early CKD-MBD mouse model. Treatment protocols with Vehicle, CaAc, LaCO₃(3% w/w mixed in diet), or the DKK1 mab (30 mg/kg tiw IP) were conducted from 14-22 wks or 22-28 wks.

Results: Residual kidney function measured by inulin clearance was 75% of normal (stage 2 CKD). Aortic Ca levels were increased by CKD at 22 weeks of age and progressively increased to 28 wks. The serum levels of BUN, Ca, Pi and PTH were normal, but a transient elevation of PTH at 15 weeks was discovered. MicroCT of the femurs revealed cortical but not trabecular bone loss (Figure 1) which was corrected by the DKK1 mab and LaCO₃ but not by CaAc therapy. FGF23 levels were decreased by LaCO₃ and CaAc but not by the DKK1 mab. Vascular Ca levels were decreased by the DKK1 mab but not by CaAc therapy.

Conclusion: We conclude that an early osteodystrophy in CKD may be causatively associated with the stimulation of VC and that the stimulus to FGF23 secretion is independent of the osteodystrophy and may be Pi or PTH.

Health Related Quality of Life in Adults with Osteogenesis Imperfecta is Impaired by Prevalence of Multiple Fractures. Jannie Hald^{*1}, Lars Folkestad², Torben Harsløf³, Malene Schmidt⁴, Hans Gjørup⁵, Dorte Haubek⁴, Kim Brixen⁶, Bente Langdahl⁷. ¹MEA Aarhus University Hospital, Tage Hansensgade 2DK-8000 Aarhus CDenmark, Denmark, ²Department of Endocrinology, Odense University Hospital; Institute of Clinical Research, University of Southern Denmark, Odense; Department of Endocrinology, Hospital of Southwest Denmark, Denmark, ³Department of Endocrinology & Metabolism, Aarhus University Hospital, Denmark, ⁴Department of Dentistry, Health, Aarhus University, Denmark, ⁵Department of Dentistry, Health, Aarhus University; Center for Oral Health in Rare Conditions, Aarhus University Hospital, Denmark, ⁶Institute for Clinical Research, Denmark, ⁷Aarhus University Hospital, Denmark

Osteogenesis imperfecta (OI) is a hereditary disease of the connective tissue (collagen type 1) with a broad clinical appearance. Common symptoms are fractures, hearing loss, dentinogenesis imperfecta (DI), growth deficiency and hypermobility.

Purpose: The aim of the present study was to determine the impact of fractures, hypermobility and DI on health-related quality of life (HRQoL) in Danish adults with OI.

Methods: A cross-sectional study of 54 Danish adult patients with OI. This investigation is part of a larger study of adult patients with OI, investigating phenotype-genotype associations. Clinical and radiographic dental examinations were performed to diagnose DI. Information about number of self reported fractures and hypermobility were collected by interviews. HRQoL was examined using the SF-36 questionnaire. The questionnaire consists of 36 questions in 8 major domains: 4 physical domains: Physical Function(PF), Role Physical(RP), Body Pain(BP) and General Health(GH) and 4 mental domains: Vitality(VT), Social Function(SF), Role Emotional(RE) and Mental Health(MH). Scores are 0-100, a higher score reflects a better self-reported HRQoL. The eight domains above were compared between OI patients with and without DI, with and without hypermobility and with less/equal to or more than 10 reported fractures.

Results: Patients with DI had impaired PF score, $p=0.04$, but similar scores for the remaining physical domains and the mental domains ($p>0.6$). Increasing number of fractures decreased the PF score ($p=0.016$), but did not affect RP, BP and GH ($p>0.2$) or the mental scores ($p>0.3$). SF-36 domains did not vary between patients reporting hypermobility and patients not reporting hypermobility, $p>0.25$.

Discussion: The phenotype of patients with OI varies considerably. We investigated HRQoL in relation to 3 phenotypical features (DI, fractures and hypermobility). The only SF-36 domain affected by DI and a high number of fractures was PF. It is not surprising that increasing number of fractures that may cause deformities and limit functionality impair the physical function score. The effect on PF seen with DI is most likely caused by the coexistence of multiple fractures and DI in severely affected patients. This needs further elucidation. Surprisingly, none of the investigated phenotypes affected the other three physical domains or mental health domains, despite severe and lifelong symptoms. This may reflect the adaptation to a congenital disease.

Changes in Circulating Sclerostin Reflect Changes in Bone Remodeling Dynamics Induced by PTH (1-84). Aline Costa¹, Serge Cremers¹, Mishaela Rubin¹, Natalie Cusano², Elzbieta Dworakowski³, Zachary Lenane¹, Chiyuan Zhang¹, Jim Sliney Jr⁴, Donald McMahon², Marise Lazaretti Castro⁵, John Bilezikian². ¹Columbia University, USA, ²Columbia University College of Physicians & Surgeons, USA, ³Columbia University, USA, ⁴Columbia University Medical Center, USA, ⁵Escola Paulista de Medicina, Brazil

The therapeutic actions of PTH in osteoporosis reflect its ability to stimulate bone modeling initially and, more persistently, bone remodeling. In osteoporosis, these actions have been described as an "anabolic window" in which bone formation is stimulated prior to bone resorption and subsequently by bone formation exceeding bone resorption under steady state therapeutic conditions. A potential mechanism to explain these observations is a negative regulatory effect of PTH on sclerostin levels. Hypoparathyroidism (HypoPT), a disorder characterized by absent or low PTH and markedly reduced bone turnover, is associated with levels of sclerostin that are higher than healthy control subjects with normal PTH levels. Treatment of HypoPT with PTH(1-84) presents an opportunity to test how changes in sclerostin levels are related to changes in circulating markers of skeletal dynamics. In this study, we focused on bone turnover markers (BTM), P1NP (bone formation) and CTX (bone resorption), at peak responsiveness to PTH(1-84) in HypoPT, 12 mos after initiation of therapy. Fifteen HypoPT patients (6 men, 9 postmenopausal women), mean age 58 ± 7yrs, were treated for 4yrs with most receiving PTH(1-84)100 µg QOD. Sclerostin was measured at baseline and at months 12, 24, 36 and 48. Initial sclerostin levels were elevated: 1.07 ± 0.38ng/mL (ref nl: 0.61ng/mL). The cohort was divided into tertiles of BTM responsiveness. No significant changes in sclerostin levels from baseline were observed in the lowest and middle tertiles. The highest tertile, in which marked reductions in sclerostin were noted, was associated with a 6.6-fold increase in P1NP (37.7 to 247.8µg/L) and a 5.4-fold increase in CTX (0.16 to 0.87ng/mL). In these responsive groups sclerostin levels were persistently suppressed (TABLE). Reductions from baseline sclerostin values were appreciated as early as 24 mos after PTH(1-84) reaching nadirs for both P1NP and CTX at month 36. The results indicate that among the most responsive subjects with HypoPT to PTH(1-84), sclerostin levels track inversely with bone remodeling. The observations provide further evidence for a sclerostin-associated mechanism by which PTH regulates skeletal dynamics.

Table. Percentage difference in sclerostin over 4 years of PTH (1-84) treatment according to peak level of P1NP and CTX at month 12

| Highest tertile group at month 12 | Sclerostin percentage change from baseline | | | |
|-----------------------------------|--|----------|----------|----------|
| | Month 12 | Month 24 | Month 36 | Month 48 |

Differentially Expressed miRNA199b-5p in Sporadic and Hereditary Parathyroid Tumors. YOON JUNG CHUNG¹, Sena Hwang², Jong Ju Jeong³, Se Hoon Kim⁴, Yumie Rhee⁵. ¹Brain Korea 21 Project for Medical Science, Yonsei University, South Korea, ²International Clinics, Severance Hospital, South Korea, South Korea, ³Department of Surgery, College of Medicine, Yonsei University, South Korea, ⁴Department of Pathology, College of Medicine, Yonsei University, South Korea, ⁵Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Objects. The molecular mechanisms involved in parathyroid tumorigenesis are poorly understood, even in multiple endocrine neoplasia type 1 (MEN 1) which is due to germline mutation in MEN1 gene. miRNAs are interesting candidates for mediating tissue-specific regulation even in benign tumors because they are associated with cancer development and progression. The aim of this study was to identify specific miRNAs associated with parathyroid tumors either sporadically or hereditarily derived. Methods. miRNA arrays containing 887 human miRNAs with four duplicate probes per miRNA were performed on total RNA extracted from parathyroid tumor samples obtained from 6 patients (3 with primary hyperparathyroidism (PHPT) and 3 with MEN 1) and 2 normal parathyroid tissues. Differentially expressed miRNA were validated by the TaqMan real-time quantitative PCR using RNU6 as endogenous control in the tissues of 15 patients with PHPT and 10 with MEN 1. Relative quantification was performed by Livak method with 20 normal parathyroid tissues as a calibrator. Results. The circulating calcium was significantly higher in patients with parathyroid tumors; 9.3 ± 0.5, 11.4 ± 1.1 and 10.6 ± 0.9 mg/dL, respectively in normal patients, patients with tumors associated with PHPT or MEN1 (p<0.05). PTH concentration showed similar pattern as calcium; 31.7 ± 11.3, 233.0 ± 203.6, and

111.1 ± 43.4 pg/mL (p<0.05) respectively. Using FDR<0.05 from microarray data, we identified 10 differentially expressed miRNAs between normal parathyroid tissues versus those from PHPT or MEN1. Among them, putative tumor-suppressor miR-193b was significantly down-regulated in PHPT (p<0.05), but not in MEN1. It also showed similar expression profile with miRNA-365 which is known to cluster with miRNA193b. We also found that miR-199b-5p was decreased in PHPT samples (p<0.05), whereas significantly was increased in those of MEN1 when compared with normal parathyroid tissues (p<0.05). Conclusions. Down-regulation of miRNA-199b-5p seems to have a distinct role in the tumorigenesis leading to the phenotypic differences in sporadic and hereditary type of parathyroid tumors. This argues for the involvement of different miRNAs in the pathogenesis of parathyroid tumors with different genetic background.

Genetic Analyses of CDKN1B and AIP Genes in Familial Primary Hyperparathyroidism. Filomena Cetani¹, Elena Pardi², Simona Borsari², Federica Saponaro², Chiara Banti², Edda Vignali², Luisella Cianferotti¹, Gabriele Di Rosa², Mario Mastinu³, Stefano Mariotti³, Claudio Marcocci¹. ¹University of Pisa, Italy, ²Department of Endocrinology & Metabolism - Section of Endocrinology & Bone Metabolism, University of Pisa, Pisa, Italy, ³Department of Medical Sciences, Endocrinology, University of Cagliari, Italy

Primary hyperparathyroidism (PHPT) is usually a sporadic disorder, but in <10% of cases occurs as part of hereditary syndromes, including multiple endocrine neoplasia types 1 and 2A (MEN1 and MEN2A), hyperparathyroidism-jaw tumor syndrome (HPT-JT) and familial isolated hyperparathyroidism (FIHP).

MEN 1 is an autosomal dominant disorder characterized by tumours in multiple endocrine glands, most commonly parathyroid, enteropancreatic and anterior pituitary glands. To date MEN1 gene germline mutations have been identified in 70-80% of MEN1 kindreds. FIHP has a heterogeneous molecular etiology, since germline mutations of MEN1, HRPT2 and CASR genes have been reported. Recently, germline mutations of cyclin dependent kinase inhibitor 1B (CDKN1B) gene, encoding for p27 protein, have been identified in 7 kindreds with MEN1 syndrome which were negative to the MEN1 genetic screening. In addition, germline mutations of the aryl hydrocarbon receptor interacting protein (AIP) gene, responsible for 15-25% of familial isolated pituitary adenoma (FIPA) syndrome, have been recently reported in a MEN1 case.

The aim of this study was to perform a genetic screening of CDKN1B and AIP genes in patients with MEN1 syndrome (25 and 22, respectively) and in FIHP probands (15 and 14, respectively). All MEN1 kindreds were previously resulted negative for MEN1 gene mutations and all FIHP families were negative for MEN1, HRPT2, CASR mutations.

Genomic DNAs from index cases were analyzed by PCR amplification of the entire coding region and splice site and direct sequencing by a 16-capillaries automatic sequencer.

A novel frameshift germline mutation of CDKN1B gene, c.372_373delCT/p.Asn124AsnfsX2, was identified in a MEN1 proband. Two mutations in exon 1 of AIP gene were detected in two MEN1 probands, namely Arg9Gln (c.26G>A) and Arg16His (c.47G>A). Both germline mutations have already been reported, Arg9Gln in one acromegalic patient and Arg16His in several FIPA families, and patients with apparent sporadic pituitary adenoma.

Our results suggest that germline CDKN1B and AIP mutations may be partially involved in parathyroid tumorigenesis, affecting a small number of MEN1 patients.

Imaging Changes in 99mTc-mibi in Patients with Primary Hyperparathyroidism Treated with Cinacalcet. Araceli Munoz-Garach¹, Diego Fernandez-Garcia², Maria Dolores Martinez del Valle-Torres³, Ana Maria Gomez-Perez², Arantazu Sebastian-Ochoa², Francisco Tinahones-Madueño². ¹, Spain, ²Endocrinologist, Spain, ³Medicine Nuclear, Spain

Introduction: Previous studies in secondary hyperparathyroidism show that treatment with cinacalcet may result in a decreased uptake of radiopharmaceutical as a result of decreased secretory activity of the parathyroid glands. However this effect has not been studied in patients with primary hyperparathyroidism (PHPT).

Objective: To assess changes in 99mTc-methoxy-isobutyl-isonitrile (MIBI) scintigraphy uptake of parathyroid adenomas in patients treated with cinacalcet.

Patients and methods: We evaluated scintigraphy changes of sixteen patients (four more patients have a negative one) treated with Cinacalcet. We determined: uptake rate (estimated as a percentage) mean and maximum uptake images obtained during both early (within 15 minutes of contrast administration) and late (an hour after dose tracer) and were reassessed after receiving treatment with Cinacalcet for a minimum

period of three months. Scintigraphy measurement was made both qualitatively and semiquantitatively. We also evaluated clinical and laboratory parameters.

Results: According to the qualitative scale 75% of analyzed patients decreased their uptake on the scan performed after a treatment period, 12% of them obtained the same results in uptake. One case out of 20 showed negative in the baseline scan but then located the adenoma in the post-treatment scan. However, in quantitative scale there is a trend to statistical significance but there are no differences between pre and post assessments, maximum and mean or early and late phase uptake.

There were no statistically significant differences between clinical parameters, biochemical and scintigraphy findings.

Conclusions: Treatment with Cinacalcet seems to decrease scintigraphy uptake of parathyroid adenomas in patients with PHPT. Further studies should evaluate the clinical relevance of this finding.

Disclosures: Araceli Munoz-Garach, None.

Major Improvements in Quality of Life After 1 Year of PTH(1-84) Therapy in Hypoparathyroidism. Natalie Cusano^{*1}, Mishaela Rubin², Donald McMahon¹, Amanda Tulley³, Jim Sliney Jr⁴, John Bilezikian¹.

¹Columbia University College of Physicians & Surgeons, USA,

²Columbia University, USA, ³Columbia University, USA, ⁴Columbia University Medical Center, USA

Hypoparathyroidism (HypoPT) is a rare disorder characterized by low serum calcium and PTH levels for which PTH replacement is under active investigation. Patients with HypoPT often complain of compromised quality of life (QOL) and subtle neurocognitive deficits, yet virtually no data exist to define these complaints or the potential effects of PTH therapy to ameliorate them. We tested the hypothesis that HypoPT patients have a decreased QOL and that PTH therapy improves such indices. 54 HypoPT subjects [age 46±14yrs; 40 women (15 postmenopausal); etiology: 27 surgical, 26 autoimmune, 1 DiGeorge; duration 13±12yrs; calcium 8.6±0.9mg/dL; PTH 2±6pg/mL] were treated with open-label PTH(1-84) 100µg qod for 1yr. At mos 0, 1, 2, 3, 4, 5, 6, 9, and 12, subjects completed the SF-36 survey, a validated measure of health-related QOL covering elements of physical (4 domains) and mental (4 domains) health. At baseline, HypoPT subjects were lower than the normative reference range in 7/8 domains (T-scores -1.4 to -0.8; p<.05). With PTH therapy, intention-to-treat analysis showed the total score increased significantly at 1mo (434±16 to 472±15; p=.023) and remained elevated through 1yr (487±14; p=.008). The mental component summary (MCS) score improved significantly over 1yr (221±9 to 252±8; p=.01), as did 3 mental health domains, generally as early as 1mo [vitality: 35±3 to 47±2; social functioning: 63±3 to 71±3; mental health (MH): 62±2 to 70±2; T-scores improving from -1.3 to -0.8, -0.9 to -0.6, -0.8 to -0.3, respectively; p<.05 for all]. The physical component summary score increased at 6mos (210±9 to 244±8; p=.003) and remained higher at 1yr, with physical functioning (PF) improving from 65±3 to 75±3 (p=.01). Ten subjects discontinued therapy between mos 1-6: 1 for nephrolithiasis and 9 for logistics of travel/other difficulties. Subjects who discontinued PTH had significantly lower MH scores at 1mo, MCS scores at 2mos, and PF and body pain scores at 4mos. These data suggest that HypoPT is associated with QOL deficits, even in the presence of eucalcemia, and that PTH therapy significantly improves QOL indices, particularly those related to mental health. The suggestion that PTH(1-84) has direct CNS effects may account for these observations. Beyond improved biochemical control in HypoPT, these results indicate that PTH(1-84) treatment of HypoPT may lead to important improvements in QOL.

Disclosures: Natalie Cusano, None.

Predictors of PTH and Association of PTH with Skeletal Outcomes in a Population-based Study. Claudie Berger^{*1}, Ohoud Almohareb², Lisa Langsetmo³, David Hanley⁴, Christopher Kovacs⁵, Robert Josse⁶, Jonathan Adachi⁷, Jerilynn Prior⁸, Tan Towheed⁹, K. Shawn Davison¹⁰, Stephanie Kaiser¹¹, Jacques Brown¹², David Goltzman¹.

¹McGill University, Canada, ²McGill University, Canada, ³Canadian Multicenter Osteoporosis Study, Canada, ⁴University of Calgary, Canada, ⁵Memorial University of Newfoundland, Canada, ⁶St. Michael's Hospital, University of Toronto, Canada, ⁷St. Joseph's Hospital, Canada, ⁸University of British Columbia, Canada, ⁹Queen's University, Canada, ¹⁰Laval University, Canada, ¹¹Dalhousie University, Canada, ¹²CHUQ Research Centre Laval University, Canada

We examined the potential determinants of circulating parathyroid hormone (PTH) and whether serum PTH is associated with skeletal outcomes in the Canadian Multicenter Osteoporosis Study (CaMos), a population-based prospective cohort study.

Year 10 (2005-07) blood samples (fasting) were analyzed in 1305 women and 566 men aged >35 years for PTH with a Diasorin Liaison machine (reference range of 22.2 to 108.9 pg/ml). Serum PTH values were log transformed to achieve a more normal distribution. Potential determinants of PTH considered included age group, race, season of blood draw, calcium and vitamin D intake (dietary and supplemental), body

mass index, height, corticosteroid and antiresorptive use, eGFR, 25-hydroxyvitamin D [25(OH)D], self-reported diagnosis of hypertension and kidney stones, sun exposure, cigarette smoking, and participation in a regular physical program or activity. As potential skeletal outcomes, we examined associations of (categorical) PTH with log-transformed bone-specific alkaline phosphatase (BAP), log-transformed C-terminal telopeptide of type 1 collagen (CTX) and BMD (L1-L4, femoral neck and total hip). A subgroup of 857 women and 361 men was used for CTX.

The mean (SD) and median of PTH were 61.8 (27.1) pg/ml and 57.2 pg/ml for women and 62.8 (30.4) pg/ml and 56.5 pg/ml for men. Determinants of higher PTH levels were older age, lower 25(OH)D, lower serum calcium levels and lower calcium supplement intake in both women and men. For women, determinants of higher PTH levels also included higher BMI, current use of corticosteroids, winter blood draws, and lower eGFR. Women and men in the 1st quartile (lowest values) of PTH had BAP levels lower by 11.0% (95% confidence interval: 5.1; 16.1) and 14.6% (5.2; 24.1), respectively, than those in the 4th quartile of PTH (highest PTH levels), however we did not find any association of PTH with CTX levels. Women in the 1st or 2nd PTH quartiles had total hip BMD values 0.04 (0.02; 0.06) g/cm² higher than those in the 4th quartile, whereas men in the 1st PTH quartile had total hip BMD values 0.03(-0.00; 0.06) g/cm² higher. We obtained similar results for L1-L4 and femoral neck BMD.

In this random community sample, age, 25(OH)D levels, calcium intake, BMI, renal function and corticosteroid use appeared to be determinants of serum PTH. Increasing serum PTH levels were associated with increased bone turnover, as reflected by serum BAP levels (but not CTX), and reduced hip and spine BMD values.

PTH (1-84) Substitution Therapy in Hypoparathyroidism: Effects on Muscle Cells, Muscle Function, Postural Stability and Quality of Life. Tanja Sikjaer^{*1}, Lars Rolighed², Niels Ortenblad³, Alexander Hess⁴, Lars Reinmark⁵, Leif Mosekilde¹.

¹Department of Medicine & Endocrinology, MEA, Aarhus University Hospital, Denmark, ²Department of Surgery P, Aarhus University Hospital, Denmark, ³Institute of Sports Science & Clinical Biomechanics, University of Southern Denmark, Denmark, ⁴Department of Clinical Neurophysiology, Aarhus University Hospital, Denmark, ⁵Aarhus University Hospital, Denmark

Myopathy and reduced quality of life (QoL) have previously been reported in patients with hypoparathyroidism (hypoPT). This may be caused by decreased activation of PTH receptors in muscle and brain.

We studied muscle function in 62 patients with chronic hypoPT randomized to 6 months of treatment with either PTH(1-84) 100 µg/d s.c. or similar placebo, administered as an add-on therapy to conventional treatment.

Mean duration of hypoPT was 12 (range: 1-37) yrs. Four subjects had idiopathic and 58 had postoperative-hypoPT. Mean age was 52±11 yrs. 85% were females.

Muscle strength was measured by an adjustable dynamometer chair. In response to PTH, Max Force Production (MFP) at elbow extension decreased significantly compared with placebo. Similarly, MFP decreased borderline significantly in response to PTH at elbow flexion, hand grip, and knee extension 60°. Moreover, hand grip Max Force (MF) and MF at elbow flexion and extension decreased borderline significantly with PTH compared to placebo.

Postural stability measured using a stadiometer in 4 different positions showed no change in response to treatment, nor did Repeated Chair Stand and Timed Up and Go tests.

Muscle biopsies obtained from the thigh showed a significantly increase in Ca²⁺ uptake and release from the sarcoplasmic reticulum in response to PTH treatment.

At baseline, needle electromyography did not show myopathy in any of the patients. Compared with placebo, PTH treatment decreased the mean duration of motor unit potentials in m. biceps brachii, in the direction towards myopathy.

The SF36v2 questionnaire showed a significantly lower baseline score, compared to the normbased population, at most subscales including the physical component score. SF36v2 and WHO-5 scores showed no changes in response to treatment.

In general, our findings suggest a slight but significant deleterious effect of PTH therapy on muscle function. Despite these findings patients did not report increased fatigue or deterioration of QoL. Accordingly, the findings are most likely of subclinical importance. During the 6-months of study, plasma calcium levels fluctuated markedly in the PTH group, until doses of calcium and active vitamin D was adjusted (down-titrated), and the large fluctuations in calcium may have compromised potential beneficial effects of PTH substitution. Accordingly, long term effects should be determined in order to evaluate whether improvements may occur in response to long term treatment.

Skeletal Microstructural Abnormalities in Hypoparathyroidism by High Resolution Peripheral Quantitative Computed Tomography. Stephanie Boutroy^{*1}, Barbara Silva¹, Mishaela Rubin², Jim Sliney Jr¹, Donald McMahon³, Chiyuan Zhang², Natalie Cusano³, John Bilezikian³.
¹Columbia University Medical Center, USA, ²Columbia University, USA, ³Columbia University College of Physicians & Surgeons, USA

Hypoparathyroidism (HypoPT) is an uncommon disorder characterized by absent or deficient production of parathyroid hormone (PTH) and hypocalcemia. Skeletal abnormalities are described dynamically by a low turnover state and by enhanced skeletal mass by BMD. Studies by us and others have suggested that the increase in BMD is associated with hypermature bone of poor quality. High Resolution Peripheral Computed Tomography (HRpQCT; Scanco Medical AG, Switzerland) has the potential to distinguish these abnormal skeletal characteristics between trabecular and cortical compartments of bone as well as to test how a loaded site (tibia) might differ from an unloaded site (ultradistal radius).

To this end, we studied 45 women (age 45 ± 12) with well characterized HypoPT. HRpQCT female-specific Z-scores were compared to normative values from the OFELY cohort.

HRpQCT female-specific-Z-scores in HypoPT subjects were summarized in the table. Trabecular number was higher and trabecular thickness was lower at both radial and tibial sites. Trabecular separation was reduced at the tibia but not at the radius. The cortical indices as measured by cortical vBMD and cortical thickness were significantly higher than normal at the radius but not at the tibia where the values were not different from normal. The lack of PTH in HypoPT appeared to be associated with enhanced cortical parameters, but only in the radius.

The data suggested that the loaded skeletal site, as typified by the tibia, has other mechanisms by which abnormal cortical enhancement in the setting of absent PTH can be prevented.

| HRpQCT parameters | Z-score (Mean \pm SEM) | |
|-------------------------|--------------------------|----------------------|
| | Radius | Tibia |
| Total Area | 0.04 \pm 0.18 | 0.57 \pm 0.15 *** |

Circulating Mesenchymal Stem Cells with Abnormal Osteogenic Potential in Patients with Ankylosing Spondylitis. Ki-Jo Kim^{*1}, Su-Jung Park², In-Woon Baek², Chong-Hyeon Yoon², Wan-Uk Kim², Chul-Soo Cho², Moo-Il Kang³.
¹College of Medicine, The Catholic University of Korea, South Korea, ²College of Medicine, The Catholic University of Korea, South Korea, ³Seoul St. Mary's Hospital, South Korea

Background: Ankylosing spondylitis (AS) is a chronic, progressive disease characterized by inflammation of entheses, leading to new bone formation, syndesmophytes, and ankylosis of joints, primarily in the axial skeleton. However, the mechanism of new bone formation has only partly been understood. In recent, it has been reported that alteration of osteoblastic differentiation of circulating mesenchymal stem cells (MSCs) may contribute to the pathologic change of bone.

Objectives: To evaluate a possible alteration of osteogenic potential of circulating MSCs in patients with AS

Methods: Eighty-nine consecutive patients with AS and twenty-five sex- and age-matched healthy controls were included. Baseline assessment included clinical, radiologic and laboratory data. Radiographs of the lumbar spine were used to detect syndesmophytes. Serum concentration of bone metabolic markers including bone specific alkaline phosphatase (BALP), osteocalcin and telopeptide of type I collagen were measured. Circulating MSCs were analysed and sorted by flow cytometry using four markers (CD34-/CD45-/CD13+/CD29+). The expression of transcription factors runt-related transcription factor 2 (RUNX2) and peroxisome proliferator-activating receptor γ (PPAR γ) were assessed by real-time RT-PCR.

Results: Serum BALP levels were elevated in AS patients compared with healthy subjects (26.5 ± 1.6 vs. 13.3 ± 0.8 ug/L, $P < 0.001$). Number of circulating MSCs was significantly higher in AS patients than controls (1500 ± 593 vs. 181 ± 55 /mL, $P = 0.031$) and positively correlated with serum BALP concentration ($r = 0.414$, $P = 0.002$). RUNX2 expression was upregulated in MSCs from AS patients compared with controls ($P < 0.05$), whereas PPAR γ expression was not different between two

groups. Clinically, circulating MSCs count was even more elevated in AS patients with syndesmophytes than those without (2718 ± 1287 vs. 734 ± 229 /mL, $P = 0.042$).

Conclusions: High number of circulating MSCs with osteogenic potential in AS patients was associated with the presence of syndesmophytes, suggesting a potential role of MSCs on new bone formation in AS.

Monocytic Expression of Osteoclast-associated Receptor (OSCAR) Is Induced in Atherosclerotic Mice and Regulated by Oxidized Low-density Lipoprotein in vitro. Kathrin Sinnigen^{*1}, Claudia Goetsch², Martina Rauner³, Nadia Al-Fakhri⁴, Michael Schoppet⁵, Lorenz Hofbauer¹.
¹Dresden University Medical Center, Germany, ²Brigham & Women's Hospital Cardiovascular Division, USA, ³Medical Faculty of the TU Dresden, Germany, ⁴Institute of Laboratory Medicine & Pathobiochemistry, Molecular Diagnostics, Philipps-University, Marburg, Germany, ⁵Department of Internal Medicine & Cardiology, Philipps-University, Marburg, Germany

The osteoclast-associated receptor (OSCAR), initially described as a co-stimulatory regulator of osteoclast differentiation, represents a potential link between bone metabolism and vascular biology. Previously, we identified OSCAR to be expressed on endothelial cells and vascular smooth muscle cells in response to proatherogenic factors such as oxidized low density lipoprotein (oxLDL). OSCAR expression increased in the aorta of the ApoE-knock-out (ApoE-KO) mouse, an atherogenic model compared to wild-type mice, and was further induced by a high-fat diet. Because monocytes play an important role in the progression of atherosclerosis, and OSCAR was first described on cells of the monocytic lineage, we assessed whether atherosclerosis also regulates the expression of OSCAR on monocytes and whether it is also regulated by oxLDL or other inflammatory mediators in vitro. Four weeks old male wild-type (WT) and ApoE-KO mice were fed a high-fat diet or normal chow for 6 weeks. Thereafter, peripheral blood mononuclear cells (PBMC) were isolated from the spleen by Biocoll density centrifugation to stain the cells with antibodies against CD14 and OSCAR for subsequent flow cytometric analysis. OSCAR surface expression on CD14-positive monocytes was increased 2-fold in PBMCs from ApoE-KO mice compared to WT mice. Feeding a high-fat diet further increased OSCAR surface expression up to 1.5-fold in ApoE-KO mice. In addition, we exposed a murine macrophage cell line, RAW 264.7 to oxLDL, TNF-alpha, and IL-6 for 24 and 48 hours. While IL-6 stimulation did not influence OSCAR expression, OSCAR mRNA levels were induced 3.5-fold by TNF-alpha, whereas oxLDL treated cells showed an 8-fold increase after 48 hours. In conclusion, monocytic OSCAR expression increases in a murine model of atherosclerosis and is induced by atherogenic stimuli in vitro, thus, suggesting a potential role in the process of atherosclerosis.

Evaluation of Cell Therapy as a Treatment Approach for Osteogenesis Imperfecta. Penelope Armada^{*1}, Liping Wang², Elena Torreggiani³, Brya Matthews², Igor Matic², David Rowe², Ivo Kalajzic².
¹Connecticut Children's Medical Center, USA, ²University of Connecticut Health Center, USA, ³University of Connecticut health Center, USA

Osteogenesis imperfecta (OI) is a genetic disorder caused by reduced or improper type I collagen production that results in bone fragility. Recent studies have been directed at silencing or correcting the mutation in bone marrow stromal cells (BMSCs) derived from patients with OI. Despite the success of these in vitro therapeutic approaches, further development of techniques for reintroducing engineered cells back

into the patient is required. Currently, the most effective transplantation has been in the fetal period.

We aimed to evaluate whether donor cells delivered locally into femurs were able to engraft, differentiate into osteoblasts, and contribute to formation of normal bone. Donor BMSCs from mice harboring the bone-specific Col2.3GFP transgene were cultured in 5% O₂ for 7 days prior to transplant to expand undifferentiated mesenchymal progenitors (Col2.3GFP- at transplantation). The osteogenesis imperfecta murine (OIM) model was utilized as the recipient. Mice underwent irradiation, then received wild-type whole bone marrow via the retro-orbital sinus, followed by intramedullary delivery of 106 donor BMSCs in the right femur.

Histological evaluation of bones was completed one month after transplantation. We detected differentiation of donor cells into Col2.3GFP+ osteoblasts and osteocytes in cortical and trabecular bone of the transplanted femur. Col2.3GFP+ cells were not found in the contralateral femur, nor were they seen in bones from mice administered systemic BMSC transplantation. Cultures derived from transplanted femurs of mice after one month showed no Col2.3GFP+ cells after 7 days in culture, but numerous Col2.3GFP+ colonies were present by day 14 indicating the presence of donor derived progenitor cells. This was not observed in cultures from the contralateral femur or from mice that underwent systemic transplantation. To evaluate the progenitor potential of transplanted BMSCs we have performed secondary transplantation of cells recovered and expanded in vitro from recipient femurs. These cells also engrafted and differentiated into GFP+ osteoblasts and osteocytes indicating the persistence of donor stem/progenitor cells.

Our results indicate that BMSCs delivered locally in OIM femurs are able to engraft, differentiate into osteoblasts and osteocytes, and maintain their progenitor potential in vivo. Future studies will address the effects of transplantation on bone parameters and assess long-term engraftment.

Demonstration of a Bone Phenotype in a Murine PKU Model and its Attenuation with an Improved Low-Phenylalanine Diet. Patrick Solverson^{*1}, Sangita Murali², Suzanne Litscher³, Robert Blank⁴, Denise Ney². ¹University of Wisconsin - Madison, USA, ²University of Wisconsin - Madison, Department of Nutritional Sciences, USA, ³University of Wisconsin - Madison, Department of Medicine, USA, ⁴University of Wisconsin, USA

Phenylketonuria (PKU) is caused by a defect in phenylalanine (phe) hydroxylase and requires a low-phe diet plus amino acid (AA) formula to prevent cognitive impairment. Skeletal fragility has been recognized as a chronic complication of PKU, but is poorly understood. Glycomacropeptide (GMP), a low-phe protein isolated from cheese whey, provides an alternative to AA formula. Our objective was to determine how the PKU genotype and dietary protein source affect growth and the biomechanical properties of bone. Male and female PKU (Pah^{enu2}) and wild type (WT) mice, all on a C57BL/6J background, were fed low-phe GMP, low-phe AA or high-phe casein diets from 3 to 23 weeks of age. Body composition was assessed by dual-energy x-ray absorptiometry (DXA) and femur biomechanics were assessed by the 3-point bending test. Femoral diaphyseal structure and ex vivo femoral bone mineral density (BMD) were also measured. Whole bone parameters were used to perform principal component analysis (PCA). Data were analyzed by 3-way ANOVA, with genotype (2 levels), sex (2 levels), and diet (3 levels) as the main factors. Regardless of diet, PKU femora were more brittle than WT femora. Regardless of genotype, AA reduced femoral cross-sectional area with a consequent reduction of maximal load. Multiple additional differences in biomechanical performance and femoral structure were observed among the groups. For example, female, but not male, PKU mice showed reduced body growth compared to WT mice. The protective effect of GMP was more dramatic in female than male PKU mice. PCA yielded 4 PCs with Eigen values > 1, which accounted for 87% of the raw data variance. All 4 PCs displayed a genotype effect. Data are summarized in the table. In summary, the increased brittleness of PKU femora suggests that the bone matrix rather than the bone mineral is abnormal. This phenotype is significantly improved with ingestion of a low-phe diet providing GMP rather than AA as a protein source. The benefits of GMP on bone development may reflect improved collagen formation, lower dietary acid and reduced metabolic stress.

Homogeneous Mutant Collagen in Osteogenesis Imperfecta Model Mice Leads to Improved Bone Phenotype through Multiple Pathways. ADI REICH^{*1}, Wayne Cabral², Joan Marini¹. ¹National Institute of Child Health & Human Development, USA, ²Bone & Extracellular Matrix Branch, NICHD, NIH, USA

Classical osteogenesis imperfecta (OI) is caused by autosomal dominant mutations in type I collagen. The Brl knock-in mouse, with a G349C substitution in one *colla1* allele, models classical OI inheritance and bone phenotype. Brl heterozygous (HET) pups have 30% prenatal lethality; survivors have a moderate bone dysplasia. Because dominant negative disorders are typically more severe in homozygous (HZ) form, it was surprising that HZ Brl perinatal lethality was comparable to WT. Surviving HZ phenotype and bone mechanical properties were intermediate between HET and WT. We investigated two murine genotypes with homogenous mutant collagen, HZ (Brl/Brl) and Brl/mov, a compound with the null mov13 *colla1* allele. Brl/mov also have normal perinatal survival and improved bone properties. We analyzed the differentiation of cultured calvarial osteoblasts (OB) from HZ and Brl/mov mice during differentiation timecourse using Osteogenesis PCR Arrays and qPCR.

Expression of OB differentiation markers was variably altered in HZ and Brl/Mov cells, rather than restored to WT levels. HZ OB displayed increased expression of *Cdh11*, *Intga2*, and the pre-osteocyte marker *E11/Pdnp*, compared to WT and HET OB. HZ OB had blunted expression of *Dmp1*, *Sost*, *Phex*, *Colla1*, *Colla2*, *Akp*, *Runx2* and *Bmp2*. In femoral tissue RNA, HZ mice had decreased expression of *Sost*, *Osx*, *Bmp2* and *Vegfa*. Immunostaining of *Dmp1* showed lighter intensity in extracellular matrix of cortical bone, compared to HET and HZ mice. In contrast, Brl/Mov OB do not display increased expression of *E11*, *cdh11* or *Intga2*, and have increased expression of *Dmp1*, *Sost*, *Colla1*, *Colla2*, & *Akp*, compared to WT, Mov13 and Brl.

Cell-matrix exchange was performed with HZ OB to study the influence of matrix composition on OB differentiation. *Colla1*, *Runx2* and *Sost* are modulated by matrix, and WT, HET and HZ cells have normal or intermediate levels on HZ matrix. In contrast, *Alp*, *BMP2* and *Itga2* are primarily determined by cellular genotype, and are hardly altered by the matrix exchange.

HZ and Brl/mov mice achieve homogeneous mutant collagen by different mechanisms and apparently attain improved bone properties by distinct pathways.

These expression patterns suggest that several compensation mechanism involving bone mineralization and remodeling, as well as cell-matrix attachment, occur in OB on homogenous mutant matrix. These pathways function to improve OI bone phenotype and could be the basis of novel therapeutic approaches

Knock-in of the p.G213R Mutation in the Mouse *Cln7* Gene Induces a Phenotype that Mimics the Human Autosomal Dominant Osteopetrosis Type II (ADO2) Disease. Evidence of Effect of Genetic Background. Imranul Alam^{*1}, Amie Gray², Shoji Ichikawa¹, Kang Chu³, Khalid Mohammad⁴, Marta Capannolo⁵, Anna Teti⁵, Michael Econs¹, Andrea Del Fattore⁶.
¹Indiana University School of Medicine, USA, ²IUPUI, USA, ³Northwestern University, USA, ⁴Indiana University, USA, ⁵University of L'Aquila, Italy, ⁶Children Hospital Bambino Gesù, Italy

ADO2 is a heritable osteosclerotic disorder that usually results from heterozygous missense mutations in the chloride channel 7 (*CLCN7*) gene. Our two labs (L'Aquila and Indianapolis) independently generated the first animal model of the disease by inserting a G-A transition at DNA position 14365 leading to Glycine-Arginine substitution at protein position 213 (analogous to a common human mutation p.G215R). Homozygous mutant mice showed lack of tooth eruption and a dramatic increase in bone mass. They died within 30 days of age with a severe osteopetrotic phenotype, thus confirming insertion of a pathogenetic mutation. Compared to WT, heterozygous B6 ADO2 mice showed significant increase of whole body aBMD (4%, $p < 0.05$) and much greater change at distal femur for BV/TV and Trab.N (75% and 65%, $p < 0.001$ and $p < 0.01$, respectively) (Table 1). In concert with ADO2 patients, bone marrow monocytes from B6 ADO2 mice, cultured with M-CSF and RANKL, showed 2-fold increase of osteoclast formation and 80% reduction of resorption pits, confirming cell autonomous impairment of bone resorption. Since the penetrance of the disorder in human is approximately 66% and severity varies considerably, we created models of phenotypic variability by cross-breeding B6 ADO2 with mice of different genetic backgrounds, namely 129, D2, Balb/c and CD1. Compared to WT, the whole body aBMD and BMC at 12 weeks of age were very high in ADO2 mice on 129 background (8% and 12%, $p < 0.0003$ and $p < 0.01$, respectively). ADO2 mice on D2 background also had significantly higher whole body aBMD (4%, $p < 0.02$). The BV/TV and Trab.N were significantly higher and Trab.Sp was significantly lower at distal femur in ADO2 mice on 129 and D2 backgrounds, while BV/TV was higher in ADO2 mice on Balb/c background and changes were not significant in CD1 ADO2 mice (Table 1). CTX/TRAcP ratio was significantly lower in all ADO2 backgrounds, except the D2 (Table 1). Our results demonstrate that we have independently generated the first bona fide mouse model of ADO2 caused by the heterozygous p.G213R *Cln7* gene mutation and that considerable variability exists for disease severity in ADO2 mice on different genetic backgrounds, consistent with the presence of genes that modify the phenotype. These mouse models will help us to identify the genes that influence penetrance and severity in human ADO2, and to test innovative therapies to treat this incurable disease.

Loss of Heterozygosity of SUFU or PTCH2 Locus Associates with Keratocystic Odontogenic Tumor. Yasuyuki Shimada^{*1}, Kei Sakamoto², Kei-ichi Morita¹, Yuji Kabasawa¹, Ken Omura¹, Akira Yamaguchi².
¹Tokyo Medical & Dental University, Japan, ²Tokyo Medical & Dental University, Japan

Background and Purpose:

Gorlin-Goltz syndrome (GGS) is an autosomal dominant genetic disease characterized by multiple developmental disorders such as skeletal deformities. The patients are prone to develop basal cell carcinoma, medulloblastoma, and cystic jaw tumor called keratocystic odontogenic tumor (KCOT). About half of the patients

harbor a loss-of-function mutation in PTCH1, a receptor of sonic hedgehog, but the genetic background of the other half remains unclear. These neoplastic lesions also develop sporadically, still, only a few of them seem to be associated with PTCH1 malfunction. These suggest a possibility that other genes in the hedgehog signaling pathway may be affected. We made a hypothesis that both of Suppressor of Fused (SUFU) and PTCH2, which regulate hedgehog signaling, may be affected in GGS and also in KCOT.

This study aims to clarify the alteration of PTCH1, PTCH2 and SUFU genes in GGS patients and also in non-GGS patients who developed KCOT. Additionally, loss of heterozygosity (LOH) analysis was performed in KCOT cells to clarify the pathogenesis of KCOT.

Study Design:

DNA sequence of all the exons of PTCH1, PTCH2 and SUFU were analyzed in 31 KCOT patients (15 GGS-related and 16 sporadic) who visited the Dental Hospital of Tokyo Medical and Dental University.

DNA was extracted from buccal swab and PCR-direct sequencing was performed. KCOT cells and stromal cells were separately microdissected from formalin-fixed paraffin-embedded surgical specimens and DNA was extracted for LOH analysis using short tandem repeat polymorphic markers. Informed consent was obtained from all patients.

Results: Of all the 15 GGS cases examined, 9 (60%) had PTCH1 mutation and one had also a PTCH2 mutation. No PTCH1 mutation was found in sporadic cases. SUFU mutation was not detected.

LOH of PTCH1, PTCH2, and SUFU locus were detected in both sporadic (33.3%) and syndromic KCOT (78.6%). Although there was no distinctive predisposition of gene loci, LOH was detected more frequently in syndromic KCOTs than sporadic ones ($P = 0.018$).

Conclusions: This study indicates that acquired alteration of SUFU or PTCH2 locus may play a significant role in the development of KCOT.

Neurofibromin Controls Bone Mineralization by Controlling Pyrophosphate Extracellular Levels. Jean De La Croix Ndong^{*1}, Philippe Crine², Xiangli Yang¹, Florent Elefteriou¹.
¹Vanderbilt University, USA, ²Enobia Pharma, Canada

Neurofibromatosis is an autosomal dominant disease (incidence: 1/3000) caused by mutations in the *NF1* gene, which encodes the RAS/GAP neurofibromin. Patients with NF1 can present with a number of skeletal maladies, including pseudoarthrosis (PA), i.e. non-bone union following fracture, and 50-80% of patients with PA also have NF1. Despite substantial advances in the past years, the etiology of NF1 PA remains unclear, and most NF1 patients with PA still require multiple and invasive surgeries. Our goal in this study was to characterize the maturation of *Nf1*^{-/-} osteoprecursor cells using bone marrow stromal cells (BMSCs) isolated from WT and *Nf1*^{lox2}^{-/-} mice or from GFP- or cre-adenovirus infected *Nf1*^{lox/lox} BMSCs. Compared to WT BMSCs, *Nf1*^{-/-} BMSCs formed a reduced number of alkaline phosphatase-positive (cfu-AP) colonies and mineralized alizarin red-positive (cfu-Ob) colonies, which was suggestive of impaired differentiation and/or mineralization. Accordingly, the expression of osteoblast differentiation marker genes, including *Coll*, *Ocn*, *Bsp*, *Runx2*, *Osx* and *Tnsalp* was decreased in *Nf1*^{-/-} BMSCs, whereas the expression of *Rankl* was increased. BMP2 treatment was able to stimulate the differentiation of *Nf1*^{-/-} BMSCs, as measured by increased number of cfu-AP and gene expression, but was unable to correct the defective mineral deposition of *Nf1*^{-/-} cells, indicating that *Nf1*^{-/-} osteoblasts are characterized by a differentiation and a mineralization defect. Further investigations revealed that levels of extracellular inorganic pyrophosphate (ePPI), a potent inhibitor of hydroxyapatite formation and propagation, were elevated in conditioned medium from *Nf1*^{-/-} BMSCs compared to WT BMSCs. The expression of *Ank*, a transporter of extracellular inorganic pyrophosphate (ePPI), *Enpp1*, an enzyme generating PPI, and *Opn*, an inhibitor of mineral nucleation was significantly increased in *Nf1*^{-/-} immature BMSCs, whereas the expression of *Tnsalp*, whose activity is to cleave PPI, was reduced. Importantly, co-treatment of *Nf1*^{-/-} BMSCs with rBMP2 (as differentiation inducer) and a recombinant form of human TNSALP (Asfotase alpha as a mean to reduce ePPI levels) rescued both differentiation and matrix mineralization in *Nf1*^{-/-} BMSCs. Taken together, our data provide a proof of concept that pharmacological enhancements to treat NF1 PA will require both stimulation of osteoblast differentiation and inhibition of ePPI accumulation to allow proper bone healing.

On the Nature of the Genetic Bases of the High Bone Mass Phenotype in Spanish Postmenopausal Women. Patricia Sarrión¹, Leonardo Mellibovsky², Roser Urreiziti¹, Maria Soler-Sala¹, Neus Cols¹, Natalia Garcia-Giralt³, Guy Yoskovitz³, Alvaro Aranguren⁴, Roberto Güerri², Xavier Nogues⁵, Adolfo Diez-Perez⁶, Daniel Grinberg^{*7}, Susana Balcells⁸.
¹Department of Genetics, University of Barcelona, CIBERER, IBUB, Spain, ²Institut Municipal D'Investigació Mèdica, Spain, ³IMIM, Spain, ⁴The University of Barcelona, Spain, ⁵Institut Municipal D'Investigació Mèdica, Spain, ⁶Parc De Salut Mar, Spain, ⁷The University of Barcelona, Spain, ⁸University of Barcelona, Spain

The purposes of this study were: to establish the prevalence of the high bone mass (HBM) phenotype in the BARCOS cohort (n=1600); to determine whether any of the HBM cases carry *LRP5* mutations that explain the phenotype; to characterize the expression pattern of osteoblast-specific and Wnt pathway genes in primary osteoblast RNA samples from two HBM cases; and to test the hypothesis of an inverse correlation between the number of common variant osteoporosis risk alleles and HBM.

Material and methods: HBM individuals within the BARCOS cohort were identified according to the criterion of a sum Zscore > 4 (total LS-Zscore + total Hip-Zscore). Relevant exons of *LRP5* were PCR-amplified and sequenced. Cosegregation analysis of markers in the *LRP5* gene region was performed in one family. Primary osteoblasts from two HBM and two control individuals were cultured and RNA was extracted. A Roche RealTime Custom Panel was used to analyse the expression of 88 osteoblast-specific and/or Wnt pathway genes. SNPs from previous GWA studies were genotyped in the HBM cases and relatives and a weighted score was obtained for each individual. These scores were plotted against BMD values.

Results: In the BARCOS cohort of postmenopausal women, 0.6% of individuals display BMD values in the HBM range. No mutations in the analysed exons of the *LRP5* gene were found in these patients. Additionally, in one familiar case in which the mother and one of the two sibs had BMD values in the range of HBM, cosegregation analysis ruled out *LRP5* involvement. Further cosegregation studies in this family allowed the exclusion of the following genes: *DKK2*, *IL6R*, *RANK*, *BMP2*, and *KRMI*. The only gene cosegregating was *RANKL*, but it was sequenced in the proband and no mutations were found. Regarding the expression analysis, five genes were found to be overexpressed in the two HBM samples: *BMP4*, *COL10A1*, *RUNX2*, *FZD3* and *SOX6*, while four were underexpressed: *DLX3*, *TWIST1*, *IL6R*, and *PPARG*.

Finally, preliminary results point to an inverse correlation between risk alleles and BMD in this group of women, although two women with the highest BMD values presented with the highest risk score. A low frequency penetrant unknown genetic variant could be a possible explanation for these cases.

Conclusions: *LRP5* is not the cause of the HBM phenotype in these cases from BARCOS cohort. The results of the expression study raise new hypotheses that should be further investigated. HBM maybe genetically heterogeneous.

Specific Effects of Activating Gsa Mutation in Specific Compartments of the Stromal/Osteogenic Lineage in vivo Explain Pathological Features in Fibrous Dysplasia (FD) and Reveal a Novel Relationship between Fat, Bone and Gsa Signaling. Cristina Remoli^{*1}, Stefania Cersosimo¹, Emanuela Spica¹, Benedetto Sacchetti¹, Alan Boyde², Pamela Gehron Robey³, Kenn Holmbeck⁴, Isabella Saggio⁵, Mara Riminucci⁶, Paolo Bianco⁷.
¹University La Sapienza, Italy, ²Queen Mary University of London, United Kingdom, ³NIH/NIDCR, USA, ⁴NIDCR, USA, ⁵Sapienza University of Rome, Italy, ⁶University La Sapienza, Italy, ⁷Universita La Sapienza, Italy

To model FD in mice, we generated transgenic lines expressing GsαR201C either constitutively or as targeted to osteoblasts. Individual FD-defining features (enhanced osteoclastogenesis, marrow fibrosis, loss of marrow adipocytes, osteomalacia) are reproduced in mice with constitutive expression of GsαR201C (FD mice), but not in mice with an osteoblast-targeted transgene. By comparative in situ and ex vivo studies, we traced each of the non-osteoblast dependent effects of Gsα mutation to mechanisms operating in different compartments of the stromal/osteogenic lineage. 1) Enhanced osteoclastogenesis in FD mice emanates from overexpression of RANKL specifically in a compartment of ALP+/ADRB2+ perivascular stromal cells in intraosseous vascular channels. Localized overexpression of RANKL in these cells in vivo drives intracortical osteoclastogenesis and osteolysis in FD mice. Ex vivo, overexpression of RANKL is reproduced in non-differentiated stromal cells expressing GsαR201C, but not in mature transgenic osteoblasts; it is induced in cognate WT stromal cells by isoproterenol but not by PTH, consistent with the

relative abundance of ADRB2 and PTHR1 receptors. 2) Osteomalacia in FD mice reflects the ectopic expression of the mineralization inhibitor Matrix Gla Protein (MGP) in mature osteoblasts. Targeted expression of GsαR201C in mature osteoblasts, however, does not induce MGP expression or osteomalacia, indicating that MGP-expressing osteoblasts can only develop from a GsαR201C-expressing precursor. 3) Marrow adipocytes in FD mice are lost by conversion to a brown adipose tissue (BAT)-like phenotype, UCP-1 upregulation and thermogenic lipolysis, which is otherwise also induced in extramedullary WAT, and enhanced in BAT, in FD mice. 4) Committed adipogenic cells hijacked to an osteogenic fate contribute to the bulk of abnormal osteogenic cells that accumulate as "fibrosis" in murine FD bone. These cells display a phenotype (ALP+/Osx-; MGP+/PLP+/UCP1+/Oil Red O-), distinct from that of WT preosteoblasts (ALP+/Osx+/PLP-), adipocyte progenitors (Sca-1+/Osx-/PLP-/ORO-) and adipocytes (ALP-/Osx-/ORO+/PLP+), and represent the unorthodox precursor of the MGP+/PLP+ osteoblasts that deposit the dysplastic, undermineralized FD bone. Activating mutations of Gsα promote osteoclastogenesis by non-differentiated perivascular osteoprogenitors, and reprogram marrow adipocytes to an aberrant osteoblastic phenotype, thus determining the key features of the FD phenotype.

The Phenotype of Subjects with Persistently Low Serum Alkaline Phosphatase in a Comprehensive Care Population. Fergus McKiernan^{*1}, Jay Fuehrer², Richard Berg². ¹Marshfield Clinic, USA, ²Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, USA

Introduction: The significance of a persistently low serum alkaline phosphatase (ALP) is unknown but could indicate the presence of an inherited metabolic skeletal disorder such as Hypophosphatasia (HPP). We studied a large rural comprehensive care population to characterize the phenotype of subjects with persistently low ALP.

Methods: Our IRB approved use of Marshfield Clinic's comprehensive paper and electronic medical record (eMR) to conduct this retrospective study. The eMR was searched between 1982 and 2011 for low serum ALP values and clusters of ICD-9 diagnosis codes that pointed towards conditions known to be associated with HPP. Plots of serial ALP values were constructed for subjects with at least 2 ALP values below the lower limits of normal in adults (40-125IU/L). Subjects whose ALP was persistently ≤ 40IU/L constituted the study population. Subjects with normal ALP and sufficient meaningful clinical narrative in the eMR served as controls. Supplemental paper charts abstraction was performed when indicated and available. Confirmed cases of HPP were validated by manual chart review and excluded from this analysis.

Results: Between 1982 and 2011, 458,833 unique subjects had 2,584,751 serum ALP values. 5,190 subjects had at least 2 ALP values ≤ 40IU/L. 269 study subjects with persistently low ALP were identified and constituted the study population. Using logistic regression models, stratified by gender and including covariates for age, male study subjects appeared more likely than controls to match the ICD-9 diagnostic clusters for calcium pyrophosphate deposition disease (CPDD), abnormal dentition and myopathy. Both male and female subjects were more likely than controls to match for disorders of phosphate metabolism. Manual chart abstraction and review of available radiographs suggested that crystalline arthritis, chondrocalcinosis, calcific tendonitis and diffuse idiopathic skeletal hyperostosis (DISH) were common in subjects with persistently low ALP but that fibromyalgia and hypermobility were not. Based on this review, 17 adult subjects were suspected to have previously unrecognized HPP but this awaits confirmation.

Conclusion: Adult subjects with persistently low ALP may have excess crystalline arthritis, chondrocalcinosis, calcific tendonitis and DISH. A subset of these individuals may harbor previously unrecognized HPP. Further clinical characterization and diagnostic evaluation of this population is underway.

Polymorphisms in Wnt Antagonist Genes and Bone Mineral Density in Postmenopausal Korean Women. Dong Ock Lee¹, Hoon Kim², Seung-Yup Ku³, Seok Hyun Kim³, Jung Gu Kim^{*3}. ¹Department of Obstetrics & Gynecology, National Cancer Center, South Korea, ²Department of Obstetrics & Gynecology, Incheon Medical Center, South Korea, ³Department of Obstetrics & Gynecology, Seoul National University College of Medicine, South Korea

Objective: The purpose of this study was to investigate the association between single nucleotide polymorphisms (SNPs) in Wnt antagonist genes and bone mineral density (BMD) in postmenopausal Korean women.

Methods: The Wnt inhibitory factor-1 (*WIF-1*) c.28G>A, c.496C>A, secreted frizzled-related protein 1 (*sFRP1*) rs3242 C>T, rs16890444 C>T, *sFRP2* c.134C>T, *sFRP3* c.598C>T, c.970C>G, *sFRP4* c.958C>A, c.1019G>A, *sFRP5* c.34A>T, c.35C>A, dickkopf 1 (*Dkk1*) c.318A>G, *Dkk2* c.437G>A, *Dkk3* c.92C>G, c.147G>T and c.1003A>G polymorphisms were analyzed in 399 postmenopausal Korean women. Serum levels of osteoprotegerin (OPG), soluble receptor activator of the nuclear factor- κ B ligand (sRANKL) and bone turnover markers were measured and BMDs at the lumbar spine and femoral neck were also examined.

Results: The *Dkks* and *sFRP1* polymorphisms and the *sFRP3* c.970C>G polymorphism were not related to BMD, whereas an association between the haplotype genotype defined by the combination of the c.958C>A and c.1019G>A polymorphisms in the *sFRP4* gene and BMD at the lumbar spine were observed. The haplotype AA homozygotes showed significantly lower lumbar spine BMD and a higher serum bone alkaline phosphatase level than other genotypes. At the lumbar spine, the haplotype AA homozygote was 4.37-times more frequently observed in women with osteoporosis than in women with normal BMD. No significant differences in OPG and sRANKL were detected among single genotypes or the *sFRP4* haplotype genotype.

Conclusion: Our results suggest that the haplotype genotype of *sFRP4* c.958C>A and c.1019G>A SNPs may be genetic factors affecting lumbar spine BMD in postmenopausal Korean women.

COMP Enhances BMP-2 Dependent Osteogenesis via Activating BMP-2 Signaling. Kazunari Ishida^{*1}, Chitrangada Acharya², Blaine Christiansen³, Jasper Yik², Paul DiCesare², Dominik Haudenschild². ¹University of California-Davis Medical Center, USA, ²University of California-Davis Medical Center, USA, ³University of California - Davis Medical Center, USA

Introduction: High doses of BMP are clinically used to initiate bone formation in spinal fusion and fracture healing, but are associated with side-effects. We hypothesize that the high doses are required due to non-physiological presentation of free unbound BMP, and that matrix-bound BMP would be more biologically relevant and therefore more effective at lower doses. Cartilage oligomeric matrix protein (COMP) is a disulfide-bonded homo-pentameric glycoprotein located in the extracellular matrix of joint tissues. COMP interacts with other cartilage matrix components and receptor complexes at the cell surface. The repeated modular structure of COMP allows it to act as a molecular 'bridge' between these binding partners. Recently, we demonstrated that COMP has multiple binding sites for TGF- β 1, and that COMP enhanced TGF- β 1 activity. The similarity of BMP-2 to TGF- β 1 suggests that BMP-2 also binds COMP. It is our hypothesis that COMP can function as a biologically appropriate carrier to promote BMP-2 osteogenic activity. Methods: To characterize the interaction between BMP2 and COMP, ELISA-type binding assays were performed. To examine the effect of COMP on BMP signaling pathway, phosphorylation of Smad and BMP receptors protein levels were examined. To test the effect of COMP on BMP-2 dependent transcription, luciferase from a BMP-dependent promoter was assayed. BMP-2-dependent osteogenesis and matrix mineralization were measured by qRT-PCR for osteogenic genes, alkaline phosphatase enzymatic (ALP) activity, and alizarin Red S staining in C2C12 cells and human MSCs. Finally, in vivo ectopic bone formation was evaluated using a rat model, and confirmed by μ CT, ALP activity, qRT-PCR, and histology. Results: COMP directly bound BMP-2 in vitro, with a pH optimum of 5.5, which was enhanced by manganese but largely unaffected by other divalent cations or EDTA. BMP-2 treatment in the presence of COMP prolonged the phosphorylation status of Smad1/5/8 and sustained both type 1 and 2 BMP receptors protein levels out to 24 hours. COMP enhanced BMP-2-dependent transcription, osteogenesis, and matrix mineralization. Finally, COMP enhanced BMP-2-dependent in vivo ectopic bone formation. Conclusion: This study demonstrated that COMP enhances BMP-2-dependent osteogenesis via sustaining the biological activity of BMP-2. Clinically, it may be possible to use COMP as a naturally-occurring carrier to reduce the dose of BMP-2 required for bone formation.

Critical Role of ALK2 Phosphorylation at Thr203 in Activation by BMP type II Receptors. Satoshi Ohte^{*1}, Mai Fujimoto², Katsumi Yoneyama², Hiroki Sasanuma², Masashi Shin², Sho Tsukamoto³, Arei Miyamoto², Toru Fukuda², Shoichiro Kokabu², Takenobu Katagiri⁴. ¹Saitama Medical University, Research Center for Genomic Medicine, Japan, ²Saitama Medical University, Research Center for Genomic Medicine, Japan, ³Saitama Medical University RCGM, Japan, ⁴Saitama Medical University Research Center for Genomic Medicine, Japan

Bone morphogenetic proteins (BMPs) induce heterotopic bone formation in skeletal muscle through binding to type I and type II transmembrane serine/threonine kinase receptors expressed on target cells. Fibrodysplasia ossificans progressiva (FOP) is a rare autosomal dominant congenital disorder characterized by progressive heterotopic bone formation in skeletal muscle. Mutations of ALK2, a BMP type I receptor, have been found in patients with FOP. We have reported that those mutant ALK2 are moderately activated and are further activated by BMP type II receptors in C2C12 cells. In this study, we report a critical role of ALK2 phosphorylation at Thr203 in the activation by BMP type II receptors. Co-transfection of each BMP type II receptor and mutant ALK2 found in FOP induced Smad phosphorylation and osteoblastic differentiation in C2C12 cells with an increase of ALK2 phosphorylation. ALK2 has nine Ser/Thr residues in the intracellular GS domain, which is the potential phosphorylation domain by type II receptors. Substitution mutation of all of the nine Ser/Thr residues by Ala/Val (GS9AV) completely destroyed the activity of ALK2 even in the presence of type II receptors. However, substitution mutation of seven Ser/Thr residues except Thr203 and Thr209 (GS7AV) was still activated by type II receptors. A mutation at Thr203, but not Thr209, completely lost the biological activity of ALK2 in spite of co-expression of type II receptors. Moreover, the substitution at Thr203 with Val in the mutant ALK2 found in FOP completely inhibited the activities in C2C12 cells. Taken together, these findings suggest that phosphorylation of ALK2 at Thr203 plays essential role in activation by type II receptors. The activation of mutant ALK2 found in FOP may be caused through enhanced phosphorylation at Thr203 by endogenous BMP type II receptors.

SA0164

High-dose BMP2 Reduces Cell Proliferation and Increases Apoptosis via DKK1 in Human Primary Periosteum-derived Cells. Nobuhiro Kamiya^{*1}, Ila Oxendine², Sasha Shafer², Harry Kim³. ¹Texas Scottish Rite Hospital for Children, USA, ²Texas Scottish Rite Hospital for Children, USA, ³Scottish Rite Hospital for Children, USA

BMP2 is a potent osteogenic factor used clinically to stimulate spinal fusion and fracture healing. Interestingly, BMP2 doses used for clinical application are much higher (500-1500 micro g/ml) than those for preclinical studies (100-300 nano g/ml) that showed positive effects of BMP2 in osteoblast differentiation and new bone formation. The effect of high-dose BMP2 on bone cells in comparison to low-dose BMP2 has not been elucidated well. The purpose of this study was to compare the effects of low and high doses of BMP2 on cell proliferation and apoptosis using human periosteum-derived cells since BMP2 is generally applied around the periosteum to stimulate osteogenesis.

We obtained human periosteum from three patients undergoing orthopaedic surgery and isolated primary periosteum-derived cells. The primary cells were treated with BMP2 in culture and cell proliferation and apoptosis were assessed by MTT and Caspase assay, respectively. MTT activity was significantly reduced with high-dose BMP2 treatment (2000 nano g/ml). In contrast, such reduction was not observed when treated with low-dose BMP2 (100 nano g/ml). Caspase activity was significantly increased with high-dose BMP2 but unchanged in the low-dose BMP2. To investigate the mechanism responsible for the alteration of cell proliferation and apoptosis, we focused on DKK1, one of well-known tumor suppressor genes while its role in bone cells is largely unknown. DKK1 expression levels assessed by qRT-PCR were dramatically increased in the high-dose group and this increase was consistent with DKK1 protein levels assessed by Western blotting. The addition of DKK1 protein to the primary cells reduced MTT activity and increased caspase activity significantly. Silencing DKK1 expression by 90% using the siRNA technique normalized cell proliferation and apoptosis in the cells exposed to high-dose BMP2. Last we examined cell cycle inhibitors that can regulate DKK1 expression. The p21 and p27 expression and p21 and p53 protein levels were all increased by BMP2 treatment. These results suggest that BMP2 has a critical role in controlling cell number via DKK1 mediated control of cell proliferation and apoptosis. In conclusion, high-dose BMP2 decreased cell proliferation and increased apoptosis. Since periosteum is important source of progenitor and osteogenic cells, further investigation on the effects of high-dose BMP2 is warranted on cell proliferation as well as differentiation.

Adipocyte Lipoprotein Lipase influences Fatty Acid Composition of Bone in Mice. Brigitte Müller*¹, Alexander Bartelt², Klaus Toedter¹, Ludger Scheja¹, Joerg Heeren¹, Andreas Niemeier². ¹University Medical Center Hamburg-Eppendorf, Germany, ²University Medical Center Hamburg-Eppendorf, Germany

Objective: Dietary lipids are transported in the circulation by lipoproteins. These lipoproteins are hydrolysed by lipoprotein lipase (LPL) to release fatty acids, or can be taken up as whole particles, thereby delivering triglycerides, cholesterol and lipophilic vitamins to target cells. The contribution of the skeleton to systemic lipoprotein metabolism is poorly understood. Here we analyze the role of adipocyte-LPL in lipid uptake into bone and determine the lipid composition in mineralized bone tissue versus bone marrow.

Methods: Uptake of radiolabeled lipoproteins and fatty acids were determined in organ extracts by scintillation counting. The physiological route of dietary lipids was followed in an oral fat tolerance test with olive oil containing tracer amounts of ³H-triolein. Mice carrying adipocyte-specific lipoprotein lipase knock-out (KO) alleles were used to study pathways responsible for lipid entry into bone. Fatty acid composition was determined by gas chromatography with internal standards.

Results: In comparison to liver, muscle and brown adipose tissue, which are among the major organs involved in dietary fat clearance, lipid uptake per mg of organ weight (specific uptake) is relatively low in calvaria, femur cortex and vertebrae. Analysis of the respective bone compartments revealed that specific uptake into bone marrow was about 3x higher than into cortical bone. However, with regard to the relative contribution to the clearance of the total fat load, the skeleton (total tissue) is the fourth most important organ involved in lipid uptake. Fatty acid composition analyses in adipocyte-LPL KO mice indicated that LPL-mediated uptake of essential polyunsaturated fatty acids into cortical bone in tibia and femur was impaired to a higher degree than uptake into bone marrow. In addition, *de novo* lipogenesis fatty acid products are increased in femur cortical bone in adipocyte-LPL KO mice.

Conclusion: The majority of postprandial lipids are taken-up by initial binding of lipoproteins to endothelial cells, subsequent hydrolysis of triglycerides by lipoprotein lipase and cellular uptake of fatty acids. The current results suggest that bone marrow adipocyte-LPL is involved in fatty acid transport into matrix-associated osteoblasts and osteocytes within the cortex of long bones and thus underline the importance of the functional interplay between bone marrow adipocytes and adjacent bone cells.

Oral Health and Biochemical Risk Factors for Bisphosphonate-associated Jaw Osteonecrosis. Claudine Tsao¹, Gelsomina Borromeo², Ivan Darby², Katrina Walsh², Neil O'Brien-Simpson², Eric Reynolds², Peter Ebeling*³. ¹The University of Melbourne, Australia, ²The University of Melbourne, Australia, ³The University of Melbourne, Australia

Introduction: Anti-resorptive drugs, including bisphosphonates, have been associated with jaw osteonecrosis (ONJ). Despite serum bone turnover markers (BTMs) being used in dentistry to assess ONJ risk, the relationship between serum BTMs and bone turnover in the periodontium is uncertain. In addition, the role of oral health and periodontal disease as risk factors for ONJ remains unclear and the role of surrogate measures of periodontal disease, including gingival crevicular fluid (GCF) pro-inflammatory mediators [interleukins (IL-1 β and IL-6) and tumour necrosis factor- α], has not been fully explored. If the pro-inflammatory effect of bisphosphonates translates to the periodontium, both periodontal disease and ONJ risk may increase.

Methods: Firstly, we compared levels of BTMs in GCF and serum in twenty healthy volunteers, who received oral examinations, and GCF and serum sampling. Serum was tested for the amino-terminal propeptide of Type I collagen (PINP) using automated non-isotopic immunoassays. GCF was tested for PINP using a radio-

immunoassay (RIA). Secondly, we investigated oral health risk factors for ONJ in participants with a history of bisphosphonate use. This cross-sectional study compared ONJ cases (n=22) with controls (n=41), who all received bisphosphonates. Oral examinations were conducted, and serum and GCF sampled. Serum was tested for IgG titres against four periodontopathic bacteria, biochemical parameters, BTMs, and with multiplex analysis. GCF underwent multiplex analysis and PINP RIA testing.

Results: In healthy volunteers, GCF PINP levels were 10-fold higher than in serum. A significant correlation was found between GCF and serum PINP levels ($r=0.629$, $p=0.002$), suggesting that assumptions regarding bone turnover activity in the periodontium may be inferred from serum levels, though confirmation from larger studies is required. In patients with bisphosphonate-associated ONJ, periodontal disease was associated with ONJ, as measured by three clinical parameters and the surrogate markers of serum IgG titres against *Porphyromonas gingivalis* (OR 2.72, $p=0.018$) and the GCF pro-inflammatory marker, IL-1 β (OR 24.7, $p=0.044$).

Conclusion: Bone turnover was higher in the periodontium than in the serum. Whilst the mechanism underlying the role of periodontal disease as an ONJ risk factor is uncertain, our results do also suggest that the role of oral microbes as a contributing aetiological agent may have been underestimated.

Altered Expression of Apoptosis-Associated miRNAs that Regulate IGF-1 Survival Signaling Underlies the Cell Autonomous Requirement of Cx43 for Osteocyte Survival. Rafael Pacheco-Costa*¹, Lucas Brun², David Southern³, Rejane D. Reginato⁴, Nicoletta Bivi⁵, Teresita Bellido⁵, Lilian Plotkin⁵. ¹Indiana University School of Medicine/Federal University of Sao Paulo, Brazil, USA, ²Universidad Nacional de Rosario, Argentina, ³Indiana University School of Medicine, USA, ⁴Federal University of São Paulo, Brazil, ⁵Indiana University School of Medicine, USA

Mice lacking connexin (Cx) 43 in osteocytes exhibit elevated prevalence of osteocyte apoptosis and MLO-Y4 osteocytic cells in which Cx43 is silenced exhibit spontaneous cell death; however, the basis of the cell autonomous requirement of Cx43 for osteocyte viability is unknown. We questioned whether the absence of Cx43 changes the expression of apoptosis-associated microRNAs (miRs), short RNA molecules that act as negative post-transcriptional regulators of gene expression and have profound effects on cell survival. Cx43 expression was stably silenced in MLO-Y4 osteocytic cells using shRNA. Silenced cells exhibit a decrease of more than 80% in the expression of Cx43 at the mRNA and protein levels compared to scramble shRNA-transfected control cells. miR21 and miR218 expression was altered in Cx43-deficient cells out of 47 apoptosis-associated miRs studied (Apoptosis-Associated miRNA Plate Array, Signosis). Results were confirmed by qPCR and showed that miR21 expression was decreased by 50% and that miR218 expression was increased by 500% in Cx43-deficient cells compared to control cells. A target of miR21 is PTEN, the phosphatase that inactivates the Akt-survival pathway; and a target of miR218 is IKK β kinase, which is required for NF κ B activation. Akt and NF κ B are known mediators of survival signaling activated in several cell types by insulin like growth factor-1 (IGF-1), which also inhibits apoptosis of osteoblasts and osteocytes. We therefore investigated whether the absence of Cx43 interferes with the anti-apoptotic effect of IGF-1. We found that whereas control cells were protected by IGF-1 from glucocorticoid-induced apoptosis, IGF-1 was ineffective in Cx43-deficient MLO-Y4 osteocytic cells. Moreover, whereas wild type HeLa cells that lack endogenous Cx43 were refractory to IGF-1, IGF-1 inhibited glucocorticoid-induced apoptosis in HeLa cells transfected with Cx43. Taken together, these results suggest that dis-regulation of miR21 and miR218 triggered by the absence of Cx43 causes resistance to the survival effect of IGF-1. Moreover, these findings raise the possibility that accumulation of apoptotic osteocytes in Cx43 deficient mice is due to the inability of osteocytes to respond to endogenous IGF-1.

Bone and Muscle Interactions during the Progression of Nfat1 Deficiency-Mediated Osteoarthritis. Qinghua Lu¹, Brent Furomoto², H. Clarke Anderson², Jinxi Wang². ¹University of Kansas Medical Center, USA, ²University of Kansas Medical Center, USA

Purpose: Osteoarthritis (OA) is the most common form of joint disease in middle-aged and older individuals. No pharmacologic therapy is currently available to cure the disease, largely because the pathogenetic mechanisms for initiation and progression of OA remain unclear. OA involves multiple joint tissues (e.g., articular cartilage, subchondral bone, and synovium) and possible interactions between these tissues have been reported. However, it is not clear whether interactions between a joint tissue and peri-articular skeletal muscles are involved in the pathogenesis of OA. This study aimed to investigate whether metabolic interactions between the subchondral bone and peri-articular skeletal muscles play a role in the pathogenesis of OA.

Methods: Transcription factor Nfat1-deficient (Nfat1^{-/-}) mice were used in this study. Age-matched wild-type (WT) mice were used as controls. All animal procedures were approved by the institutional animal care and use committee. Joint tissues with skeletal muscles around the joint were harvested from hips, knees, and shoulders of Nfat1^{-/-} and WT mice at 1, 2, 3, 4, 6, and 12 months of age for histopathological, immunohistochemical, and gene expression analyses.

Results: At 3-6 months of age, focal loss of proteoglycan staining with chondrocyte clustering was seen in the articular cartilage of Nfat1^{-/-} joints. Chondrocyte hypertrophy occurred in the deep-calcified zones of Nfat1^{-/-} articular cartilage. Some of the subchondral bone marrow cells differentiated into chondrocytes, which subsequently underwent endochondral ossification, leading to thickening of the subchondral bone. These bony changes were accompanied by abnormal chondrocyte differentiation and endochondral ossification in the periosteum and deep layer of skeletal muscles, forming chondro-osteophytes near joint margins in the later stage. The expression of bone morphogenetic protein (BMP)-2 and (BMP)-4 was significantly increased in Nfat1^{-/-} subchondral bone than WT subchondral bone before and during the abnormal chondrocyte differentiation in peri-articular muscles.

Conclusions: During the process of Nfat1 deficiency-mediated OA, overexpression of BMP in the subchondral bone may stimulate pathological chondrocyte differentiation and endochondral ossification in periosteum and deep layer of muscles near the joint margins. This in turn compromises the function of affected joints and speeds the progression of OA.

Comparison of 3D UTE (Ultrashort Time-to-Echo) MRI Versus Micro-CT For Quantitative Evaluation of the Temporomandibular Joint (TMJ) Condylar Morphology. Won Bae¹, Sheronda Statum², Daniel Geiger³, Koichi Masuda², Jiang Du¹, Christine Chung². ¹University of California, San Diego, USA, ²University of California, San Diego, USA, ³Sapienza University of Rome, Italy

Purpose: Temporomandibular dysfunction involves osteoarthritis of the temporomandibular joint, including degeneration of the mandibular condyle. Morphologic changes of the bone and fibrocartilage occurs, and it would be useful to evaluate them using non-invasive means. The purpose of this study was to determine the accuracy of novel 3D UTE MRI versus micro CT (mCT) for quantitative evaluation of mandibular condyle morphology.

Material and Methods: Three TMJ condyles specimens were harvested from cadavers. Novel 3D UTE MRI (TR=50 ms, TE=0.03 ms, voxel size=104 μm) was performed on 3-Tesla General Electric HDx, and mCT was performed using Skyscan 1076 (18 μm isotropic voxel size). MR datasets were spatially-registered with mCT dataset using FSL-FLIRT software. Bony contour of the condyles were segmented (ImageJ Segmentation Editor plugin) using global threshold (Figure 1A; mCT) or manual approach (Figure 1B; MRI, performed by two observers). Manual segmentation took less than 20 min per sample. Using Matlab, bone surface coordinates (Figure 1C,D), volume of segmented regions, and Gaussian curvature (Figure 1E,F) were determined for quantitative evaluation of joint morphology. Agreement between techniques (MRI vs. mCT) and observers (MRI vs. MRI) were determined by the means of intraclass correlation coefficient (ICC) analysis.

Results: Between MRI and mCT, the average deviation of surface coordinates (Figure 1G) was 116 μm, approximately the resolution of MRI. Average deviation (Figure 1H) of the Gaussian curvature and the volume, from MRI to mCT, was 2.2 and 4.4%, respectively. ICC coefficient for the three measures (surface, volume,

curvature) was each greater than 0.992. Between observers, the ICC coefficients were all greater than 0.997.

Conclusions: 3D UTE MR evaluation of TMJ condyle morphology including shape, volume and curvature shows high accuracy against mCT and between observers. The technique may be useful for clinical evaluation of temporomandibular joint dysfunction. Future work includes cartilage evaluation, as well as comparison of normal and degenerated mandibular condyles.

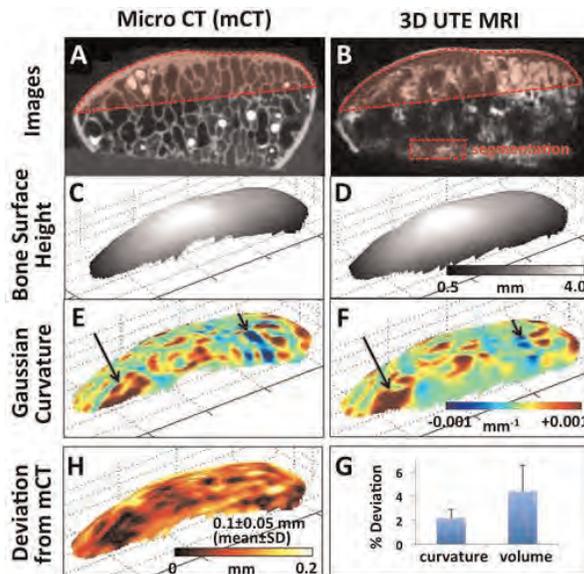

Figure 1. (A) Micro CT and (B) 3D UTE MR datasets were segmented to determine (C,D) bone surface coordinates and (E,F) Gaussian curvature in 3D. Gaussian curvature shows regions with bowl-shape (positive curvature; long arrows) and saddle-shape (negative curvature; short arrows). (G) The deviation of bone surface determined from MRI was in close agreement with that from micro CT, with a mean deviation of approximately 100 μm. (H) Deviation of the curvature and volume were small as well, showing a high accuracy of MR technique to evaluate condyle morphology.

Cyclooxygenase-1 Plays an Important Role in C2C12 Myogenic Differentiation. Chenglin Mo¹, Orisa Igwe², Marco Brotto³. ¹University of Missouri-Kansas City, USA, ²University of Missouri, USA, ³University of Missouri-Kansas City, USA

Our previous studies have shown that prostaglandin E₂ (PGE₂) signaling through EP1 receptor is critical for myogenic differentiation in C2C12 myoblasts. Treatment with 50nM PGE₂ considerably increased myotube cell area and number of fully matured myotubes, whereas treatment with SC51322, a specific EP1 inhibitor, significantly attenuated myotube development. Cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) are the rate-limited enzymes in PGE₂ synthesis. To determine which COX is responsible for PGE₂ production in myogenesis, we first investigated the expression of COX-1 and COX-2 by Real-Time (RT) PCR and Western Blot (WB) analyses in C2C12 myoblasts. Both PCR and WB results indicated that COX-1 had higher expression than COX-2. Next, we did a time-course study of mRNA expression of COX-1, COX-2, and the three known isoforms of PGE₂ synthase (mPGES-1, mPGES-2 and cPGES) during myogenic differentiation. After the onset of differentiation, COX-1 expression was upregulated by 2-fold at 6 and 12h, and returned to baseline levels (time 0) at 24h, followed by a 2-fold downregulation at 48h. On the other hand, COX-2 expression was downregulated over this period, reaching a 5-fold downregulation at 48h. The WB results showed similar trends to those observed with RT-PCR; only COX-1 was upregulated at 12h, and returned to baseline levels at 48h. For PGES, the gene expression of mPGES-1 and cPGES did not show significant changes, but mPGES-2's profile was similar to that of COX-1, showing upregulation by 4- and 2-fold at 6 and 12h, respectively. Furthermore, the effects of the specific COX-1 inhibitor (FR122047), specific COX-2 inhibitor (NS-398), and non-specific COX-1/2 inhibitor (Indomethacin) on myogenic differentiation were tested. FR122047 (7.5 μM) and indomethacin (100 μM), but not NS-398 (50 μM), significantly decreased myotube area after 96h of differentiation (myotube area was ~45% and ~53% of control, respectively). The co-treatment with EP1 agonist 17-phenyl trinor and PGE₂ successfully rescued myotube cell area reduction that had been induced by treatments with FR122047 and Indomethacin. Our results provide

strong evidence that EP1 signaling is essential for myogenesis, and indicate that COX-1 may play a more prominent role in myogenic differentiation than COX-2.

Effects of Ti, PMMA, UHMWPE, and Co-Cr Particles on Differentiation and Functions of Bone Marrow Stromal Cells. Yunpeng Jiang^{*1}, Zheng Song², Paul Wooley², Shang-You Yang³. ¹Wichita State University, USA, ²Orthopaedic Research Institute, Via Christi Health, USA, ³Wichita State University, USA

Purpose:To examine variant types of orthopaedic biomaterials particles on differentiation and functions of bone MSC cell.

Methods:Bone marrow stromal cells (MSCs) were isolated from femurs of BALB/c mice by density centrifugation over Histopaque®-1083. Cells were cultured in regular culture medium or in complete-osteoblast-induction medium including 10mM β -glycerol phosphate, 100nM L-ascorbic acid, and 10nM dexamethasone. The cells were respectively co-cultured with micron-sized Ti, PMMA, UHMWPE, and Co-Cr particles at various doses. MTT assay was performed periodically for cell viability and proliferation, and immunocytochemical osteocalcin stain was also performed. Alkaline phosphatase (ALP) activities were assayed in the culture media and cell lysates; while real-time PCR performed to examine gene expression of RANKL, LRP, OSX, and Runx2.

Results:Challenge with low doses of Titanium, UHMWPE, or Co-Cr particles markedly promoted bone marrow cell proliferation while high dose of Co-Cr significantly inhibited cell growth ($p < 0.05$). Interestingly, the MSCs co-cultured with PMMA particles appeared in slow growth pattern, even at low concentration (0.63mg/ml). However, co-culturing the cells with low dose of PMMA-particles (0.63 mg/ml) in complete induction medium revealed significantly stronger ALP activity whereas Ti, UHMWPE, and Co-Cr groups showed relatively minimal ALP activity, in comparison with non-particle controls ($p < 0.05$). Further, immunocytochemistry stain exhibited considerably more osteocalcin-positive cells in PMMA-challenged cultures than other groups. Comparison of the gene expression profiles among the cells following Ti, HPE, or Co-Cr challenges did not find significant difference in LRP5, RANKL, Runx2, Osterix/Sp7; whereas all these gene expressions were elevated following PMMA challenge ($p < 0.05$).

DISCUSSION:Evidence suggests that adverse cellular responses to particulate wear debris are critical in the periprosthetic osteolysis and the pathogenesis of aseptic prosthetic loosening. While macrophage-mediated foreign body reaction and osteoclastogenesis are the major factors to resorb periprosthetic bone, wear debris-interacted bone marrow stromal cells may play an equally important role in regulation of differentiation and functions of osteoclasts and bone remodeling. The current study suggested that various types of wear debris particles behaved differently in the differentiation, maturation, and functions of osteoblasts. PMMA particles did not show marked influence on cell proliferation, unlike other types of particles which promoted cell proliferation at low concentration and resulted in accelerated cell death at high doses. Also, PMMA particles promoted the differentiation and maturation of bone MSCs with higher ALP activities, more osteocalcin+ cells and elevated expression of osteoblast markers.

Genetic Variant on PLIN4 is Associated with Obesity Phenotypes and BMC in Females. Mai Abdel-Ghani^{*1}, Laura Tosi², Joseph Devaney³, Todd Spock⁴, Karin Kuhn⁴, Eric Rupe⁴, Clare Griffiths⁵, Heather Gordish-Dressman³, Eric Hoffman³, Priscilla Clarkson⁶. ¹USA, ²Children's National Medical Center, USA, ³Research Center for Genetic Medicine Children's National Medical Center, USA, ⁴George Washington University School of Medicine, USA, ⁵F. Edward Hébert School of Medicine Uniformed Services University of the Health Sciences, USA, ⁶University of Massachusetts Amherst, USA

The purpose of this study was to examine a single nucleotide polymorphism (SNP) rs8887 in Perilipin 4 (PLIN4) due to its expression in adipose tissue and its functional role in obesity and possible impact on bone mineral density. Whole blood samples were collected from 133 healthy subjects of whom 67 are males and 69 are females average age of 22.05 ± 4.82 yrs for females and 23.31 ± 5.61 yrs for males. A Dual energy xray absorptiometry (DXA)measured bone mineral density(BMD) lean mass, fat mass. Genomic DNA was extracted from blood for genotyping. Genotypes for rs8887 in PLIN4 were obtained using a TaqMan allelic discrimination assays. All PCR reactions were analyzed using an ABI 7900 Quantitative Real Time PCR system. Mean quantitative adiposity and bone measurements were compared in relation to SNP genotypes using analysis of covariance (ANCOVA) methods. Significant associations were found in both males and females. In males, significant associations with PLIN4 were seen with total fat mass ($p = 0.0136$), total lean mass ($p = 0.0268$) and lean mass of the arms ($p = 0.0097$). Males homozygous for the T allele showed increased total fat mass to males with a single copy of the C allele; TT (N=13;

21727 \pm 1269 g), CC (N=25; 17819 \pm 909 g),CT(N=29; 17187 \pm 845g).Males who were homozygous for the minor T allele had reduced total lean mass than males with a single copy of the C allele; TT (N=13; 55370 \pm 1249g), CC (N=25; 58880 \pm 894g), CT(N=29; 59450 \pm 831g).Males homozygous for the T allele showed decreased arms lean mass in contrast to males with a single copy of major C allele; TT (N=13; 6524 \pm 207g), CC (N=25; 6866 \pm 148g),and CT (N=29; 7275 \pm 137g).In females, significant associations were found with total fat mass ($p = 0.0157$) and bone mineral content ($p = 0.0216$). Females who were homozygous for the C allele showed a greater mean total fat mass in comparison to both heterozygotes and those homozygous for the T allele;TT (N=17; 20097 \pm 757g),CC (N=19; 22882 \pm 706g),CT (N=31; 20553 \pm 551g). Females homozygous for the T allele exhibited increased mean BMC in comparison to those homozygous for the T allele;TT (N=17; 2608 \pm 70), CT (N=31; 2430 \pm 52), CC (N=19; 2359 \pm 65). There was a suggestion of an association between total BMD and PLIN4, although it did not reach statistical significance ($p = 0.0523$). This study demonstrates an association between a variant in PLIN4 and adiposity phenotypes and BMC in females.

Muscle Derived Factor(s) Enhance the Activation of the PI3K/Akt Pathway in the Osteocyte in Response to Fluid Flow. Nuria Lara^{*1}, Leticia Brotto², Marco Brotto¹, Lynda Bonewald¹, Mark Johnson³. ¹University of Missouri - Kansas City, USA, ²UMKC School of Nursing, USA, ³University of Missouri, Kansas City Dental School, USA

Skeletal muscle is known to apply load to the skeleton. We sought to determine if muscle also secreted factors that might condition the response of the skeleton to loading. Osteocytes are the primary mechanosensory cells in bone and so we studied the effects of conditioned media (CM) from various muscle cell/fiber types on the response of the MLO-Y4 osteocyte-like cells to fluid flow shear stress (FFSS), as an *in vitro* model system for mechanical loading. C2C12 cells were induced to undergo myogenesis and CM was collected at various stages of myogenic differentiation. Also, adult mouse Soleus (Sol), an oxidative, slow twitch muscle type, and Extensor Digitorum Longus (EDL) muscle, a glycolytic, fast twitch muscle type, were isolated and stimulated *ex vivo* to produce CM for these studies. We observed that under resting conditions the addition of 10% C2C12 CM induced a rapid, but transient activation of the Akt signaling pathway, peaking at 15 minutes and returning to baseline by 2 hours in a concentration and cell type dependent manner. This activation was observed as early as Day 3 of C2C12 differentiation when myoblast fusion had started, but maximal activity was observed at day 5 coinciding with the formation of fully mature myotubes. FFSS applied to MLO-Y4 cells for 2 hours in the presence of 10% myotube CM resulted in a 6 fold increase in pAkt compared to a 3 fold increase under non-treated conditions or when 10% CM from myoblasts or blank C2C12 differentiation media was present. A similar enhanced increase in pAkt in response to FFSS was observed in the presence of EDL CM, but not in the presence of Sol CM suggesting muscle specific effects. Downstream of increases in pAkt, we observed increased β -catenin nuclear translocation in the presence of CM from myotubes in MLO-Y4 cells. We also observed activation of β -catenin only when EDL CM was present. These data provide evidence that specific muscle cell types produce soluble factors that alter the sensitivity of MLO-Y4 osteocyte like cells to fluid flow shear stress. These data support our hypothesis that beyond a mechanical interaction there is a very specific molecular coupling of muscle and bone. These data could provide a molecular basis for the high concordance between the diseases of osteoporosis and sarcopenia that exists within the aging human population.

SA0190**Polymorphisms Associated with Physical Activity and Body Composition.**

Eric Rupe*¹, Laura Tosi², Todd Spock³, Karin Kuhn⁴, Mai Abdel-Ghani⁵, Clare Griffiths⁶, Heather Gordish-Dressman⁷, Eric Hoffman⁸, Joseph Devaney⁷. ¹The George Washington University, USA, ²Children's National Medical Center, USA, ³The George Washington University School of Medicine & Health Sciences, USA, ⁴The George Washington University School of Medicine & Health Sciences, USA, ⁵USA, ⁶Uniformed Services University of the Health Sciences, USA, ⁷Children's National Medical Center Research Institute, USA, ⁸Children's National Medical Center, USA

Objective: To explore whether six single nucleotide polymorphisms (SNPs) previously associated with leisure-time exercise behavior in an older population (mean 45.9 years) – rs12405556 (LEPR gene), rs10946904 (PRSS16 gene), rs1766581 (SIP1L2 gene), rs2762527 (PAPSS2 gene), rs9633417 (SGIP1 gene), and rs667923 (DNASE2 gene) – are associated with body and bone composition, strength, change in strength after resistance training, and physical activity in two healthy, college-aged populations of men and women.

Subjects and methods: We genotyped six SNPs in two populations. First we studied individuals enrolled in a resistance-training program of the non-dominant arm (n = 753, mean 24 years) from the FAMUSS cohort. We measured associations of the SNPs with these phenotypes: whole arm muscle (MRI), subcutaneous arm fat (MRI), bone volumes of the arm (MRI), 1-repetition max (1RM) and elbow flexion strength, before and after 12 weeks of resistance training.

Second, we examined the influence of the SNPs on physical activity levels and body measurements in the MB-UMASS cohort (n = 136, mean 22.5 years). In this study, subjects completed the International Physical Activity Questionnaire, and were measured for four criteria (by DEXA): bone mineral density, lean mass, fat mass, and percent tissue fat.

Hardy-Weinberg equilibrium was validated for each SNP. Associations and phenotypes were tested using ANCOVA. For those with a significant F-test, pair-wise comparisons were performed and p-values adjusted for multiple comparisons using the Sidak method, including appropriate covariates.

Results: We found two associations with strength/muscle measurements in the FAMUSS cohort: rs10946904 with baseline and change in 1RM in men, and rs12405556 with change in muscle volume in women. We found three SNPs to be associated with body measurements: rs12405556 with baseline total body volume, total fat, and total lean mass, all in men; rs10946904 with baseline subcutaneous fat in women; and rs1766581 with bone mineral content in women. Finally, we found two SNPs to be associated with total physical activity – rs10946904 for males and rs2762527 for females.

Discussion: We found that numerous SNPs, previously associated with physical activity in an older population, effect body composition in young individuals. We also found associations with muscle strength and response to resistance training. The same genotypes that were associated with response to training were associated with physical activity. These variants may influence skeletal muscle response to resistance training and may respond to aerobic intervention. This needs further exploration. Finally, being able to corroborate previous findings for two SNPs regarding their association with exercise behavior further supports their significance.

SA0192**The Relation between Age-related Declines in Hand Grip Strength and Arterial Stiffness in Korean Men. SANG HYEON JE¹, Duck Joo Lee*².**

¹Ajou University Hospital, Department of Family Medicine, South Korea,

²Ajou University School of Medicine, South Korea

Background:The hand grip strength (HGS) is an indicator of overall muscle strength as well as aging. We evaluate the associations between HGS and other clinical markers of aging in Korean men

Methods:We collected data from 5412 men who visited the Health Promotion Center in Gejeje city, Korea for health examination in 2003-2009. Tests for fasting blood sample, HGS, lipid profile, homocysteine, blood pressure and routine blood chemistry and spirometry were performed. Pulse wave velocity was used at the carotid artery level to assess arterial stiffness. Men were categorized into three HGS groups (low, medium, and high). The men also were grouped into three aged groups; young, middle and old aged groups. Odds ratio was estimated using low HGS as a reference group.

Results:Age, arterial stiffness, uric acid, homocysteine and FEV1/FVC were statistically significantly different across three HGS and aged groups (P<0.05). Compared to low HGS group, odds ratio for the arterial stiffness in medium group was 0.72 and 0.23 in high group. This finding was statistically significant in the middle aged group (P<0.05). Other clinical markers of aging in each aged group did not differ by HGS.

Conclusions: in middle aged Korean men, 40-59 years old, HGS may be related to arterial stiffness

SA0193**Wnt/ Ca²⁺ Signaling Pathway Takes Shape in Muscle-bone Crosstalk.**

Sandra Romero-Suarez*¹, Cheng Lin Mo¹, Mark L Johnson², Lynda Bonewald³, Marco Brotto³. ¹University of Missouri-Kansas City, USA, ²University of Missouri-Kansas City, USA, ³University of Missouri - Kansas City, USA

Integrative biological approaches have led to the discovery of new physiological roles for bone and skeletal muscle as autocrine, paracrine, and endocrine organs. We tested the effects of conditioned media from MLO-Y4 osteocyte-like cells (MLO-Y4-CM) and primary osteocytes (PO-CM) derived from 4 months wild type mouse, and found that MLO-Y4 CM and PO-CM enhanced myogenic differentiation of C2C12 myoblasts into myotubes as detected by histomorphometric measurements. Wnt signaling is involved in various aspects of bone and skeletal muscle development and regeneration. In osteocytes, Wnts are over expressed upon fluid flow shear stress; also they are released by osteocytes. To test our hypothesis that osteocytes can biochemically signal to muscles via the Wnt pathway, we treated C2C12 muscle cells with low, physiological concentrations of Wnt3a. Wnt3a accelerated myogenic differentiation and enhanced nuclear translocation of β -catenin, which is required for transcription of the key muscle transcription factor, MyoD. This pathway showed to play a crucial role in the enhancement of myogenic differentiation produced by 10ng Wnt3a, 10% and 1% MLO-Y4 CM and PO-CM respectively. The potent effects of Wnt3a on stimulating the β -catenin signaling pathway in C2C12 muscle cells, strongly correlated with an increased sensitivity to calcium released from the sarcoplasmic reticulum by caffeine, suggesting adaptive changes of the excitation-contraction coupling machinery. These data were consistent with the upregulation of some of the essential genes related to intracellular calcium homeostasis (i.e., IP3R types 1 and 3; Stim-2; Camk2d; and SERCA-1 and 2). These findings suggest that MLO-Y4 CM and PO-CM through activation of β -catenin signaling pathway may alter intracellular Ca²⁺ release and activate an alternative Wnt/Ca²⁺ pathway that promotes or assists with myogenic differentiation. The molecular mechanisms leading to these effects of bone CM in osteocytes are currently under investigation.

SA0194**Ability of Cyclosporine to Induce Oxygen Free Radicals in a Rat Osteoblast Cell Line. Min Hyung Jung*¹, Heung Yeol Kim².**

¹School of Medicine, Kyung Hee University, Kyung Hee Medical Center, South Korea, ²School of Medicine, Kyung Hee University, Kyung Hee Medical Center, South Korea

Objective : This study examined the ability of Cyclosporine (CsA) to induce apoptosis in a rat osteoblast cell line.

Material & methods : Rat osteoblast ROS 17/2.8 cells were cultured, and treated with with 0.1-40 μ g/mL CsA for 24 hours after plating of cells. Cell viability was determined by the MTT assay. Western Blot Analysis was done with primary antibodies to caspase-3 and caspase-8. Reactive oxygen species synthesis was measured by flowcytometry.

Results: Cell viability decreased in dose-dependent manner with increasing concentrations of CsA. Treatment of ROS 17/2.8 cells with 0.1, 0.5, 1, 5, 10, 20, or 40 μ g/mL CsA caused 85%, 80%, 73%, 60%, 45%, 40%, and 27% cell viability, respectively. Western blot analysis showed reduced caspase-3 expression and induced caspase-8. The oxygen free radicals in a dose-and time-dependent manner were increased by CsA.

Conclusions : These results suggest that CsA can induce oxygen free radicals which appears to trigger apoptosis by activating pro-apoptotic signals. CsA plays a role in the post-transplantation bone diseases via the induction of apoptosis in osteoblast.

Identification of CARP-1 Target Cells in Bone and Response to PTH in Osteoblastic Cells. Sonali Sharma^{*1}, Chandrika Mahalingam¹, Shazia Zamal², Edi Levi³, Arun Rishi⁴, Nabanita Datta⁵. ¹Endocrinology, Wayne State University School of Medicine, USA, ²Oncology, VA Medical Center, USA, ³Pathology, VA Medical Center, USA, ⁴Oncology, Karmanos Cancer Institute, VA Medical Center, USA, ⁵Endocrinology, Cardiovascular Research Institute, Karmanos Cancer Institute, Wayne State University School of Medicine, USA

Bone mass is dependent on osteoblast proliferation, differentiation and life-span of osteoblasts. Intermittent administration of parathyroid hormone (PTH) increases bone mass but the mechanism of action are complex and have not been clearly established. PTH control of osteoblast cell cycle regulatory proteins and suppression of mature osteoblasts apoptosis has been previously demonstrated in the process of bone formation both in vitro and in vivo. Cell Cycle and Apoptosis Regulatory Protein (CARP)-1 (aka CCAR1) is a novel regulator of apoptosis signaling by diverse agents including cell growth and differentiation factors. Here we investigated presence of CARP-1 in bone cells, and its role in transducing PTH-dependent molecular signaling in osteoblasts. Ten to twelve-week old mice femora were immuno-stained with anti-CARP-1 polyclonal antibody. Our results demonstrate significant presence of CARP-1 in osteocytes and in osteoblasts and a minimal to absent levels are observed in the marrow cavity or in chondrocytes. Further, treatment of 7-day differentiated MC-4 (MC3T3-E1 clone-4) mouse osteoblastic cells with PTH or PTH-related peptide (PTHrP) for 30 min to 5 hr followed by Western blot analysis reveals 2-3 fold down-regulation of CARP-1 protein when compared to vehicle treated control cells. Mechanism of apoptosis by CARP-1 involves activation of p38 Mitogen Activated Protein Kinase (MAPK) and increase in p21^{WAF-1/CIP-1} protein, a cyclin dependent kinase inhibitor. Our studies further show a 3-5 fold down-regulation of pp38-MAPK and p21 protein expression with concomitant attenuation of CARP-1 abundance in differentiated MC-4 cells following PTH induction. Although PTH treatment elicited a 1.5-2 fold increase in pro caspase-9 expression, no activation of caspase 3 activity was noted pointing again antiapoptotic activity of PTH in osteoblastic cells. Our findings are indicative of a role for CARP-1 in apoptosis signaling pathways in osteoblasts and possibly in osteocytes. Taken together we propose CARP-1 as a potential regulator and may be an important target gene of the PTH and PTHrP response; hence would be a good candidate to study PTH bone anabolic action.

Apolipoprotein D Deficient Mice Show Altered Bone Metabolism: A Structural and Cellular Characterization. Corine Martineau^{*1}, Quafa Najyb², Louise Martin-Falstrault³, Eric Rassart², Robert Moreau⁴. ¹Université du Québec à Montréal, Canada, ²UQAM, Canada, ³UQAM, Canada, ⁴University of Quebec At Montreal, Canada

This pilot study aimed at evaluating the impact on bone metabolism of apolipoprotein D (Apo D), a glycoprotein of the lipocalin family associated to high density lipoprotein (HDL) in mammals. Apo D is a multi-ligand, multi-functional transporter of small hydrophobic molecules namely arachidonic acid, progesterone, pregnenolone and bilirubin. Its expression is induced by several stresses such as growth arrest and inflammation. In the brain, it is thought to be involved in maintenance and repair of the nervous system although its precise role remains to be determined. To assess its potential function in bone metabolism, plasma samples were analyzed for calcemia, phosphatemia and ALP activity. Microcomputed tomography (MicroCT) and histomorphometry analyses were performed on bones harvested from ApoD-deficient or transgenic mice (overexpressing human Apo D in the brain) at different ages in both genders. Also, gene expression of Apo D, its internalization and cellular localization were determined in osteoblastic cells by RT-PCR and confocal microscopy. Plasmatic ALP activity was found to be enhanced in 9-month-old Apo D KO females ($p < 0.001$ vs WT, Bonferroni post-test), whereas calcemia and phosphatemia were normal in all groups. MicroCT data showed that Apo D-deficient females develop increasing osteopenia with age (6 month-old and 9-month-old $p < 0.05$ vs WT, Bonferroni post-test); these results were confirmed by Von Kossa staining. Histochemistry analysis of femora sections attributes the low bone mass to bone formation dysfunction with normal TRAP-positive cell distribution, yet less ALP-positive cells. No significant differences in bone status were observed in the Apo D-transgenic mice nor in the male Apo D-deficient mice. Apo D mRNA was shown to be expressed in osteoblastic cell line MC3T3-E1 and primary cultures from mouse bone marrow. Apo D added to culture medium was readily internalized by osteoblasts and recent assays also suggested that stress conditions provoke its nuclear translocation, agreeing with a stress-defense function. The sum of these results points toward a role for Apo D in osteoblastic function. In perspective, a thorough investigation of the cellular mechanisms regulating Apo D in osteoblasts under normal and stress conditions is needed to fully unravel the function of this apolipoprotein in bone metabolism, and could lead to new clinical approaches in the prevention and treatment of bone disorders.

Calcium-Sensing Receptors (CaSRs) in Mature Osteoblasts Regulate Bone Formation and Maintenance of Bone Mass: Studies in Osteocalcin (OCN) Conditional Knockout Mice. Nathan Liang¹, Tsui-Hua Chen¹, Zhiqiang Cheng², Alfred Li¹, Christian Santa Maria¹, Chia-Ling Tu¹, Wenhan Chang³, Dolores Shoback^{*4}. ¹UCSF, USA, ²University of California, San Francisco, USA, ³Endocrine Unit, VA Medical Center, University of California, San Francisco, USA, ⁴VA Medical Center, USA

CaSRs play key roles in osteoblast (OB) differentiation by controlling growth, mineralization, and gene expression. Prior conditional (c) CaSR knockout (KO) models, in which the CaSR is deleted across the OB lineage [using 2.3 KB collagen 1 (Col1) Cre mice], showed early death, stunted growth, fractures and a block in differentiation in the OB lineage. To determine the role of CaSRs in cells late in OB lineage when mineralization, maturation, and transition to osteocytes occur, we bred CaSR cKO's by crossing ^{flx/flx}CaSR with OCN-Cre mice [^{OCN}CaSR (-/-)]. In contrast to ^{Col1}CaSR(-/-), ^{OCN}CaSR(-/-) mice grew as did control (cont). At 12 weeks of age, micro-CT (uCT) of trabecular (Tb) and cortical (Ct) bone and histomorphometry (HM) were performed to assess bone structure and turnover. uCT showed osteopenia of Tb bone with reduced BV/TV (bone volume/tissue volume) in male [$0.11 \pm 0.01\%$ (KO) vs $0.15 \pm 0.01\%$ (cont) ($p < 0.02$; N=12)] and female [$0.08 \pm 0.01\%$ (KO) vs $0.11 \pm 0.01\%$ (cont) ($p < 0.001$; N=13 or 15)] mice and reduced CD (connectivity density) in male [154.75 ± 19.35 (KO) vs 211.08 ± 28.25 #/mm³(cont) ($p = 0.058$) and female [107.15 ± 13.74 (KO) vs 157.30 ± 15.47 #/mm³(cont) ($p < 0.02$)] mice. Tb number (N) was significantly reduced in ^{OCN}CaSR(-/-) vs cont mice [males: 4.76 ± 0.22 vs 5.28 ± 0.19 #/mm; females: 4.22 ± 0.16 vs 4.64 ± 0.19 #/mm. ($p < 0.05$ for both)]. Tb thickness (Th) was significantly lower in female ^{OCN}CaSR(-/-) mice ($p < 0.02$) and Tb spacing (Sp) was greater in male mice ($p < 0.05$) – indicating an overall disruption of Tb microarchitecture in both genders. HM in males showed reduced BV/TV [16.57 ± 1.58 , ^{OCN}CaSR(-/-) vs $20.70 \pm 1.61\%$, cont ($p < 0.04$)], increased ES (eroded surface)/BS (bone surface) [1.39 ± 0.16 , ^{OCN}CaSR(-/-) vs $0.95 \pm 0.11\%$, cont ($p < 0.02$)], increased # osteoclasts (N.Oc)/BS [1.21 ± 0.13 , ^{OCN}CaSR(-/-) vs $0.84 \pm 0.11\%$, cont ($p < 0.02$)] and increased MAR (mineral apposition rate) [2.13 ± 0.11 , ^{OCN}CaSR(-/-) vs 1.81 ± 0.08 mcm/day, cont ($p < 0.02$)]. No significant differences were seen in TbN, TbTh or TbSp. qPCR showed reduced mRNA encoding OB genes (OCN, sclerostin, Col1) in bone from ^{OCN}CaSR(-/-). These findings are compatible with lowered bone mass in ^{OCN}CaSR(-/-) mice due to a turnover imbalance favoring resorption over formation due to loss of CaSR activation in late OB's and osteocytes.

Cytotoxic Therapies Significantly Alter the Composition of the Cells Comprising Murine Hematopoietic Stem Cell Niches. Julie Quach^{*1}, Maria Askmyr², Tanja Jovic², Hannah King², Cesar Nombela-Arrieta³, Kirby White², Emma Baker⁴, Nicole Walsh⁵, Leslie Silberstein³, Louise Purton⁶. ¹St. Vincent's Institute, Australia, ²St. Vincent's Institute, Australia, ³Joint Program in Transfusion Medicine, Children's Hospital Boston, Harvard Medical School, USA, ⁴St. Vincent's Institute, Australia, ⁵St Vincent's Institute of Medical Research, Australia, ⁶St. Vincent's Institute, The University of Melbourne, Australia

Hematopoietic stem cells (HSC) are regulated within the bone marrow (BM) in anatomical locations termed HSC niches. Cancer therapies are known to significantly impair hematopoiesis, however, their effects on HSC niche cells are largely unknown. Using adult male mice, we have extensively analyzed the effects of irradiation or chemotherapy on HSC niche cells. Our studies have focused on putative HSC niche cell types that are also important in regulating bone: endothelial cells (ECs), adipocytes, mesenchymal stem and progenitor cells (MSPCs), osteoblasts (Obs) and osteoclasts (Ocs).

We used histomorphometric analysis to quantitate the numbers of these cells in tibiae at numerous intervals up to 140 days post-therapy. Bone volume was assessed in femurs and vertebrae using microCT analysis. Fluorescence-activated cell sorting (FACS) was used to purify MSPCs and Obs for further analysis.

The earliest histological change observed was to ECs: significant vessel dilation throughout the BM was observed at early time points in response to all three therapies, although vessel number was largely unchanged. Interestingly, the vasculature changes were restricted to sinusoids, as arteries were unaltered.

Adipocytes (which are negative regulators of HSCs) significantly increased between days 7-35 post-therapy in the different treatment groups. The numbers of

MSPCs also increased at early time points post-therapy, but expressed higher levels of adipocyte-commitment genes (PPAR γ and adiponectin) compared to those critical for Ob differentiation (Runx2 and Osx). Hence the enhanced adipocyte formation observed in the mice was likely due to altered fate commitment of MSPCs.

All treatments resulted in a net bone loss with an associated increase in bone turnover (as indicated by increases in the numbers of Obs and Ocs). Inhibition of Ocs by a single dose of the bisphosphonate, zoledronic acid (ZA) prevented this bone loss, but in contrast to recent reports, did not significantly impair HSC numbers or function. A major difference in our study is that bone volume was not elevated above normal levels in response to ZA, whereas mice in the other studies were osteopetrotic when analyzed for HSCs.

In conclusion, niche cells that are important in regulating both HSCs and bone remodeling are highly susceptible to cancer therapies. Reducing damage to these niche cells may in turn improve blood cell recovery in cancer patients.

Does Collagen Trigger Migration of Reversal Cells into Vacated Bone Resorption Lacunae? Mohamed Abdelgawad*¹, Kent Soe², Lars H. Engelholm³, Per Kjaergaard-Andersen², Niels Behrendt³, Jean-Marie Delaisse⁴. ¹Clinical Cell Biology Department (KCB), Denmark, ²Vejle Hospital, University of Southern Denmark, Denmark, ³Finsen Laboratory, Rigshospitalet, Denmark, ⁴Vejle Hospital, IRS, University of Southern Denmark, Denmark

Bone remodelling involves bone resorption by osteoclasts, bone formation by osteoblasts, and a poorly investigated intermediate reversal phase coupling resorption to formation. The very first step of the reversal phase is the departure of the osteoclasts from the resorption lacunae and the arrival of so-called reversal cells. We previously showed that reversal cells belong to the osteoblast lineage, but the mechanism making them migrate into the resorption lacunae is not known. Our hypothesis is that collagen type I left in the lacunae by the osteoclasts exerts a haptotactic effect on these cells. Here we investigated this hypothesis as well as the underlying molecular mechanism.

We coated therefore the lower side of the membrane of transwells with native collagen or control molecules, and seeded osteoblast lineage cells in the upper chamber. Cells of two distinct origins were used: human adipocyte-derived stem cells differentiated into osteoblasts (ADSC), and primary osteoblasts obtained from outgrowths from human bone (HOB). Migration to the lower side of the membrane was quantified after an overnight culture in the presence or absence of an inactivator of urokinase plasminogen activator receptor associated protein (uPARAP), a collagen receptor involved in osteoblast migration, or of an inactivator of matrix metalloproteinases (MMPs), collagenolytic proteinases believed to be involved in uPARAP function.

Native collagen type I significantly increased the haptotactic migration of both ADSCs and HOBs, compared to collagen denatured into gelatine, vitronectine, or BSA. Inactivation of uPARAP significantly decreased their response to native collagen, and inactivation of MMPs significantly decreased that of ADSCs, the only cell type tested so far.

In conclusion, these observations support that native collagen type I left in the resorption lacunae by the osteoclast may contribute to the recruitment of reversal cells into these lacunae. This process requires recognition by the collagen receptor uPARAP. MMP-specific alterations of native collagen are likely to be involved in this mechanism, since MMP inactivators inhibit it, and since random alterations obtained through simple denaturation into gelatine results in a loss of haptotactic response.

Endothelin Signaling Promotes Terminal Differentiation of TMOB Cells via Increased BMP@ and Nos3 Expression. Michael Johnson*¹, Kathryn Konicke², Rachel Garbo³, Robert Blank¹, Baozhi Yuan¹, Jasmin Kristianto⁴, Suzanne Litscher³. ¹University of Wisconsin, USA, ²University of Wisconsin, USA, ³University of Wisconsin, USA, ⁴University of Wisconsin-Madison, USA

Ece1, encoding endothelin-converting-enzyme 1, is a positional candidate gene for a pleiotropic quantitative trait locus (QTL) affecting femoral size, shape, mineralization, and biomechanical performance. ECE1 is a membrane bound protease that converts biologically inert "big endothelin" (big ET) to mature endothelin 1 (ET1). ET1, in turn, is known to promote osteogenic metastases in prostate and breast cancer. In order to define the potential role of ECE1 in osteogenesis, we exposed TMOB cells to supplemental big endothelin (25ng/ml) over the course of *in vitro* differentiation, hypothesizing that this treatment would increase mineralization. Cells were grown for six days in growth medium and then switched to mineralization medium for an additional 15 days. An aliquot of cells were harvested at day 0 and

every three days thereafter and analyzed for markers of osteoblast maturation. We did not observe a difference in cell proliferation between big ET and control cells. TMOB cells exposed to big ET showed greater mineralization than control cells (Figure, N = 6, p = 0.008). In growth medium, ET-1 exposed osteoblasts showed increased expression of *Bmp2* and *Nos3* message, which persisted following the change to mineralization medium (N = 6, p = 0.008 and 0.002, respectively). Although previous work showed that ET1 exposure inhibited *Dkk1* expression, this was not the case in our experiment, as we observed transient early increases of both *Dkk1* and *Sost* message in cells treated with big ET. This disparity likely reflects differences in the cells studied. In mice, both *Ece1* and *Bmp2* expression vary concordantly as a function of *Ece1* genotype, and mirror the findings in TMOB cells. BMP2 is known to promote osteogenesis and NO production is known to be a necessary intermediate in loading-induced bone modeling. Our findings demonstrate that endothelin signaling, delivered as big ET, enhances *in vitro* mineralization of TMOB cells and suggest that this occurs in part via BMP2 and/or NO signaling.

Periostin Deficiency, Inhibit Beta Catenin Response to PTH and Induce Cortical Porosity through Osteocytic RANKL Expression. Nicolas Bonnet*¹, Serge Ferrari². ¹Division of Bone Diseases, Geneva University Hospital & Faculty of Medicine, S, Switzerland, ²Geneva University Hospital & Faculty of Medicine, Switzerland

Periostin is a matricellular protein expressed in osteocytes and the periosteum and mediates *Sost* in response to loading. Gene profiling in bones exposed to PTH have identified an increase of periostin (*Postn*). Since PTH inhibits *Sost* and activates β catenin, we investigated the influence of *Postn* on β catenin, osteoblastic/osteocytic genes and cortical response to PTH. To evaluate the role of *Postn* on β catenin, we used TOPGAL; *Postn*^{-/-} and *Postn*^{+/+} mice, which express a TCF β Galactosidase reporter. Activation of β catenin was evaluated by X-Gal staining on femoral sections, after intermittent PTH (iPTH). Activation of β catenin was evaluated on calvariae from these mice exposed to recombinant POSTN (rPOSTN), PTH or vehicle (Veh) followed by counting X-Gal positive cells (+). PTH effects on gene expression were evaluated on calvaria and confirm *in vivo* on osteoblastic/osteocytic fraction by qRT-PCR. Femur cortical structure in response to iPTH (40ug/kg x5weeks) was evaluated by microCT in adult *Postn*^{-/-} mice. *In vivo*, iPTH activated β catenin in TOPGAL; *Postn*^{+/+} but not in *Postn*^{-/-}. *Postn*^{-/-} cells have lower X-Gal (+) vs *Postn*^{+/+}. PTH increased the number of X-Gal (+) cells from TOPGAL; *Postn*^{+/+} (+73.1% vs Veh, p<0.0001) but not *Postn*^{-/-} (+7.9% vs Veh, NS). Moreover, rPOSTN increased the number of X-Gal (+) cells in *Postn*^{+/+} and even more so in *Postn*^{-/-} (+28.6% vs Veh, p<0.05, and +70.5% vs Veh, p<0.001). Gene expression of Runx2, Osx and Alp were all significantly lower in osteoblasts from *Postn*^{-/-} vs *Postn*^{+/+}. Moreover, PTH decreased Runx2, Osterix, OPG (-41.6%, -82.3% and -22.8% vs Veh, p<0.01) and increased RANKL (+460.0% vs Veh, p<0.01) in *Postn*^{+/+}, with no effect in *Postn*^{-/-} except for RANKL (+605.3% vs Veh, p<0.01). In osteocyte fractions, *Postn*^{-/-} have higher RANKL vs *Postn*^{+/+} (+355%, p<0.001). Moreover, PTH increased RANKL only in *Postn*^{-/-} osteocyte fractions (+596% vs Veh, p<0.01). Finally, iPTH significantly increased cortical volume (CtBV) and thickness (CtTh), but not porosity (CtPo), in *Postn*^{+/+}, whereas in *Postn*^{-/-}, iPTH increased CtPo and pores width (+126.7% and +81.5% vs Veh, p<0.05) but not CtBV nor CtTh. These results highlight the role of periostin on β catenin and PTH effects on osteocytic gene expression. They suggest that PTH-stimulated periostin expression mediates PTH anabolic effects on cortical and prevents PTH-induced porosity by reducing the osteocyte RANKL production.

Disclosures: Nicolas Bonnet, None.

Targeting Osteoclasts to Promote Bone Regeneration; Adenosine Receptors Regulate Osteoclast Formation and Promote Bone Regeneration in a Calvarial Defect Model. Aranzazu Mediero^{*1}, Tuere Wilder², Bruce Cronstein³. ¹NYU SCHOOL OF MEDICINE, USA, ²Department of medicine, NYU School of Medicine, USA, ³NYU Medical School, USA

Various types of orthopedic procedures, including spinal fusion and repair of bone defects due to trauma, infection or metastatic disease, require formation of new bone. Adenosine, generated from the catabolism of adenine nucleotides, modulates cell function by interacting with specific cell-surface receptors (A1, A2A, A2B, A3). In previous studies we have demonstrated that adenosine A1 receptor blockade and A2A receptor stimulation diminishes osteoclast formation without directly affecting osteoblast formation or function. We therefore determined whether targeting adenosine receptors affected bone regeneration in a murine model. Male C57Bl/6 mice were anesthetized and a 3mm trephine defect was formed and covered with a collagen scaffold soaked in saline or 1 μ M adenosine receptor agonists/antagonists. Animals received the appropriate treatment daily until sacrifice. At 0, 2, 4, 6 and 8 weeks calvarias were harvested and prepared for microCT and histology. XenoLight Rediject Bone Probe 680 was injected intravenously in mice at different time points. Eight weeks after surgery microCT examination of mouse calvaria demonstrate that an A1R antagonist (DPCPX), A2AR agonist (CGS21680M) or dipyrindamole (blocks adenosine uptake and increases extracellular adenosine levels) markedly enhances bone regeneration (77 \pm 0.2%, 60 \pm 2% and 79 \pm 2% bone regeneration respectively vs 32 \pm 4% in control mice, p<0.001, n=5 mice per condition) whereas an A3R agonist (IB-MECA) had no effect (32 \pm 3% regeneration, n=5). Alkaline phosphatase and osteocalcin immunostaining at the sites of bone formation was increased in defects treated with DPCPX, CGS21680 and Dipyrindamole. In contrast, TNF α , Semaphorin4D and PlexinB1 immunostaining was diminished in DPCPX, CGS21680 and Dipyrindamole treated defects. TRAP staining revealed fewer osteoclasts in DPCPX, CGS21680 and Dipyrindamole treated defects (14 \pm 1, 17 \pm 1 and 16 \pm 1 Osteoclast/IpF respectively vs 24 \pm 1 Osteoclast/IpF for control, p<0.001) and *in vivo* imaging with a marker for new bone formation (XenoLight Rediject) showed greater bone formation in the treated mice. Targeting osteoclasts via appropriate adenosine receptor blockade or stimulation leads to increased bone regeneration in a murine model of bone regeneration. The mechanism by which adenosine receptor-mediated suppression of osteoclast function/accumulation stimulates bone regeneration likely involves suppression of semaphorin4D permitting increased osteoblast formation of bone.

The Role of Oxygen in Blastema Formation and Skeletal Regeneration. Mimi Sammarco^{*1}, Jennifer Simkin², Ken Muneoka², Danielle Fassler². ¹Tulane University, USA, ²Tulane University, USA

One out of every 200 people in the U.S. will suffer an amputation, and this number is expected to double in the next 40 years. Amputation has protracted effects on vocational outcome, individual productivity, and personal independence far beyond the initial trauma. While complete limb regeneration in humans may someday become the ultimate therapy, the ability to coordinately control bone regeneration would reduce pain from ectopic bone spurs, and provide a better fit for prosthetics, resulting in a better quality of life in the near term. Amputation of the digit tip within the terminal phalangeal bone of rodents, monkeys, and humans results in near-perfect regeneration from a cell population called the blastema, which has been well characterized in both adult and neonatal mice. However, it remains unclear why amputations within the more proximal phalangeal elements, or within limbs, fail to produce the same regenerative result. The long term goal of this work is to understand the influence of oxygen on bone regeneration, so that these mechanisms can be exploited to confer regenerative capacity where it is lacking. The objective of this study is to gain insight into the role of oxygen in the regenerative process by manipulating oxygen within the digit tip to alter the regenerative process. Our central hypothesis is that a biphasic oxygen response facilitates the regenerative process. The basis of this hypothesis stems from the biphasic nature of the regenerative models, and oxygen's known influence in the process of wound healing. Our data shows that the highly proliferative, undifferentiated blastema initiates in a low oxygen environment. Upon exposure to increased oxygen tension, the blastema begins redifferentiation into bone, supporting the idea of a biphasic oxygen response that drives the regenerative process. Here we present a novel multi-tissue slice culture model and use our *in vitro* system to show that oxygen influence during bone regeneration is temporally specific. We propose that small increases in oxygen tension coordinately control bone ossification and directly contribute to the redifferentiation of the blastema. Research enabled by this work will lead to a defined mechanistic understanding of oxygen's role in bone regeneration and identify therapeutic targets to enhance regenerative capacity.

Use of Vwc2 Protein as a Novel Approach to Induce Bone Formation. Ahmad Almeahmadi^{*1}, Yoshio Ohyama², Haytham Jaha², Sundharamani Venkitapathi², Reem Aljamaan², Yoshiyuki Mochida³. ¹Goldman School of Dental Medicine, Boston University, USA, ²Boston University, Henry M. Goldman School of Dental Medicine, USA, ³Boston University, Henry M. Goldman School of Dental Medicine, USA

Objective: We have recently reported that a novel secretory protein, von Willebrand domain containing 2 like (Vwc2l), promotes osteoblast mineralization *in vitro*. In the present study, Vwc2, a highly homologous protein to Vwc2l was characterized.

The objective of our study is to investigate the effect of Vwc2 on bone formation.
Methods: The expression of Vwc2 in MC3T3-E1 (MC) osteoblastic cell line was investigated by real time PCR at RNA level and by Western Blotting (WB) analysis at protein level. The presence of Vwc2 protein in bone was also examined by immunohistochemistry (IHC) and WB analysis. The effect of Vwc2 on Activin signaling was examined in MC osteoblastic cell line by WB. To characterize the function of Vwc2 protein, recombinant Vwc2 protein (rVwc2) was added into mouse calvaria *ex vivo* cultures and the extent of newly synthesized bone formation was analyzed.

Results: Vwc2 transcript is detected in MC cells with the highest expression observed at day 7 during biomineralization. The expression pattern of Vwc2 protein in the cultured media from MC cells was similar to that of Vwc2 transcript. The localization of Vwc2 protein was observed by IHC in mouse developing maxilla. The effect of Vwc2 on Activin signaling was examined and we found that Vwc2 inhibited activin initiated Smad2 phosphorylation. The effect of rVwc2 on mouse calvaria bone formation was examined and the results showed increased bone formation.

Conclusion: Our data demonstrated that Vwc2 is expressed in osteoblasts/bone and has the ability to increase bone formation. The data obtained from this study may provide insights to the biological functions of this novel protein and help to develop a new molecular design for bone loss therapies (Treatment of osteoporosis, Craniofacial reconstruction and bone regeneration).

Frizzled Homolog 1 (FZD1) Mediates the Effect of E2F1 on Osteoblast Differentiation and Mineralization. Shibing Yu^{*1}, Laura Yerges-Armstrong², Yanxia Chu³, Joseph Zmuda⁴, Yingze Zhang⁵. ¹University of Pittsburgh Medical Center, USA, ²University of Maryland, USA, ³UPMC, USA, ⁴University of Pittsburgh Graduate School of Public Health, USA, ⁵University of Pittsburgh, USA

The mechanisms underlying transcriptional regulation of FZD1 gene expression and the roles of FZD1 in osteoblast differentiation and mineralization are not well understood. The goal of the present study was to investigate the potential roles of transcription factor E2F1 in regulating FZD1 expression and in osteoblast differentiation and mineralization. Co-transfection of an E2F1 expression plasmid and FZD1 promoter construct resulted in increased FZD1 promoter activity in an E2F1 dose dependent manner in Saos2 osteoblast-like cells. In addition, direct binding of E2F1 to the FZD1 promoter was detected using both a ChIP assay and EMSA. Consistent with these results, endogenous FZD1 mRNA and protein expression in Saos2 cells was activated by E2F1 overexpression. Increased expression of FZD1 by E2F1 subsequently promoted the expression of osteoblast markers including Osteocalcin (OCN), Alkaline phosphatase (ALP) and Collagen type I (Col I) and differentiation of Saos2 cells. Saos2 cells overexpressing E2F1 had significantly stronger Alizarin Red-S (AR-S) staining compared to control Saos2 cells when treated with osteoblast differentiation medium. Knockdown of FZD1 by siRNA significantly reduced the mineralization ability of Saos2 cells and abolished the enhanced osteoblast mineralization stimulated by E2F1 *in vitro*. Our study demonstrates that FZD1 plays a critical role in osteoblast differentiation and mineralization and that FZD1 is required for E2F1-dependent regulation of osteoblast mineralization.

Higher Strontium Consumption Stimulates Osteoblast Differentiation and Increase Bone Formation in Goats. Junjing Jia^{*1}, Guozhou Liao², Yueyuan Fan³, Hua Rong³, Zhiqiang Xu⁴, Xi Zhang⁵, Dahai Gu³, Qichao Huang², Zhenhui Cao³, Qiuye Lin⁶, Sizheng Gao³, Qiuye Lin³, Changrong Ge⁷, Wei Yao⁸. ¹University of California, Davis, USA, ²Faculty of Food Science, Yunnan Agricultural University, China, ³Yunnan Provincial Key Laboratory of Animal Nutrition & Feed, Yunnan Agricultural University, China, ⁴Yunnan Agricultural University, China, Peoples Republic of China, ⁵Yunnan Agricultural University, Peoples Republic of China, ⁶Yunnan Agricultural University, China, Peoples Republic of China, ⁷Yunnan Agricultural University, China, Peoples Republic of China, ⁸University of California, Davis Medical Center, USA

Many researchers have reported that strontium (Sr⁺) plays important role in increasing osteoblast differentiation and bone formation in human and in animals. In one of our previous studies, we demonstrated that higher strontium consumption increased biomarkers for bone formation, and increased bone mineral density (BMD), bone mineral content (BMC) and strength in a "red-bone" goat strain. This study was designed to investigate cellular and molecular mechanisms of strontium both in vivo and in vitro in goat.

In vivo Study: Eight six months old red-boned lambs (high bone Sr⁺ content) and eight normal lambs were sacrificed and samples from cartilage and distal tibia were taken to detect osteoblast differentiation gene markers.

In vitro Study: Periosteum-derived mesenchymal stem cells (PMSCs) were isolated from red-boned and common lambs six months of age. PMSCs were cultured in osteogenic medium containing dexamethasone, ascorbic acid and β-glycerophosphate. Goat osteoblasts were identified by ALP staining. Cells were stained with crystal violet staining for total colony forming units (CFU-F) and Alizarin Red staining for osteoblastic units (CFU-Ob). The expressions of osteoblast differentiation gene markers were detected at 14 days.

Results: In vivo study showed that red-boned goats had significantly higher alkaline phosphatase (ALP), osteocalcin (bglap) and RUNX2 genes expressions in cartilage and distal tibia. In vitro study showed that PMSCs of red-boned goat have shown higher rate of proliferation than those of common goat. PMSCs in red-boned goat can go through passage 15 compared with passage 10 in PMSCs of common goat. PMSCs in red-boned goat exhibited the greater osteogenic properties with higher activity of ALP as well as more calcium nodules than those in control group. Both ALP and osteocalcin expressions, were higher in PMSCs derived from red-boned goat compared to those derived from common goat.

In conclusion: Higher strontium consumption stimulates osteoblast differentiation and increase bone formation in goats.

Kinetics of Bmp2 Gene Expression in Primary Calvarial Osteoblasts: Gene Regulatory Network Constructed with ARCANe and Linked to Ingenuity Pathway Transcriptional Module. Stephen Harris^{*1}, Alexander c Lichtler², Shuo Chen³, Marie A Harris³. ¹University of Texas Health Science Center at San Antonio, USA, ²U. of Connecticut Health Center, USA, ³U. of Texas Health Science Center at San Antonio, USA

Mechanism of Bmp2 action on Osteoblasts is not well understood. There is a clear collection of genes stimulated and repressed by Bmp2 action on osteoblasts both in vivo and in vitro. For example, conditional removal of Bmp2 gene in osteoblasts results in dramatic decreased expression of Osterix and VegfA, Dlx3 and many others. We treated confluent primary calvarial osteoblasts with 100 ng/ml of recombinant Bmp2(rBMP2) and collected RNA at 1,2,4,8,16,24, and 72 hrs after this single treatment and carried out robust gene expression analysis using the Illumina Mouse W6 v2 microarray with 45,000 probes, analyzed the data with Genome Studio RNA expression module software and used a set of 1415 genes that were Bmp2 regulated at any time point, with Differential Expression Pvalue <0.005 and at least 1.7 fold change from the 0hr, 24hr, or 72 hr control time points. Using Ingenuity Pathway(IPA) and David Bioinformatic, we identified several relevant functional cluster and pathways. We used David to get a list of the transcription factor activity related genes in the 1415 geneset and used this Gene Ontology Class of 43 transcription factor(TF) dataset to construct a gene regulator network(GRN) of links between these TF and the genes they directly regulate using the reverse genetic engineering principals of the algorithms in ARCANe, implemented in the geWorkbench programs. We set the parameters at P<.05 with bootstrapping set at 20 with a consensus threshold at 0.001. We found 8 major clusters of genes around the TF Nfatc3 and Nfatc1, Alex4, Osterix, Dlx3, Egr2, Hey1, LBH, and AES. Each cluster contained from 10 to 50 candidate genes directly regulated by these TF, with some links between the clusters. Using the literature based pathway components of IPA, and the new transcriptional regulator of IPA, approximate 25% of the links identified in the GRN were supported by at least 1 reference in the IPA database. Then GRN implies that initial Bmp2 action is on increased growth related genes and Notch signaling. At later time points, the differentiation program is activated. This Bmp2 regulated GRN network will serve as a starting module for further validation and extension using whole genome sequencing and mapping of Bmp2 modulated enhancers.

microRNA Expression Analysis Using Next Generation Sequencing in Primary Human Bone Cells treated with Parathyroid Hormone or Dexamethasone. Navya Laxman^{*1}, Carl-Johan Rubin², Hans Mallmin³, Olle Nilsson⁴, Christian Tellgren-Roth⁵, Andreas Kindmark³. ¹Uppsala University, Sweden, ²Uppsala University, Sweden, ³Uppsala University Hospital, Sweden, ⁴Department of Surgical Sciences, Uppsala University, Sweden, ⁵Department of Immunology, Genetics & Pathology, Rudbeck laboratories, Uppsala University, Sweden

MicroRNAs (miRNAs), are a class of post-transcriptional regulators. They are naturally occurring, small non-coding RNA molecules, about 21–25 nucleotides in length. They bind to complementary sequences in the 3' UTR of multiple target mRNAs, usually resulting in their silencing.

We have previously used miRNA LNA(Locked Nucleic Acid) arrays to assess global miRNA expression in human osteoblasts(HOB), and identified approximately 90 miRNAs with significant expression levels, and also identified a subset of miRNAs exhibiting interindividual and/or gender differences. We have shown statistically significant correlations between miRNA and mRNA abundance of genes involved in bone metabolism in HOB. In the present project, we applied next generation sequencing techniques to comprehensively assess miRNA expression in HOB cells treated with parathyroid hormone (PTH) and dexamethasone (DEXA).

HOB cells were isolated from human trabecular bone collected from donors undergoing total hip replacement, and subsequently treated for 2 and 24 hours with PTH or DEXA or left untreated. Small RNA was isolated from these cells and cDNA synthesized using SOLiD library protocol. Second generation sequencing was performed using SOLiD4 on barcoded library constructs of small RNA 50bp plus barcode, at the Uppsala Genome Center. Sequence reads were aligned to a scaffold consisting of all known miRNA sequences, and number of sequence reads mapping uniquely to each miRNA were counted.

A total of 207 million reads from the small RNA library constructs was obtained, and normalized absolute expression was retrieved for the 500 most abundant miRNAs. The 75 miRNAs that exhibited the highest mean expression across the four experiments per individual were taken for downstream analyses. Expression levels were set to percent of each, and results showed a significant effect of treatment with PTH versus treatment with DEXA at 2 hours and even more pronounced at 24 hours on miRNA abundance. Interestingly, several miRNAs exhibiting significant differences in abundance have predicted mRNA targets involved in bone metabolism, e.g. miR-197 targeting Insulin-like growth factor1(IGF) and Wnt pathway members. miR-31 also showed differential expression.

miRNA absolute abundance data from next generation sequencing show that PTH and DEXA affect miRNA abundance in primary human bone cells, and that these miRNAs in turn are correlated to levels of mRNAs known to affect bone metabolism.

Sequential Expression of Sox11 and Sox4 Is Essential for Osteoblastogenesis and Bone Development. Jogeswar Gadi^{*1}, Min Jung Lee², Ajita Jami³, Kyoung Min Kim⁴, Han-Sung Jung⁵, Sung-Kil Lim⁶. ¹Yonsei University College of Medicine Seoul South Korea, South Korea, ²Department of Oral Biology, College of Dentistry, Yonsei University, South Korea, ³Division of Endocrinology & Endocrine Research Institute, Yonsei University College of Medicine, South Korea, ⁴Yonsei University College of Medicine, Republic of Korea, ⁵Department of Oral Biology, College of Dentistry, Yonsei University, South Korea, ⁶Yonsei University College of Medicine, South Korea

The high-mobility-group (HMG) domain containing transcription factors *Sox11* and *Sox4* belongs to the *SoxC* family and were found to be expressed in pre-osteoblast cells. We found that *Sox11* expression was restricted to the early stage of osteoblastogenesis by contributing in the commitment of osteoblast cells from the mesenchymal cells. *Sox11* plays an important role in the early osteoblastogenesis by regulating *Runx2* and *Osterix*. In addition to this *Sox11* involved in survival and anti apoptotic activity of MC3T3-E1 cells and primary calvaria cells. Furthermore, the induction of osteoblast differentiation inhibits the expression of *Sox11* in MC3T3-E1 cells on day7, where the *Sox4* expression was found to be sequentially increased with the progression of osteoblast differentiation at mRNA and protein levels. We also found that *Sox4* overexpression simulates the TCF/LEF reporter activity and influences the expression of Wnt signaling genes and osteoblast marker genes. All

together, we hypothesize that both the *Sox11* and *Sox4* expression was essential for the early and late stages of osteoblastogenesis respectively.

TNF α Suppresses BMP2-induced Osteoblasts Differentiation via CREBH-mediated *smurf1* Expression. Won-Gu Jang¹, Eun-jung Kim¹, Hyuck Choi², Sin-hye Oh², Byung-Chul Jeong³, Sung-Woong Hur⁴, Jeong-Tae Koh^{*5}.
¹Korea Research Institute of Bioscience & Biotechnology (KRIBB), South Korea, ²Research Center for Biomaterialization Disorders, School of Dentistry, Chonnam National University, South Korea, ³Chonnam National University School of Dentistry, South Korea, ⁴Chonnam National University, South Korea, ⁵Chonnam National University, South Korea

Inflammation is a major risk factor for bone loss. The proinflammatory cytokine tumor necrosis factor α (TNF α) has been introduced to activate inflammatory responses via the regulated intramembrane proteolysis (RIP) of endoplasmic reticulum (ER) membrane-anchored transcription factors. cAMP response element-binding protein H (CREBH), a liver-enriched ER-bounded bZIP transcription factor, is regulated by UPR-dependent proteolytic cleavage in the liver. Here, we identified that TNF α suppresses BMP2-induced osteoblast differentiation via regulating CREBH-dependent *smurf1* expression. TNF α increased CREBH expression via NF- κ B signaling pathway, and induced the subcellular localization of CREBH to nucleus. Overexpression of CREBH suppressed BMP2-stimulated osteogenic gene expressions such as alkaline phosphatase (ALP) and osteocalcin (OC) in preosteoblast MC3T3E1 cells. TNF α induction of CREBH mRNA expression and CREBH promoter activities were significantly suppressed by BAY11-7082, an NF- κ B inhibitor. Moreover, BAY11-7082 recovered TNF α -suppressed Runx2, ALP and OC with decreased CREBH expression. In addition, inhibition of CREBH expression using siCREBH released TNF α -suppressed osteoblast differentiation. Finally, we found that TNF α or CREBH increased *smurf1* expression in MC3T3E1 cells. Moreover, CREBH-induced *smurf1* increased degradation of Smad1. Our results suggest that ER-bounded bZIP transcription factor CREBH may be a noble negative regulator of osteoblast differentiation, which induces *smurf1*-mediated Smad1 degradation. Furthermore, these provide us some information how TNF α suppresses BMP2-induced osteoblast differentiation.

Action of Small Molecular Inhibitors on Anabolic Effects of Intermittent PTH Treatment. Maki Uyama^{*1}, Masmitsu Kawanami¹, Masato Tamura².
¹Periodontology & Endodontics, Grad. Sch. Dent. Med., Hokkaido University, Japan, ²Biochem. & Mol. Biol., Grad. Sch. Dent. Med., Hokkaido University, Japan

Parathyroid hormone (PTH) is both anabolic and catabolic effects in bone depending on the mode of administration. Systemic intermittent administration of PTH stimulates bone formation in animals and human, and recombinant human PTH (1-34) [teriparatide] is used for the treatment of osteoporosis. Several investigations have previously shown that several molecules such as RANKL, OPG, Runx2, osterix or SOST are a target gene for PTH in bone. In vivo and in vitro studies also indicate that PTH regulated anti-apoptotic signaling, promoted osteoblast differentiation and increased the production and/or activation of osteogenic growth factors such as IGF-1 or BMP. However, up to now, the molecular mechanisms underlying bone anabolic action of PTH remain controversial. Recently, from high-throughput screening of synthetic compound libraries, a novel class of small molecule inhibitors that blocks canonical Wnt signaling or BMP/Smad signaling pathway was identified. IWP-2 prevents palmitoylation of Wnt proteins by Porcupine, thereby blocking Wnt secretion and activity. It also blocks phosphorylation of Lrp6. IWR-1 promotes β -catenin phosphorylation by stabilizing Axin-scaffolded destruction complexes, thereby blocking Wnt signaling pathway. Therefore, we investigate the effects of these small molecular inhibitors on anabolic effects of intermittent PTH treatment in order to examine target signaling pathway for intermittent PTH in osteoblasts and the level of a molecule depending on the mode of administration. In this study, osteoblastic cells were challenged with PTH intermittently or continuously with small molecular inhibitors, and then ALP activity, matrix mineralization, mRNA expression, cell number, 5-bromo-2-deoxyuridine (BrdU) incorporation were determined. Intermittent PTH(1-34) treatment of MC3T3-E1 cells caused an increase in ALP activity, whereas RANKL expression was down-regulated. In these cells, IWR-1, IWP-2 or BMP/Smad signaling inhibitor dorsomorphin regulated ALP activity and mineralization by intermittent PTH treatment. These observations indicated that involvement of canonical Wnt and BMP/Smad signaling pathway in anabolic effects of intermittent PTH treatment in osteoblasts. We also consider the anabolic effects of intermittent treatment with PTH in osteocyte.

Differential Effects of 1,25-dihydroxyvitamin D on *in vitro* Mineral Deposition: Interaction between Osteoblast Stage of Maturation and Culture Medium Calcium Concentration. Dongqing Yang^{*1}, Gerald Atkins², Andrew Turner³, Paul Anderson⁴, Howard Morris⁵.
¹The University of Adelaide, Australia, ²University of Adelaide, Australia, ³Musculoskeletal Biology Research, Chemical Pathology, SA Pathology, Australia, ⁴Musculoskeletal Biology Research, University of South Australia, Australia, ⁵SA Pathology, Australia

Reports of 1,25-dihydroxyvitamin D (1,25D) activity on osteoblasts include either stimulation or inhibition of mineralization. Maturation markedly influences the effects of 1,25D in culture including inhibition of proliferation, enhancing mature osteoblast mineral deposition [1] and 1,25D induction of RANKL mRNA [2]. Bone mineral deposition *in vitro* is enhanced by increasing medium calcium [3]. We now report the interaction between osteoblast maturation, the level of extracellular calcium in the culture medium and the response to 1,25D on *in vitro* mineral deposition. Confluent primary calvarial cells (C57BL/6 mouse pups 1-3 day old) (Calvarial cells) were cultured in differentiation medium for 24 days [4]. Osteoblast-like cells (isolated from 4 week-old C57BL/6 mice femoral cortices) (Cortical cells) were cultured in proliferation medium. Confluent cells were cultured in differentiation medium over 21 days. The effects of 1.8 and 2.8 mM total extracellular calcium on mineralisation (alizarin red staining) and gene expression (real-time RT PCR) were assessed. Calvarial cells exhibited properties of less mature osteoblasts than Cortical cells including reduced levels of mineral deposition (Calvarial cells 36% of Cortical cells, $p < 0.01$) and the induction of RANKL mRNA by 1,25D in Calvarial cells (Day 24, 3-fold, $P < 0.01$) but not in Cortical cells. Mineral deposition in Calvarial cultures was inhibited by 1,25D in 1.8 mM Ca²⁺-medium. (Day 24 28%, $p < 0.01$) with no effect of 1,25D in 2.8 mM Ca²⁺-medium. 1,25D in 1.8 mM Ca²⁺-medium induced the expression of both MEPE (600%, $p < 0.01$) and SOST (1300%, $p < 0.01$). In contrast, 1,25D influenced mineral deposition by Cortical cells only in 2.8 mM Ca²⁺-medium (Day 21, 120%, $p < 0.01$), without an effect on MEPE and SOST mRNA expression. Our findings indicate that 1,25D influences mineral deposition differentially according to osteoblast differentiation and perhaps also skeletal site, which may account for some of the controversy surrounding this issue. Our results suggest that the effect of 1,25D on early stage, calvaria-derived osteoblast-like cells is to inhibit mineral deposition, whereas the effect on mature, cortical bone-derived cells is to enhance mineral deposition, in particular in response to increased extracellular calcium.

Substrate Recognition of Human Menaquinone-4 Biosynthetic Enzyme UBIAD1. Kimie Nakagawa^{*1}, Yuri Uchino², Yoshitomo Suhara³, Toshio Okano¹.
¹Kobe Pharmaceutical University, Japan, ²Kobe Pharmaceutical University, Japan, ³Shibaura Institute of Technology, Japan

Vitamin K serves as a cofactor for vitamin K-dependent carboxylase (gamma-glutamyl carboxylase : GGCX). GGCX converts glutamate residues into gamma-carboxyglutamate (Gla) residues in vitamin K-dependent proteins, such as blood coagulation factors and bone formation factors. There are two forms of naturally occurring vitamin K, phyloquinone (PK) and menaquinones (MK-n). Moreover, menadiol or vitamin K₃ (K₃) is a synthetic compound lacking a side chain. Clinically, MK-4 the most common form of vitamin K, has been shown to prevent bone fractures. This osteoprotective effect is more pronounced in MK-4 than in PK, and hence MK-4 has been used to treat osteoporotic patients in Japan. MK-4 has been shown to act as a ligand for the steroid and xenobiotic receptor (SXR) in human osteoblastic MG-63 cells. Menaquinone-4 (MK-4) is ubiquitously present in extrahepatic tissues, with particularly high concentrations in the brain, kidney and pancreas of humans and rats. It has consistently been shown that PK is endogenously converted to MK-4. This occurs either directly within certain tissues or by interconversion to K₃, followed by prenylation to MK-4. No previous study has sought to identify the human enzyme responsible for MK-4 biosynthesis. Recently, we identified that the MK-4 biosynthetic enzyme is UbiA prenyltransferase domain containing 1 (UBIAD1) [*Nature*, 2010;468:117]. Vitamin K derivatives were converted to MK-4 by UBIAD1. In this study, we analyzed the substrate recognition and specificity of UBIAD1. We evaluated the conversion of several derivatives with 1,4-naphthoquinone structure. MG-63 cells were treated with several derivatives with 1,4-naphthoquinone structure at the concentrations of 1-100 μ M in the medium for 24hrs. The concentration of MK-4 converted from derivatives was measured by LC-APCI-MS/MS. We further evaluated inhibitory activity of derivatives against conversion of K₃ to MK-4 using deuterium-labeled compounds. As a result, 1,4-naphthoquinone

(K₃ with demethylation of 2-methyl substitute) was not converted to MK-4 in MG-63 cells. Some compounds with modification of 3-substitute did not convert to MK-4, but inhibited the conversion of K₃ into MK-4. These results showed that 2-methyl substitute of substrate for UBIAD1 required for conversion reaction, and modification of 3-substitute affect the conversion reaction of UBIAD1. These data is beneficial for the development of the ligand which controls the MK-4 biosynthetic activity of UBIAD1 in bone.

Delayed Healing and Increased Callus Adiposity in a Murine Model of Type 2 Diabetes. Matthew Brown¹, Kiminori Yukata², Regis O'Keefe³, Robert Mooney¹, Michael Zuscik⁴. ¹University of Rochester Medical Center, USA, ²University of Tokushima Graduate School, Japan, ³University of Rochester, USA, ⁴University of Rochester School of Medicine & Dentistry, USA

Introduction: Impaired healing and non-union of skeletal fractures is a major public health problem, with morbidity exacerbated in patients suffering from diabetes mellitus (DM). DM is prevalent worldwide, affecting approximately 25.8 million US adults, with >90% having obesity-related DM type 2 (DM2). While fracture healing in DM type 1 (DM1) has been studied using animal models, an investigation into the tissue and molecular basis for delayed healing in an animal model of DM2 has not yet been performed.

Methods: Male C57BL/6J mice at 5 weeks of age were placed on either a control low-fat diet or a high-fat diet (HFD) for 12 weeks. A mid-diaphyseal open tibia fracture was induced at 17 weeks and fixated using an intra-medullary spinal needle. Mice were sacrificed at days 7, 10, 14, 21, 28, and 35 for various endpoints, including micro-computed tomography (microCT), histology, and biomechanical testing.

Results: Mice provided the HFD for 12 weeks displayed increased body weight and impaired glucose tolerance, both characteristic of DM2. Compared to control mice, HFD mice administered tibia fractures showed a trend towards decreased cartilage area at days 10, 14, and 21. Woven bone area was significantly ($p < 0.05$) reduced in HFD mice at days 21 and 28. MicroCT data also showed impaired bone formation in HFD mice. Adiposity in the external callus was increased in HFD mice at later time points, achieving significance ($p < 0.05$) at days 21 and 35. Finally, HFD mice had significantly ($p < 0.05$) weakened healed fractures compared to controls at day 35, with mean torque to failure of 25 vs. 35 N*mm.

Discussion: Fracture repair studies in animal models of DM1 have demonstrated impaired chondrogenitor proliferation, premature cartilage resorption, decreased callus bone content, and biomechanically inferior fracture repair. Data from our DM2 mouse model also show delayed healing, which was distinctly characterized by increased callus adiposity in HFD mice at the end of the woven bone formation stage and during callus remodeling. This suggests altered mesenchymal stem cell (MSC) fate determination, with a shift to the adipocyte lineage at the expense of the osteoblast lineage. We hypothesize that PPAR-gamma expression is upregulated in HFD mice, driving the proposed fate switching. We further speculate that the altered callus microenvironment in HFD mice contributes to inferior fracture healing, possibly by interfering with osteoblast-osteoclast coupling.

Effects of Resveratrol on Proliferation and Differentiation of Human Bone Marrow-derived Osteoblasts. Marie Orstrup^{*1}, Torben Harsløf², Søren Kildeberg Paulsen³, Steen Bønløkke Pedersen⁴, Bente Lomholt Langdahl¹.

¹Aarhus University Hospital/MEA, Entrance 3B/Tage-Hansens Gade 28000 Aarhus C, Denmark, ²Department of Internal Medicine M, Regional Hospital Randers, Denmark, ³Department of Medicine, Regional Hospital Silkeborg, Denmark, ⁴Department of Endocrinology & Internal Medicine MEA, Aarhus University Hospital, Denmark

Background and Purpose:

Resveratrol (RSV) is a dietary supplement with anti-inflammatory effects. It inhibits NFκB, and reduces OVX-induced bone loss, and immobilization-induced bone loss in rodents. Increased levels of IL6 (thus increased inflammation) will result in increased degradation of bone and thereby decreased bone mass. RSV may alter bone turnover by affecting osteoblast and osteoclast proliferation and differentiation. In studies of hMSC-TERT cells, ST2 cells from murine bone marrow and hBMSCs from one fetal bone marrow RSV stimulates osteoblastic proliferation and differentiation dose-dependently. The aim of this study is to investigate if RSV has effects on proliferation and differentiation of bone marrow-derived osteoblasts from healthy adult human donors.

Methods: Human mesenchymal stem cells were derived from the bone marrow of 13 healthy adult human donors. Cell cultures from each donor were stimulated with different doses of RSV (10^{-8} M – 10^{-3} M)+/- vitamin D and compared with serum free (SF) conditions. Proliferation was assessed by thymidine incorporation, cell count by methylenblue (MET) assay, and differentiation by alkaline phosphatase (ALP), procollagen type1 (PINP), and osteoprotegerin (OPG), all corrected for cell number.

Results: RSV impaired proliferation, assessed by thymidine incorporation, at higher doses (0.80 ± 0.07 at 10^{-6} M compared to SF, $p < 0.02$), but with no effect on cell number. Alkaline phosphatase was reduced by RSV at higher doses (0.80 ± 0.07 at 10^{-5} M and 0.82 ± 0.07 at 10^{-6} M compared to SF, $p < 0.02$ and $p < 0.05$, respectively). At higher doses of RSV there was an increase in PINP, but only borderline significant. All doses of RSV seemed to increase OPG, but not significantly. Co-stimulation with vitamin D altered the response with respect to ALP and OPG. The reduction of ALP by RSV was neutralized, and low doses of RSV in combination with vitamin D even tended to increase ALP. Furthermore, OPG was significantly decreased.

Conclusion: Earlier studies have shown dose-dependent stimulation of proliferation and differentiation of osteoblast-like cells, without co-stimulation with vitamin D. In this first study of hBMSCs from adults RSV, in high doses, inhibited proliferation, and the effects on differentiation were ambiguous since ALP was reduced, while PINP and OPG were increased. Significant interactions with vitamin D were seen.

Increase Rate of Osteogenic Differentiation in Human Mesenchymal Stem Cells by Low Intensity Ultrasound in Stimulated Microgravity. Sardar Uddin^{*1}, Yi-Xian Qin². ¹Stony Brook University, USA, ²State University of New York at Stony Brook, USA

Disuse osteopenia induced by microgravity (MG) during long duration space flight has been known to cause adverse effect on bone density and quality. The reduction in bone mass can be due to decreased osteoblast activity and/or decreased number of osteoblasts. Mesenchymal stem cells (MSC) are well known as progenitor cells to osteoblast, previous experiments have shown significant decrease in osteogenic differentiation of human MSCs in simulated MG [1]. Considering that the effects of MG are partially attributed to the lack of mechanical force on bone, which alters gene expression, as well as proliferation and differentiation [2], we reasoned that Low-intensity pulse ultrasound (LIPUS) provides the essential mechanical stimuli to increase the rate of differentiation of hMSC along the osteogenic lineage.

Human MSC was cultured in StemLife Media (LifeLine Cell Technology, MD) with initial seeding density of 250,000 cells per Opticell cartilage. The cells were allowed to grow to confluency and MG stimulations were started at day 7 post confluency (PC-Day 7). Cells were divided into five groups (n=4/group), MSC (Control), gravity (G), gravity + LIPUS (GU), microgravity (M) and microgravity + LIPUS (MU). Growth media changed to differentiation media (StemLife Media + 50 μg/ml ascorbic acid + 10 mM β-glycerolphosphate + 10nM dexamethasone) except for control group at PC-Day7.

Stimulated MG environment was created by putting Opticell into *in vitro* rotary system, with rotation set at 15 RPM. LIPUS groups were stimulated everyday with 30mW/cm² for 20 min. Cells were kept at 37C, in a 5% CO₂ environment during the

experiment and medium was changed every second day. Cells were analyzed for ALP activity after 7 days of stimulation and matrix mineralization (Alizarin red staining) was analyzed after 12 days of simulated MG exposure.

Alizarin red (AZ) analyses (Fig 1) shows significant increase in calcification in MU group (~50%) compare to M group. Significant decrease of calcification was also observed between G (~80%) and M group. Higher mineralization was observed in GU group (~87%) compare to G group. Furthermore, M cells show ~77% reductions in ALP activity then G cells, application of LIPUS increase ALP activity by ~32% in MU samples. GU samples also show significant increase in ALP activity by ~46% (Fig 2).

Collectively, these results strongly suggest that LIPUS increases the rate of osteogenic differentiation of hMSCs in an MG environment.

Regulation of BMP/Smad Signaling and Osteoblastic Cell Differentiation by Receptor Tyrosine Kinase Pathways in Mesenchymal Stem Cells. Emmanuel Biver¹, Cvrlil Thouverev², David Magne³, Joseph Caverzasio⁴. ¹University hospital of Lille, France, ²Division of Bone Diseases, Switzerland, ³University of Lyon, France, ⁴Division Bone Diseases, Switzerland

Bone morphogenetic proteins (BMPs) are important activators of mesenchymal stem cell (MSC) differentiation into osteoblasts and are often used to improve orthopedic treatments. Mitogenic growth factors such as platelet-derived growth factors (PDGF) and fibroblast growth factors (FGF) stimulate MSC proliferation through activation of tyrosine kinase receptors (RTK) and inhibit osteoblastic cell differentiation. In this study, we investigated the effects of PDGF or FGF receptor signaling on BMP2-induced osteogenic differentiation of human MSCs and C3H10T1/2 pluripotent mesenchymal cells. Inhibition of PDGF or/and FGF receptor activity enhanced BMP2-induced MSC and C3H10T1/2 osteoblastic differentiation as shown by increased alkaline phosphatase activity, osteoblast markers expression and matrix mineralization. This effect was associated with increased Smad phosphorylation and transcriptional activity, indicating that RTK signaling interferes with Smad signaling. Since mitogen-activated protein kinases (MAPKs) ERK and JNK negatively regulated Smad transcriptional activity induced by BMP2 in MSC. Associated with these effects, BMP2-induced MSC differentiation was enhanced by the JNK inhibitor. Also, the PI3K/AKT pathway was also found to positively regulate BMP2/Smad signal through inhibition of GSK3.

In conclusion, growth factor-induced RTK signaling pathways strongly modulate BMP2/Smad signal and related MSC osteogenic differentiation. Understanding the

molecular networks by which BMPs enhance the differentiation of mesenchymal cells may help to improve the use of these cells for orthopedic treatments.---

Stage-specific Embryonic Antigen-4 is a Marker of Human Deciduous Periodontal Ligament Stem Cells. Noriaki Kawanabe¹, Hiroaki Fukushima², Satoko Murata², Yoshihito Ishihara³, Takeshi Yanagita⁴, Tarek Balam², Takashi Yamashiro². ¹Okayama University Hospital, Japan, ²Okayama University, Japan, ³Okayama University, Department of Orthodontics, Japan, ⁴Okayama University Hospital, Japan

Although human deciduous teeth are an ideal source of adult stem cells, no method for identifying deciduous periodontal ligament (D-PDL) stem cells has been developed. In the present study, we investigated whether stage-specific embryonic antigen (SSEA)-4 is a marker that could be used to isolate D-PDL stem cells. Five deciduous teeth were collected from 5 healthy patients who were undergoing orthodontic treatment at Okayama University Hospital. SSEA-4 expression in D-PDL cells was detected by immunocytochemistry and flow cytometry. SSEA-4+ D-PDL clonal cells were isolated by flow cytometry. Adipogenic, osteogenic, chondrogenic, and neuronal differentiation *in vitro* was assessed to examine SSEA-4+ D-PDL cells' multipotentiality. D-PDL cells met the minimum criteria for mesenchymal stem cells (MSC): they showed plastic adherence, specific surface antigen expression, and multipotent differentiation potential. SSEA-4+ D-PDL cells were detected *in vitro* and *in vivo*. Flow cytometric analysis demonstrated that 22.7% of the D-PDL cells were positive for SSEA-4. SSEA-4+ clonal D-PDL cells displayed multilineage differentiation potential; i.e., they were able to differentiate into adipocytes, osteoblasts, chondrocytes, and neurons, *in vitro*. A clonal assay demonstrated that 61.5% of the SSEA-4+ D-PDL cells had adipogenic, osteogenic, and chondrogenic potential. Our present study demonstrated that SSEA-4+ D-PDL cells are a subset of multipotent stem cells. Hence, SSEA-4 is a specific marker that could be used to identify D-PDL stem cells.

The Notch Target Gene, Sox2, May Mediate Notch-induced Maintenance of Bone Marrow Derived Mesenchymal Stem/progenitor Cells. Teng Long¹, Cuicui Wang², Regis O'Keefe², Matthew Hilton³, Yufeng Dong². ¹University of Rochester, USA, ²University of Rochester, USA, ³University of Rochester Medical Center, USA

We previously identified the RBPjk-dependent Notch signaling pathway as an inducer of mesenchymal stem/progenitor cell (MSC) proliferation and an inhibitor of MSC differentiation during mouse bone development, although the mechanism underlying this regulation remains unknown. Since SOX2 has been identified as an important regulator of stem/progenitor cell maintenance including MSCs, we set out to demonstrate that SOX2 is important for mediating the Notch-induced maintenance of bone marrow derived MSCs *ex vivo*. We first cultured the MSCs on plates coated with recombinant protein for the extracellular domain of the Notch ligand, JAGGED1, or control protein-IgG. Gene expression analyses indicated that JAGGED1 induced Notch signaling enhanced expression of the stem cell transcriptional regulators, SOX2, OCT4 and NANOG, as well as, the Notch target gene, HES1. Cell proliferation assays using BrdU labeling also demonstrated that JAGGED1 mediated Notch signaling increased MSC proliferation by more than 20%. These data indicated that Notch activation could both enhance MSC proliferation and maintain multipotency *ex vivo*. To further identify the direct target gene(s) that contribute to the Notch-mediated maintenance of MSCs, the SOX2, OCT4 and NANOG promoters were analyzed using TESS software. Interestingly, 2 putative RBPjk binding sites were identified at -1326 to 1331 and -1233 to -1238 in the SOX2 promoter. To investigate whether SOX2 is regulated at a transcription level by Notch signaling, we cloned 2 deletion fragments of the SOX2 promoter into a luciferase vector, including a 1.8kb fragment containing both putative RBPjk binding sites and a 0.6kb fragment that lacks RBPjk binding sites. Co-transfection experiments showed that the 1.8kb promoter fragment activity was significantly induced by Notch signaling using a NICD expression plasmid, whereas the 0.6kb fragment showed no difference between control and NICD. In addition, mutation of RBPjk binding sites in the 1.8kb fragment led to a significant reduction of SOX2 promoter activity indicated that RBPjk is also involved in SOX2 transcription. Finally, ChIP assays determined that endogenous RBPjk binds to DNA fragments containing both RBPjk binding sites of the SOX2 promoter within human MSCs. Collectively, these data indicate that SOX2 is a target of RBPjk-dependent Notch signaling and may play a functional role in the Notch-mediated maintenance of MSCs.

Wnt-dependent Osteogenic Commitment of Mesenchymal Stem Cells Using a Novel GSK3 β Inhibitor. David Cook*¹, Simon Felgett², Mary Elizabeth Pownall², Patrick O'Shea³, Paul Genever¹. ¹University of York, United Kingdom, ²University of York, United Kingdom, ³AstraZeneca, United Kingdom

Mesenchymal stem cells (MSCs) can differentiate into multiple lineages including osteogenic, adipogenic and chondrogenic cells. Wnt signalling has been implicated in controlling MSC fate. Here we show that a novel glycogen synthase kinase 3 β inhibitor, AR28, is a potent activator of canonical Wnt signalling in vitro and in vivo. AR28 induced nuclear translocation of β -catenin in the mouse mesenchymal cell line, C3H10T1/2, and human MSCs. Western blot analyses showed that levels of active β -catenin increased up to 6-fold with AR28 administration compared to vehicle controls. Using a TCF-luciferase reporter we demonstrated that AR28 activated canonical Wnt signalling in a time- and dose-dependent manner in C3H10T1/2 cells. AR28 at 2.5 μ M increased reporter expression ~100-fold greater than 20mM LiCl and was comparable to 100ng/ml Wnt3a. AR28 induced 58% embryonal axis duplication in *Xenopus laevis* embryos, when injected into the ventral marginal zone. In-situ hybridisation confirmed secondary regions of chordin expression in 98% of AR28 injected samples, marking a second Spemann organiser region, typical of pronounced Wnt signalling.

To determine the effects of AR28 on MSC osteogenesis we used standard differentiation inducers; β -glycerophosphate, L-ascorbic acid and dexamethasone. In these conditions, AR28 caused a significant ($p < 0.05$) decrease in alkaline phosphatase activity compared to vehicle controls. However, Alizarin Red staining identified small increases in mineralisation with AR28 during early differentiation. AR28 increased mineralisation in basal conditions, which was enhanced by the addition of β -glycerophosphate and L-ascorbic acid. Increases in ALP staining could also be identified in these conditions with AR28 addition. Exposure of MSCs to AR28 for 7 days before osteogenic induction also increased mineralisation. Under adipogenic conditions, AR28 treatments at 0.05 μ M generated significant ($p < 0.05$) reductions in adipogenesis, measured by Oil Red O staining. A 10% reduction in FABP5/BODIPY positive cells was detected with as little as 63.2nM AR28 with a corresponding rescue of proliferation.

Therefore AR28 is a potent activator of canonical Wnt signalling capable of inducing time- and dose-dependent responses. Our findings indicate that potent osteo-inducers like dexamethasone can mask Wnt-dependent responses in vitro, allowing new strategies to dissect the mechanisms controlling Wnt-induced bone formation.

Vitamin D Metabolism and Action in Human Marrow Stromal Cells: Effects of Chronic Kidney Disease. Shuanhu Zhou*¹, Meryl Leboff¹, Sushrut Waikar², Julie Glowacki¹. ¹Brigham & Women's Hospital, USA, ²Brigham & Women's Hospital, USA

Human marrow stromal cells (hMSCs) are a target of 1,25-dihydroxyvitamin D [1,25(OH)₂D₃] action to promote their differentiation to osteoblasts, but they also participate in vitamin D metabolism by converting 25OHD₃ to 1,25(OH)₂D₃ by the 1 α -hydroxylase (CYP27B1), which we showed to be upregulated by 25OHD₃, IGF-1, and PTH, and downregulated by 1,25(OH)₂D₃ and age (Endocrinol. 151:14, 2010; J Bone Mineral Res 26:1145,2011; Aging Cell 10:962,2011). This supports an autocrine/paracrine role of vitamin D metabolism in osteoblastogenesis of hMSCs, but its clinical significance is unknown. Chronic kidney disease (CKD) is associated with impaired renal biosynthesis of 1,25(OH)₂D, low bone mass, and increased fracture risk. We tested the hypothesis that CKD influences hMSCs' production and responses to 1,25(OH)₂D. Subjects were recruited/enrolled from patients scheduled for arthroplasty for non-inflammatory osteoarthritis. The hMSCs were obtained from tissues discarded during surgery. First, there was a range of estimated glomerular filtration rates (eGFR, 30 to 145 mL/min/1.73 m²), with a significant inverse correlation with age ($r = -0.255$, $p = 0.0033$, $n = 92$). Second, there was a significant positive correlation between *in vitro* osteoblastogenic stimulation (alkaline phosphatase activity) by 1,25(OH)₂D₃ and eGFR ($r = 0.37$, $p = 0.039$, $n = 31$). In addition, we obtained hMSCs from one orthopedic patient who had been undergoing hemodialysis for 2+ years. There was decreased constitutive expression of CYP27B1 and increased CYP24A1 in hMSCs from the dialysis subject, compared with an age/gender-matched control. Nevertheless, osteoblastogenesis was stimulated in hMSCs from both the dialysis and control subjects by 1,25(OH)₂D₃ (10 mM), 25OHD₃ (100 mM), or D₃ (1000 mM); this suggests that 25OHD₃-sufficiency may play an important role in skeletal health in elders and in those with CKD. In summary, hMSCs from subjects with low eGFR and even one receiving hemodialysis synthesize 1,25(OH)₂D. Osteoblastic bone formation in CKD patients may not be optimal unless there is sufficient serum 25OHD substrate for the MSCs to synthesize and respond to local 1,25(OH)₂D.

Localized Elevation of Cytosolic Free Calcium is Required for Uropod Retraction and Osteoclast Migration. Benjamin Wheal*¹, Natsuko Tanabe², S. Jeffrey Dixon¹, Stephen Sims³. ¹The University of Western Ontario, Canada, ²Nihon University School of Dentistry, Japan, ³The University of Western Ontario, Canada

Osteoclasts are large multinucleated cells responsible for the resorption of bone and other mineralized tissues during physiological remodeling and pathological bone loss. Active osteoclasts are highly motile and alternate between cycles of bone resorption and migration. However, little is known regarding the subcellular mechanisms that regulate osteoclast motility. We hypothesized that changes in the concentration of cytosolic free calcium contribute to the regulation of osteoclast migration. Our purpose was to characterize subcellular changes in cytosolic calcium of osteoclasts and the possible role of calcium in regulating osteoclast motility. Cytosolic calcium was monitored by digital fluorescence imaging of fura-2-loaded osteoclasts using alternating excitation wavelengths of 345 and 380 nm with emission at 510 nm. The pixel-by-pixel ratio of fluorescence intensity at 345/380 nm provided a spatial map of calcium concentration within the cell. Changes in osteoclast morphology were captured by time-lapse microscopy on an inverted phase-contrast microscope coupled to a CCD camera. Migrating osteoclasts exhibited a polarized morphology with lamellipodia extending forward at the leading edge of the cell and the uropod undergoing retraction at the rear, generating net forward movement. Migrating osteoclasts displayed a distinct spatiotemporal pattern of cytosolic calcium that consisted of a localized elevation of calcium in the uropod that lasted for up to 20 minutes and coincided with retraction of the trailing edge. A calcium gradient was observed, increasing from the cell body to the trailing edge with a significant elevation in fluorescence ratio from 0.82 ± 0.03 at the front to 1.26 ± 0.15 at the rear ($n = 6$ osteoclasts). Calcium elevation in the uropod was blocked in osteoclasts loaded with the cytosolic calcium chelator BAPTA. BAPTA-loaded osteoclasts continued to extend lamellipodia but failed to detach from the substrate, giving rise to dramatically elongated, highly branched morphologies. This highly branched morphology was unique to BAPTA-loaded osteoclasts, and the density of branching increased markedly over time. These findings reveal a novel spatiotemporal pattern of cytosolic calcium in osteoclasts, with a localized transitory elevation being required for uropod retraction – a heretofore unrecognized role for subcellular calcium signaling in the regulation of osteoclast migration.

In vitro Generation of Osteoclasts from Interleukin (IL)-3-dependent Mouse Bone Marrow Cells. HUIXIAN HONG*¹, Zhenqi Shi¹, Shunqing Wang², Xu Feng³. ¹UAB, USA, ²Department of Hematology2, First Municipal People's Hospital, Guangzhou Medical College, Guangdong, China, ³University of Alabama at Birmingham, USA

Standard methods for *in vitro* generation of osteoclasts from primary murine bone marrow cells mainly involve the use of either mononuclear cells purified by Ficoll-Hypaque density gradient centrifugations or M-CSF-dependent bone marrow cells prepared by 2- to 3-day M-CSF treatment of whole bone marrow cells. These conventional protocols are sufficient to prepare osteoclasts *in vitro* to investigate the molecular mechanism of osteoclast formation, function and survival, but they are inadequate for studies aimed at elucidating the molecular mechanism controlling differentiation and proliferation of osteoclast precursors or delineating molecular events in early osteoclastogenesis. Here, we describe an alternative method for *in vitro* generation of osteoclasts, which involves the use of interleukin (IL)-3-dependent murine bone marrow cells. Bone marrow cells, isolated from 6- to 8-week old C57BL/6 were cultured in α -MEM containing 10% FBS in tissue culture dishes overnight to remove stromal cells. Then, non-adherent bone marrow cells were harvested and continued in α -MEM containing 10% FBS without (control) or with IL-3 (1 ng/ml) for 6 days. While no cells survived in the control culture after the 6-day culturing, the IL-3-treated culture gave rise to a significant number of surviving cells. These IL-3-dependent cells were capable of differentiating into osteoclasts in response to M-CSF and RANKL stimulation. Moreover, these IL-3-dependent cells can be further expanded by plating them in non-treated plastic dishes followed with M-CSF treatment; they continued to survive and proliferate in non-treated plastic dishes in the presence of M-CSF for up to 4 days. After 4-day M-CSF treatment, these cells can be lifted by EDTA, and were still able to differentiate into osteoclasts upon subsequent stimulation of M-CSF and RANKL. Importantly, we found that IL-3 dependent bone marrow cells can be infected by retrovirus encoding GFP. In conclusion, we have developed a new strategy to generate murine osteoclasts *in vitro* using IL-3-dependent cells prepared by 6-day IL-3 treatment of murine bone marrow cells. A key advantage of this new method is the IL-3-dependent cells can be infected by retrovirus, permitting further experimental manipulations to express or knock down genes in IL-3-dependent cells for studying the molecular mechanism controlling differentiation and proliferation of osteoclast precursors or delineating molecular events in early osteoclastogenesis.

A Network of Collagen Fibers Supporting Pre-osteoclast Trafficking from the Bone Marrow to the Bone Surface? Thomas Andersen*¹, Helene Kristensen², Jean-Marie Delaisse³. ¹Vejle Hospital, CSFU-IRS, University of Southern Denmark, Denmark, ²Vejle Hospital, Denmark, ³Vejle Hospital, IRS, University of Southern Denmark, Denmark

Differentiation of osteoclast progenitor cells into mononucleated TRAcP+ pre-osteoclasts occurs in the bone marrow. But how are these cells dispatched to the future bone resorption sites? We hypothesized that the collagen type III/I-rich reticulin network of the bone marrow might provide a structural framework for localization and migration of differentiating pre-osteoclasts towards the bone surface.

Therefore, adjacent sections from decalcified paraffin-embedded iliac crest biopsies from 11 human controls were either stained for reticular fibers, or double-immunostained for different combinations of proteins, including collagen type I and III, an endothelial cell marker (CD34), and osteoclast markers (TRAcP, cathepsin K, and OSCAR, a collagen receptor involved in osteoclast differentiation). The association between mononuclear cells positive for osteoclast markers and capillaries or collagen fibers was quantified through histomorphometry, and further analyzed by 3D-reconstructions.

Numerous mononuclear TRAcP+ cells were identified within the bone marrow. These cells showed on average 80% overlap with other osteoclast markers such as cathepsin K and OSCAR, demonstrating that they are pre-osteoclasts. Staining for reticulin, collagen type I, III, and CD34, combined with 3D-reconstructions, revealed collagen III/I-rich reticulin fibers forming a network throughout the bone marrow. These fibers were connected to the capillary network and to bone remodeling compartment canopies, forming a continuum with the collagen present in these structures. Interestingly, combining the latter stainings with staining for TRAcP or OSCAR highlighted the tight association of pre-osteoclasts with these collagen-rich structures. More precisely, double-immunostainings revealed that 93% of the TRAcP+ or OSCAR+ pre-osteoclasts were associated with collagen fibers within the bone marrow. At least 7% of the TRAcP+ or OSCAR+ pre-osteoclasts were associated with the collagen present along larger CD34+ vessels within the bone marrow.

In conclusion, the close association of pre-osteoclasts with the collagen III/I-rich reticulin and capillary networks supports the hypothesis that these linear structures provide a physical support for trafficking of differentiating pre-osteoclast towards the bone remodeling compartment canopies covering bone surfaces undergoing bone remodeling.

c-Fos Plays an Essential Role in Up-regulation of RANK Expression in Osteoclast Precursors. Atsushi Arai*¹, Toshihide Mizoguchi², Suguru Harada³, Yasuhiro Kobayashi², Yuko Nakamichi⁴, Hisataka Yasuda⁵, Josef M. Penninger⁶, Kazuhiro Yamada², Nobuyuki Udagawa⁴, Naoyuki Takahashi⁷. ¹Matsumoto Dental University, Japan, ²Matsumoto Dental University, Japan, ³Chugai Pharmaceutical Co., Ltd., Japan, ⁴Matsumoto Dental University, Japan, ⁵Oriental Yeast Company, Limited, Japan, ⁶Institute of Molecular Biotechnology of the Austrian Academy of Sciences, Austria, ⁷Matsumoto Dental University, Japan

Purpose: We previously reported that RANK-positive cells were detected as osteoclast precursors in bone tissues in RANKL^{-/-} mice but not in c-Fos^{-/-} mice (J Cell Biol 184:541, 2009). It has been also shown that medullary thymic epithelial cells and intestinal antigen-sampling microfold cells are detected as RANK-positive cells. Then, we examined the role of c-Fos in the up-regulation of RANK expression in osteoclast precursors as well as medullary thymic epithelial cells and intestinal antigen-sampling microfold cells. Methods: Frozen sections of the tibia, spleen, thymus and small intestine were prepared from wild-type (WT) mice, RANKL^{-/-} mice, and c-Fos^{-/-} mice and subjected to immunohistochemistry. Splenic macrophages were prepared from WT and c-Fos^{-/-} mice, and they were cocultured with calvarial osteoblasts. Splenic macrophages were also treated with or without CSF-1. Expression of RANK was examined in those macrophages. Over-expression of c-Fos and that of RANK in c-Fos^{-/-} macrophages were examined for RANK expression and osteoclastic differentiation, respectively. Results and Discussion: (1) RANK-positive cells were similarly distributed in the thymus and intestine in WT, RANKL^{-/-} and c-Fos^{-/-} mice. In contrast, RANK-positive cells were detected in tibiae in WT and RANKL^{-/-} mice but not in c-Fos^{-/-} mice. These results suggest that c-Fos is involved in RANK expression in a cell type-specific manner. (2) CSF-1 receptor (c-Fms)-positive cells were similarly detected in tibiae of WT, RANKL^{-/-}, and c-Fos^{-/-} mice. RANK expression in WT macrophages was up-regulated by coculturing with RANKL^{-/-} osteoblasts as well as WT osteoblasts. The expression of RANK in WT macrophages was increased by the treatment with CSF-1, but not in c-Fos^{-/-} macrophages. These results suggest that CSF-1 but not RANKL expressed by osteoblasts was involved in the up-regulation of RANK expression in osteoclast precursors. (3) The over expression of c-Fos in c-Fos^{-/-} macrophages up-regulated RANK expression. However, the over-expression of RANK in c-Fos^{-/-} macrophages failed to rescue their osteoclastic differentiation potential. Conclusions: c-Fos is a transcription factor essential for osteoclasts differentiation. Our results also suggest that the up-regulation of RANK expression in osteoclast precursors which occurs in bone microenvironment is also tightly regulated by c-Fos-mediated signaling.

Effect of Dietary Aromatic Amino Acids on Osteoclastic Differentiation. Mona El Refaey*¹, Kehong Ding¹, Qing Zhong², Jianrui Xu¹, Mark Hamrick¹, William Hill³, Xing-Ming Shi¹, Norman Chutkan¹, Monte Hunter¹, Wendy Bollag¹, Karl Insogna⁴, Carlos Isles². ¹Georgia Health Sciences University, USA, ²Medical College of Georgia, USA, ³Georgia Health Sciences University & Charlie Norwood VAMC, USA, ⁴Yale University School of Medicine, USA

Epidemiologic data shows a strong association between low protein intake and fractures in the elderly population. We have previously shown that aromatic amino acid (Phenylalanine, Tyrosine and Tryptophan) supplementation prevented bone loss in aging C57Bl6 mice placed on a low protein diet. Bone histomorphometry and markers of bone turnover demonstrated that a low protein diet suppressed bone formation and increased bone breakdown. In vitro studies with aromatic amino acids showed them to be the most potent in stimulating elevations of intracellular calcium and increases in phospho c-Raf in Bone Marrow Stromal cells (BMSCs). However, we had not previously examined the effect of aromatic amino acids on osteoclastic activity. To assess osteoclastic differentiation we examined the effects of aromatic amino acids on vitronectin, matrix metalloproteinase 9 and calcitonin receptor gene expression. We found that all aromatic amino acids downregulated vitronectin, calcitonin receptor and matrix metalloproteinase gene expression as measured by real time PCR. Taken together our data are consistent with aromatic amino acids stimulating BMSC differentiation down the osteoblastic pathway and at the same time downregulating osteoclastic differentiation by suppressing remodeling gene expression resulting in a net increase in bone mass.

Hsp90 Inhibitors Enhance Osteoclast Formation *in vitro* in a MITF-dependent Manner through the Induction of Stress Responses. Julian Quinn^{*1}, Ryan Chai², A. Gabrielle J. Van Der Kraan³, Matthew Gillespie¹, John Price². ¹Prince Henry's Institute of Medical Research, Australia, ²Dept of Biochemistry, Monash University, Australia, ³Prince Henry's Institute, Australia

We previously found 17-allylamino-demethoxygeldanamycin (17-AAG; an Hsp90 inhibitor and anti-cancer therapeutic) increased MDA-MB-231 breast cancer invasion of bone in nude mice, and reduced trabecular bone mass in C57black/6 mice. 17-AAG also enhanced osteoclast formation *in vitro* despite the importance of Hsp90 client proteins in osteoclast differentiation. As 17-AAG also induces stress responses via heat shock factor-1 (HSF1), we investigated whether this may underlie osteolytic actions of 17-AAG.

17-AAG and structurally unrelated Hsp90 blockers CCT018159 and NVP-AUY922 dose-dependently enhanced osteoclast formation from bone marrow and RAW264.7 cells and increased Hsp70 protein levels, indicating stress responses. C-terminal Hsp90 blockers novobiocin and coumestrolin caused neither osteoclast enhancement nor Hsp70 induction. We then employed HSF1 ablation to study 17-AAG actions. HSF1 inhibitor KNK437 did not affect RANKL-elicited osteoclast formation but blocked its enhancement by 17-AAG. pGIPZ-lentiviral shRNA knockdown of HSF1 in RAW264.7 cells reduced 17-AAG-enhanced osteoclast formation and Hsp70 levels. 17-AAG also failed to enhance osteoclast formation in RANKL-stimulated bone marrow cells from HSF1^{-/-} (but not littermate HSF1^{+/+}) mice. Overexpression of HSF1 isoforms in RAW264.7 cells by retrovirus did not enhance osteoclast formation, but made cells responsive to lower levels of 17-AAG, suggesting HSF1 is necessary but not sufficient for 17-AAG actions. Stress inducing chemotherapeutic compounds also enhanced osteoclast formation.

To investigate cellular actions of 17-AAG and HSF1 we studied RANKL-elicited intracellular factors. NFκB, p38, c-fos and NFATc1 levels were not enhanced by 17-AAG treatment, and NFκB- and NFAT-responsive luciferase assays showed no enhanced signals with 17-AAG. However, MITF protein levels were greatly enhanced by 17-AAG in RAW264.7 cells; this enhancement was blocked by KNK437. Consistent with this, 17-AAG action on osteoclast formation in RANKL-stimulated bone marrow progenitors was maximal after 3 days of culture, while TGFβ (which enhanced NFATc1 levels and was unaffected by KNK437) enhanced osteoclast formation only when present prior to day 3.

These results indicate Hsp90 blockade that induces an HSF1-dependent stress response enhances osteoclast formation in an NFATc1-independent but MITF-dependent manner. This suggests cell stress itself may enhance osteolysis by increasing progenitor responses to RANKL.

Rolofylline, an Adenosine A₁R Antagonist, Inhibits Osteoclast Differentiation as an Inverse Agonist. Wenjie He^{*1}, Tuere Wilder², Bruce Cronstein³. ¹New York University Medical Center, USA, ²NYU Medical Center, USA, ³NYU Medical School, USA

Background: Previous work from our laboratory has uncovered a critical role of adenosine A₁ receptor (A₁R) in osteoclastogenesis both *in vivo* and *in vitro*. Adenosine may be generated by hydrolysis of extracellular adenosine nucleotides including CD39, ecto-5'-nucleotidase (CD73) and nucleotide pyrophosphatase phosphodiesterase 1 (NPP-1). Interestingly selective A₁R agonists neither affect basal osteoclast formation nor do they reverse A₁R-mediated inhibition of osteoclast formation. In this study, we determined whether ectonucleotidase-mediated adenosine production was required for osteoclast formation and, when we saw no effect, determined whether the A₁R was constitutively activated and the antagonist was acting as an inverse agonist to mediate its effects on osteoclast formation.

Methods: Osteoclasts were generated from bone marrow mononuclear cells (BMMs) extracted from wildtype, CD39KO, CD73KO and NPP-1KO mice using differentiation factors M-CSF and RANKL. The A₁R specific antagonist, rolofylline, was added to the culture media. TRAP+ staining was performed and Acp5 and Ctsk mRNA expression were examined to study osteoclastogenesis. Intracellular cAMP concentration was determined by ELISA.

Results: A₁R blockade inhibits osteoclast differentiation of BMMs derived from wildtype mice in a dose-dependent manner (IC₅₀=1μM p<0.05, n=3). A₁R blockade similarly inhibits osteoclast formation by BMMs from CD73KO, CD39KO and NPP-1KO mice in a dose-dependent manner (IC₅₀=1μM, 1μM, and 0.1μM, respectively, p<0.05 for all, n=3) for all three knockouts, although baseline osteoclast formation was significantly less (310 in CD73 KO vs 91 in wildtype, p<0.05, n=3) in BMMs from CD73KO mice. Moreover, in the absence of agonist rolofylline (1μM) caused an increase of cAMP content of BMMs by ~8.56 fold (p<0.05, n=3). Similarly, rolofylline (1μM) promotes increased cAMP production in normal human BMMs by ~22.3 fold, which is consistent with our findings that rolofylline inhibits human BMMs-derived osteoclast formation (p<0.001, n=3; IC₅₀=1nM).

Conclusions: Based on these findings we hypothesize that the A₁R is constitutively activated in osteoclast precursors, thereby diminishing basal adenylate cyclase activity, and that the A₁R antagonist acts as an inverse agonist to release the A₁R-mediated inhibition of basal adenylate cyclase activity. The constitutive activity of A₁R promotes osteoclast formation and downregulation of this activity blocks osteoclast formation.

TACE Activity Regulates Osteoclastogenesis and Physiological Bone Remodeling. Kyung-Hyun Park-Min^{*}, Lionel Ivashkiv. Hospital for Special Surgery, USA

Ecotodomain shedding has been shown to be critical for the function of various membrane proteins, including TNF, Notch, and epidermal growth factor receptor (EGFR). TNF-alpha converting enzyme (TACE, also called ADAM17) is the major sheddase of TNF and releases TNF from the cell surface upon various kinds of stimulation. In addition to TNF, TACE plays a role in the shedding of more than 70 different membrane-anchored molecules, some of which are implicated in osteoclastogenesis. Since several targets of TACE are implicated in various disease conditions including rheumatoid arthritis and cancer, TACE inhibitors have been developed for therapeutic uses. However, they have failed due to low efficacy or high side-effects, creating a demand to develop highly specific TACE inhibitors. Therefore, an understanding of disease-specific TACE action will offer a more specific targeting platform for blocking TACE activity. We hypothesize that TACE activity regulates osteoclastogenesis and inflammatory bone lysis. Interestingly, we observed that TACE expression is dynamically regulated in both normal- and disease-conditioned osteoclast precursor cells by RT-qPCR. To test the role of TACE during osteoclast differentiation, we generated mice in which TACE is conditionally deleted in myeloid precursors, including osteoclast precursor cells. *In vitro* osteoclastogenesis in TACE conditional deficient mice (TACE^{ΔM}) showed delayed kinetics compared to that of littermate control mice. However, this difference *in vitro* resulted in a significant *in vivo* change in bone phenotype in TACE^{ΔM} mice. Our data show that TACE activity is required for normal osteoclast differentiation and in maintaining bone homeostasis.

TNF and IL-1 Synergistically Promote Osteoclastogenesis in RANKL- and RANK IVVY Motif-dependent Manner. Joel Jules^{*1}, Zhenqi Shi², Monica Lewis³, Xu Feng⁴. ¹University of Miami Miller School of Medicine, USA, ²University of Alabama at Birmingham, USA, ³University of Alabama at Birmingham, USA, ⁴University of Alabama at Birmingham, USA

Tumor necrosis factor-α (TNF) and interleukin-1 (IL-1) are not only elevated in various bone diseases but are also involved in bone loss associated with these disorders. While TNF and IL-1 can enhance osteoclast survival and function, osteoclastogenesis induced by TNF or IL-1 requires the receptor activator of NF-κB (RANK) ligand (RANKL) which activates its receptor RANK. However, it is still unclear whether TNF and IL-1 together can promote osteoclastogenesis in the absence of RANKL. This study seeks to address the combined effect of TNF and IL-1 on osteoclastogenesis in relation to RANKL. We showed that TNF and IL-1 together cannot mediate osteoclastogenesis from bone marrow macrophages (BMMs) in the absence of RANKL. But, they can synergistically promote osteoclastogenesis in the presence of RANKL. Also, TNF and IL-1 can synergistically mediate osteoclastogenesis from BMMs pretreated with RANKL for as short as 18 hours. Moreover, TNF and IL-1 can still induce osteoclastogenesis synergistically 2 days after the 18-hour RANKL priming. RANK has a specific cytoplasmic motif (IVVY) which plays a critical role in osteoclastogenesis by committing BMMs to osteoclast lineage. To determine if the RANK IVVY is required for osteoclastogenesis synergistically induced by TNF and IL-1, we prepared BMMs expressing a chimeric receptor consisting of the external domain of human Fas linked to mouse RANK cytoplasmic domain (Ch1) or mouse RANK with mutated IVVY motif (Ch2). These chimeric receptors can be specifically activated by a human Fas activating antibody (hFas-AB). TNF and IL-1 can synergistically promote osteoclastogenesis from BMMs expressing Ch1 in the presence of hFas-AB, but their ability to induce osteoclastogenesis from Ch2-expressing BMMs in the presence of hFas-AB is dramatically impaired. Importantly, this finding was further recapitulated with BMMs from knockin mice bearing inactivating mutations in the IVVY motif and those from wild-type control mice. Taken together, our data indicate that TNF and IL-1 can synergistically mediate osteoclastogenesis in the presence of RANKL, and the IVVY motif is crucially required for osteoclastogenesis synergistically induced by TNF and IL-1. Significantly, these findings have revealed new insights into the regulatory mechanism of TNF and IL-1 in osteoclast biology and also support the notion that the IVVY motif has the potential to serve as a promising therapeutic target for bone loss in many bone disorders.

Tspan4 Co-localizes with $\beta 3$ Integrin and Is Required for Osteoclast Differentiation. Loise Salles*¹, Jonah Saltzman¹, Leslie Morse², Li Zhang¹, Prateek Jha¹, Ricardo Battaglini³. ¹The Forsyth institute, USA, ²Harvard Medical School, USA, ³The Forsyth Institute, USA

The fusion of mononuclear precursors to form multinucleated cells is an essential event for osteoclast differentiation and activation. However, the molecular mechanisms involved in this process are not completely understood. In order to better understand the molecular basis of osteoclast fusion we conducted a microarray screening aimed at identifying genes specifically upregulated during the late stages of RANKL-stimulated RAW 264.7 differentiation, a time when cells begin to fuse to one another to form multinucleated osteoclasts. We identified a Tetraspanin (Tspan) family member, Tspan 4, whose expression was upregulated during the later stages of RANKL-induced osteoclast differentiation. Tetraspanins are a family of transmembrane proteins that have been shown to mediate cell fusion. In addition, members of the Tspan family can associate with other tetraspanins, with integrins and with members of the immunoglobulin superfamily of cell adhesion molecules and signaling receptors to form tetraspanin microdomains (TEMs) on the cell surface. Finally, Tspan 4 has been shown to form complexes with both $\alpha 3 \beta 1$ and $\alpha 6 \beta 1$ integrin in several cell types, but the function of these complexes remains unknown. We performed confocal microscopy analysis of differentiated osteoclasts and observed Tspan 4 and $\beta 3$ integrin co-localization to the osteoclast plasma membrane. Addition of a neutralizing human specific anti-Tspan 4 antibody significantly inhibited RANKL-induced formation of TRAP+ osteoclasts. Tspan 4 mRNA silencing in RAW 264.7 mouse monocytes had the same inhibitory effect. Accordingly, qPCR analysis of mRNA from RANKL-stimulated Tspan 4-silenced cells showed a significant reduction in the expression of Tspan 4 as well as osteoclast markers TRAP, Cathepsin K, mmp-9 and src. Conversely, overexpression of Tspan 4 in RAW 264.7 cells enhanced RANKL induced osteoclast formation. In summary, we show that Tspan 4 is upregulated during RANKL induced osteoclast differentiation. Also, we show that Tspan 4 co-localizes with $\beta 3$ integrin on the osteoclast membrane. Functional studies show that Tspan 4 is required for normal osteoclastogenesis, potentially through its interaction with $\beta 3$ integrin. Our results also suggest that Tspan 4 may be a novel therapeutic target for osteoporosis and other osteolytic diseases

Anti-Resorptive Agent Modulates Mucosal Barrier Immunity of the Oral Cavity in Mouse ONJ Models. Sil Park*¹, Davood T. Quje², Ichiro Nishimura³. ¹UCLA, School of Dentistry, USA, ²UCLA, Weintraub Center, USA, ³University of California, Los Angeles, USA

Statement of problem: Anti-resorptive agents have predictably been used to treat multiple myeloma, bone metastatic cancer and osteoporosis. In spite of different pharmacological mechanisms, these drugs appear to induce abnormal responses in the oral environment and in some cases result in osteonecrosis of the jaw (ONJ). ONJ involves abnormalities of oral mucosa tissue, which is known to be one of the most efficient barrier tissues. We have hypothesized that ONJ occurs where the injury-induced mucosal barrier immunity is modulated by anti-resorptive agents.

Object: The objectives of this study were to test this hypothesis in mouse bisphosphonate-related ONJ model and to evaluate the involvement of gamma delta T cells in the pathogenesis of BRONJ using T cell receptor delta null (TCRD^{-/-}) mice.

Material and method: Female wild type and TCRD^{-/-} mice with the C57Bl6 background were treated by intravenous (retro-orbital) injection of zoledronic acid (ZOL: 540.5ug/kg; the metabolic scale equivalent dose of Reclast®) and extraction of maxillary left first molar. Control wild type mice were injected with vehicle solution and underwent the molar extraction. At 1 week and 4 weeks of tooth extraction, whole blood, maxilla, femurs, skin and intestine were harvested. The development of ONJ was determined by clinical and histological examination at week 4. Bone remodeling was characterized by serum chemistry and micro-CT analyses of maxilla and femur. Gamma delta T cells in the barrier tissues were evaluated by immunohistology.

Result: ZOL group showed the highest prevalence of BRONJ (83%) and the largest necrotic bone area, which were decreased in TCRD^{-/-} group (50%) and Control (12.3%). The anti-resorptive effect of ZOL in wild type and TCRD^{-/-} mice were equivalent at the tooth extraction site of maxilla and the distal trabecular bone of femurs. The infiltration or activation of gamma delta T cells in the barrier tissues appeared to increase by the ZOL treatment.

Conclusion: The BRONJ mouse model was established with single dose of bisphosphonate injection and dental extraction without any additional systemic alterations. The prevalence and the severity of BRONJ were decreased under the absence of gamma delta T cell. This study may suggest that stressed osteoclasts by anti-resorptive agent may abnormally modulate the oral mucosa barrier-derived cytotoxic immunity involving gamma delta T cells. Importance of Proteolytic Degradation of Osteoprotegerin by Lysine-specific Gingipain in Periodontal Osteoclastogenesis. Yoichi Miyamoto¹, Masamichi Takami¹, Kentaro Yoshimura¹, Kazuyoshi Baba², Atsushi Yamada³, Ryutaru Kamijo¹, Toshifumi Maruyama¹, Kenji Mishima², Marie Hoshino², Rika Yasuhara², Tomohito Akiyama*⁴. ¹Showa University School of Dentistry, Japan, ²showa univ., Japan, ³Showa University School of Dentistry, Japan, ⁴Showa University School of Dentistry, JAPAN, Japan

Periodontitis is a chronic inflammatory disease accompanied by alveolar bone resorption by osteoclasts. Among subgingival microflora, *Porphyromonas gingivalis* is regarded as a potent etiological agent for periodontitis. *P. gingivalis* secretes the cysteine proteases called gingipains, which are classified by their cleavage site specificities, i.e., arginine-specific gingipains (HRgpA and RgpB) and lysine-specific gingipain (Kgp). While it is well known that gingipains are involved in exacerbation of periodontitis, their role in osteolysis had not been fully elucidated. We found previously that Kgp degraded osteoprotegerin (OPG), an osteoclastogenesis-inhibitory factor secreted by osteoblasts, and suppressed osteoclast differentiation induced by active vitamin D and various Toll-like receptor (TLR) ligands *in vitro* (Biochem J 419:159-166, 2009). Osteoclast differentiation is induced not only by calcium-regulating hormones and TLR ligands but also by various cytokines such as TNF α , IL-1b, and IL-17A especially in inflammatory situations including periodontitis. In this study, we investigated the effects of Kgp on osteoclast differentiation induced by these proinflammatory cytokines *in vitro*. In the co-culture system of mouse calvarial osteoblasts and bone marrow cells, differentiation of osteoclasts was induced by TNF α , IL-1b, or IL-17A in the presence or absence of Kgp. Kgp augmented the osteoclast differentiation induced by TNF α and IL-1b. On the other hand, Kgp did not enhance the osteoclast differentiation induced by IL-17A. Proteolytic degradation of these cytokines by Kgp in a cell-free system was compared with that of OPG. TNF α and IL-1b were less susceptible, but IL-17A was more susceptible to the degradation by Kgp than OPG. These results indicate that the enhancing effect of Kgp on inflammatory cytokine-induced osteoclast differentiation is dependent on the difference in the degradation efficiencies of each cytokine and OPG. Then we investigated the cleavage sites in OPG after treatment with Kgp. N-Terminal amino acid sequences of OPG fragments revealed that Kgp primarily cleaved OPG in its death domain resemble region, which might prevent dimer formation of OPG required for inhibition of RANKL. Collectively, it is suggested that degradation of OPG by Kgp is a crucial event in the osteoclastogenesis and development of bone loss in periodontitis.

Prevention of Wear Particle-induced Osteolysis by a Novel V-ATPase Inhibitor Saliphenylhalamide (SaliPhe) through Inhibition of Osteoclast Maturation and Bone Resorption. An Qin*¹, Taksum Cheng², Zhen Lin³, Lei Cao⁴, Shek Chim⁵, Nathan Pavlos⁶, Jiaki Xu⁷, Kerong Dai⁴, Ming Hao Zheng⁶. ¹School of Surgery, The University of Western Australia, Australia, ²University of Western Australia, Australia, ³Centre for Orthopaedic Research, School of Surgery, The University of Western Australia, Western Australia, Australia, ⁴Department of Orthopaedics, Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, P.R. China, China, ⁵School of Pathology & Laboratory Medicine, The University of Western Australia, Western Australia, Australia, ⁶University of Western Australia, Australia, ⁷University of Western Australia, Australia

Wear particle-induced peri-implant loosening (aseptic prosthetic loosening) is one of the most common causes of total joint arthroplasty. It is well established that extensive bone destruction (osteolysis) by osteoclasts is responsible for wear particle-induced peri-implant loosening. Thus, inhibition of osteoclastic bone resorption should prevent wear particle induced osteolysis and may serve as a potential therapeutic avenue for prosthetic loosening. Here, we demonstrate for the first time that saliphenylhalamide, a new V-ATPase inhibitor attenuates wear particle-induced

osteolysis in a mouse calvarial model. In vitro biochemical and morphological assays revealed that the inhibition of osteolysis is partially attributed to a disruption in osteoclast acidification and polarization, both a prerequisite for osteoclast bone resorption. Interestingly, the V-ATPase inhibitor also impaired osteoclast differentiation via the inhibition of RANKL-induced NF- κ B and ERK signaling pathways. In conclusion, we showed that saliphenylhalamide affected multiple physiological processes including osteoclast differentiation, acidification and polarization, leading to inhibition of osteoclast bone resorption in vitro and wear particle-induced osteolysis in vivo. The results of the study provide proof that the new generation V-ATPase inhibitors, such as saliphenylhalamide, are potential anti-resorptive agents for treatment of peri-implant osteolysis.

Rosiglitazone Affects Osteoclast Activity in Type 2 Diabetes Mellitus. Shivani Agarwal^{*1}, Mishaela Rubin², Sanil Manavalan¹, Donald McMahon³, Antonio Nino⁴, Lorraine Fitzpatrick⁴, John Bilezikian³. ¹Columbia University, USA, ²Columbia University, USA, ³Columbia University College of Physicians & Surgeons, USA, ⁴GlaxoSmithKline Pharmaceuticals, USA

Rosiglitazone (RSG), a PPAR- activator, is associated with an increased risk of fractures in postmenopausal women with Type 2 Diabetes Mellitus (T2D), yet the mechanism for this is not well understood. Circulating osteogenic precursor (COP) cells, which contribute to bone formation, have been characterized in the peripheral circulation using flow cytometry and antibodies against osteocalcin (OCN) and early stem cell marker. Previously, we found that alterations in COP cells were present in patients treated with RSG as compared to metformin (MET), with an increase in the sub-populations of mature osteogenic cells. We hypothesized that circulating osteoclastic cells would also be affected by RSG as compared to MET.

73 subjects were randomized to RSG or MET for 52 weeks followed by an open-label period of 24 weeks of MET alone for all subjects. Osteoclast activity was measured in peripheral blood mononuclear cells by performing cell sorting for CD34+ cells, which give rise to hematopoietic stem cells and then assaying for TRAP-5b levels. We found that TRAP-5b levels in circulating sorted CD34+ cells increased between weeks 0 and 52 in both groups (RSG: 1.0 ± 3 to 10.8 ± 5 U/L; $p=0.035$; MET: 1.0 ± 3 to 13.4 ± 6 U/L, $p=0.007$). When all subjects were changed to MET, TRAP-5b levels increased further in the initial RSG group (to 23.6 ± 5 U/L, $p=0.05$ vs wk 52), but did not rise further in MET (9.7 ± 4 U/L, $p=NS$ vs wk 52) with continued MET. These data suggest that circulating osteoclast precursor cell activity increases with both RSG and MET. Contrary to our expectations, the increase was similar in both treatment groups. However, the additional increase in the RSG group after the first year, when changed to MET, suggests an initial MET-specific effect which may wane over time. It is therefore possible that RSG not only increases fracture risk by accelerating COP maturity, but by increasing osteoclast activity beyond the time of administration of the drug. Further studies of lineage allocation and bone remodeling will help to shed light on the negative impact of RSG on bone.

Overexpression of DRG2 Results in Increased Number and Activity of Osteoclast. Hye-Seon Choi^{*1}, Ke Ke², JW Park². ¹University of Ulsan, South Korea, ²University of Ulsan, South Korea

Small GTPases are key regulators of the actin cytoskeleton of osteoclast (OC), playing multiple roles in OC, although their functions have not been clearly defined. Developmentally regulated GTP-binding protein 2 (DRG2) is a new member of GTP-binding protein family, suggesting a possible role in OC. The role of DRG2 in bone remodeling has been examined using DRG2-transgenic (TG) mice. Overexpression of DRG2 increased OC caused increased fusion and survival of OC and elevated bone resorption on dentine slices in vitro. Mature OC from DRG2-TG mice increased large OC with actin ring by fortified M-CSF signaling via enhancing activation of ERK, Akt, c-Src, Rac1 and Rho, compared with that from wild type mice. DRG2 may form a network that generates the increased bone loss, especially associated with high level of M-CSF.

Plasma Membrane Ca²⁺-ATPase-mediated Calcium Efflux Controls Osteoclast Differentiation and Survival. Youngkyun Lee^{*1}, Hyung Joon Kim², Hong-Hee Kim². ¹Kyungpook National University School of Dentistry, South Korea, ²Seoul National University, South Korea

The precise regulation of Ca²⁺ dynamics is crucial for proper differentiation and function of osteoclasts. While Ca²⁺ oscillation induced by receptor activator of NF- κ B ligand in osteoclast precursors is indispensable for osteoclastogenesis, Ca²⁺ oscillation gradually disappears in mature osteoclasts. Whereas PLC γ and IP₃ receptor have been linked to the initiation of Ca²⁺ oscillation, molecules involved in the termination of Ca²⁺ oscillation remain unidentified. In the present report, we identified expression of plasma membrane Ca²⁺ ATPase (PMCA) to be greatly increased during osteoclastogenesis. We also show that PMCA is an intrinsic negative regulator of Ca²⁺ oscillation during osteoclast differentiation. RNA interference (RNAi) studies that transiently eliminate (or knockdown) PMCA expression, as well as inhibition of PMCA using antagonists reveal significant increases in Ca²⁺ oscillation during osteoclastogenesis, both in vitro and in vivo. Interestingly, overexpression of PMCA impaired Ca²⁺ oscillation and osteoclast differentiation. The increased expression of PMCA in mature osteoclasts played an additional role in preventing osteoclast apoptosis in the face of massive Ca²⁺ entry. Thus, our results propose an updated model of Ca²⁺ dynamics during osteoclast differentiation and maturation.

The Role of the Akt/GSK3beta/NFATc1 Axis during Osteoclastogenesis. Jang Bae Moon¹, Jung Ha Kim¹, Nacksung Kim^{*2}. ¹Chonnam National University Medical School, South Korea, ²Chonnam National University Medical School, South Korea

RANKL induces osteoclast differentiation through activation of various signaling pathways such as NF- κ B and Akt. Although the PI3K/Akt pathway has been shown to be important for osteoclastogenesis, however, the molecular events involved in osteoclast differentiation have not been revealed. Herein, we demonstrate that Akt induces osteoclast differentiation of through regulating the GSK3beta/NFATc1 signaling cascade. Inhibition of the PI3K by LY294002 reduces formation of osteoclasts and attenuates the expression of NFATc1, but not that of c-Fos. Conversely, overexpression of Akt in bone marrow-derived macrophages (BMMs) strongly induced NFATc1 expression without affecting c-Fos expression, suggesting that PI3K/Akt-mediated NFATc1 induction is independent of c-Fos during RANKL-induced osteoclastogenesis. In addition, we found that overexpression of Akt enhances formation of an inactive form of GSK3beta (phospho-GSK3beta) and nuclear localization of NFATc1, and that overexpression of a constitutively active form of GSK3beta attenuates osteoclast formation through down-regulation of NFATc1. Furthermore, BMMs from SHIP knockout mice show the increased expression levels of phospho-Akt and phospho-GSK3beta, as well as the enhanced osteoclastogenesis, compared to WT. However, overexpression of a constitutively active form of GSK3beta attenuates RANKL-induced osteoclast differentiation from SHIP-deficient BMMs. Taken together, our data suggest that the PI3K/Akt/GSK3beta/NFATc1 signaling axis plays an important role in RANKL-induced osteoclastogenesis.

Changes in Gene Expression and Transcription Factor Binding Patterns in Response to 1,25-Dihydroxyvitamin D₃ and PTH During IDG-SW3 Osteocyte Progression. Hillary St John^{*1}, Kathleen Bishop², Alex Carlson², Nancy Benkusky², Mark Meyer², Lynda Bonewald³, J. Pike². ¹UW Madison, USA, ²University of Wisconsin-Madison, USA, ³University of Missouri - Kansas City, USA

Osteocytes are derived from osteoblast precursors through a process that involves the progressive secretion and mineralization of osteoid and the formation of a lacunar space occupied by individual osteocytes. Entombed cells play complex roles in bone remodeling; in bone formation and resorption under a variety of dietary, mechanical and physiologic stimuli; and in mineral homeostasis through the secretion of hormones such as FGF23 that control phosphate metabolism. Both the differentiation and mature cell function of the osteocyte are regulated by a number of systemic hormones that include 1,25(OH)₂D₃ and PTH, as well as numerous growth factors and inflammatory cytokines; the target genes and the molecular mechanisms that underlie these processes are not well defined. In the current study, we employed the mouse osteocytic IDG-SW3 cell line to explore cellular responses to both

1,25(OH)₂D₃ and PTH during the 35 day (d) program of differentiation from the cell's origin as an osteoblast to its final state as a mineralized, osteoid-surrounded osteocyte. RNA from cells treated 24 hr earlier with either vehicle, 1,25(OH)₂D₃ or PTH was isolated on d3 (osteoblastic), d14 (early osteocyte) and d35 (late osteocyte) and then subjected to direct candidate-specific qRT-PCR analysis and/or to RNA-sequencing analysis. Genome-wide ChIP-seq analysis was also conducted at these time points to correlate transcription factor activity with genes regulated by these hormones. Many genes were modulated in response to 1,25(OH)₂D₃ and/or PTH at each stage of differentiation: d3 (e.g., VDR, PTHR1, MEIS2), d14 (e.g., RUNX1) and d35 (e.g., FGF23, SOST, RANKL). With regard to 1,25(OH)₂D₃, GO term analysis of global RNA-seq results indicate that these networks include those characterized by ossification, apoptosis, vasculature development, and immune response. ChIP-seq analysis of the VDR/RXR cistromes revealed extensive overlap, as expected, and confirmed the location of 1,25(OH)₂D₃-regulated enhancers at multiple genes previously identified, including those at the VDR, RANKL, and SPP1 genes and at many additional genes as well. Most of these sites to which the VDR bound colocalized with sites containing RUNX2, C/EBPβ and/or p300. Determination of the transcriptome for PTH response and the cistrome for its CREB DNA binding factor is ongoing. These studies provide new insight into the complex and diverse actions of both 1,25(OH)₂D₃ and PTH during osteocyte differentiation.

Sclerostin Stimulation of Osteocytic Osteolysis Involves Expression of Carbonic Anhydrase II. Masakazu Kogawa¹, Asiri Wijanavaka¹, Renee Ormsby¹, Lynda Bonewald², David Findlay³, Gerald Atkins³. ¹University of Adelaide, Australia, ²University of Missouri - Kansas City, USA, ³University of Adelaide, Australia

Sclerostin (SCL) is a product of mature osteocytes embedded in mineralised bone and is a negative regulator of bone mass and osteoblast differentiation. Pre-osteocytes and osteocytes have been identified as cellular targets for SCL, and SCL by targeting these cells is an anti-anabolic agent.⁽¹⁾ SCL may also have a catabolic action through promotion of osteoclast formation and activity by osteocytes, in a RANKL-dependent manner.⁽²⁾ While osteocytes have been reported to have resorptive activity during lactation,⁽³⁾ a role for SCL in osteocytic osteolysis has not been described. To test whether SCL has direct catabolic activity via the osteocyte itself, we examined the effect of recombinant human SCL (rhSCL) on bone resorptive marker gene expression in cultures of both human primary pre-osteocytes and the mouse osteocyte-like cell line, MLO-Y4. We found that rhSCL stimulated the mRNA expression of carbonic anhydrase II (CA2), an enzyme that generates protons. rhSCL also clearly increased CA2 protein expression analysed by western blotting and immunofluorescence. Consistent with this, treatment with rhSCL significantly lowered intracellular pH (pHi) in both cell types and a similar trend was observed for extracellular pH (pHo). To investigate whether SCL-induced acidification resulted in decalcification and degradation of bone, mineralised cultures of human osteocyte-like cells were treated with rhSCL. Media from cells treated with SCL had higher total calcium concentrations compared to untreated cells; this effect was reversed with the CA inhibitor, acetazolamide (AZ). To investigate the specific importance of CA2 for the effect of SCL on osteocytes, we knocked down CA2 expression in MLO-Y4 cells using siRNA. rhSCL reduced the pHo in scramble-siRNA transfected controls but had no effect on pHo in CA2 siRNA transfected cells. AZ also abolished this activity of rhSCL. Treatment with rhSCL also resulted in a significant increase in extracellular ionised calcium levels, an effect blocked using AZ in control cells but not in CA2 siRNA transfected cells. Taken together, these results show that SCL stimulates CA2 expression in osteocyte-like cells, resulting in acidification of extracellular media and calcium release from a bone-like matrix. We conclude that SCL may have a direct catabolic action via the induction of osteocytic osteolysis.

Live Imaging of Fluid Flow-induced Ca²⁺ Signaling of Osteoblasts and Osteocytes in Bone: Implications for Gap Junctional Intercellular Communication. Yoshihito Ishihara^{*1}, Yasuyo Sugawara², Hiroshi Kamioka³, Noriaki Kawanabe⁴, Keiji Naruse⁵, Takashi Yamashiro⁵. ¹Okayama University, Department of Orthodontics, Japan, ²Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Sc, Japan, ³Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Sc, Japan, ⁴Okayama University Hospital, Japan, ⁵Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Sciences, Japan

Bone cells respond to mechanical stimuli by producing a variety of biological signals, and one of the earliest events is intracellular calcium ([Ca²⁺]_i) mobilization. Our recently developed *ex vivo* live [Ca²⁺]_i imaging system revealed that bone cells in intact bone explants showed autonomous [Ca²⁺]_i oscillations, and osteocytes specifically modulated these oscillations through gap junctions. However, the behavior and connectivity of the [Ca²⁺]_i signaling networks in mechanotransduction have not been investigated in intact bone. We herein introduce a novel fluid-flow platform for probing cellular signaling networks in live intact bone, which allows the application of capillary-driven flow just on the bone explant surface while performing real-time fluorogenic monitoring of the [Ca²⁺]_i changes. In response to the flow, the percentage of responsive cells was increased in both osteoblasts and osteocytes, together with upregulation of *c-fos* expression in the explants. However, enhancement of the peak relative fluorescence intensity was not evident. Treatment with 18 α-GA, a reversible inhibitor of gap junctional intercellular communication, significantly blocked the [Ca²⁺]_i responsiveness in osteocytes without exerting any major effect in osteoblasts. On the contrary, such treatment significantly decreased the flow-activated oscillatory response frequency in both osteoblasts and osteocytes. These findings indicated that flow-induced mechanical stimuli accompanied the activation of the autonomous [Ca²⁺]_i oscillations in both osteoblasts and osteocytes via gap junction-mediated cell-cell communication. Although how the bone sense the mechanical stimuli *in vivo* still needs to be elucidated, the present study suggests that cell-cell signaling via augmented gap junction-mediated [Ca²⁺]_i mobilization could be involved as an early signaling event in mechanotransduction.

Genetic Variants in GPR177 and LRP5 may be Association with Risk of Lumbar Spine Fracture. Lee O'Brien^{*1}, Haojun Ouyang², John Krege³, Jared Kohler⁴. ¹Lilly, USA, ²Eli Lilly & Company, USA, ³Eli Lilly & Company, USA, ⁴Biostat Solutions, Inc, USA

A genetic biomarker that can predict osteoporotic fracture risk with a high sensitivity and specificity would be clinically valuable. The goal of this study was to associate genetic variants in genes from the Wnt and RANK pathways with vertebral fracture risk, using 1111 Caucasian subjects from a carefully phenotyped cohort. Postmenopausal women with osteoporosis from the MORE trial (NCT00670319) were radiographically assessed at baseline using a visual semiquantitative scale and the semiquantitative scores for T4 to L4 were summed to generate a spinal deformity index (SDI). The SDI at baseline was assessed as an ordinal categorical variable (binned scores were 0, 1-3, 4-6, >6) using ordinal logistic regression; the model included covariate adjustments for baseline bone mineral density (BMD), age and genotype as fixed effects. GPR177 is an evolutionarily conserved transmembrane protein necessary for Wnt protein secretion, and variants in this gene have previously been associated with BMD with genome-wide significance. 14/142 variants genotyped in GPR177 were associated with SDI score. The SDI odds ratio for having two copies of the rare allele (10.5% in the genetic cohort) for rs6671127 was 0.50-0.56 (CI's 0.33-0.86, unadjusted p = 0.0063), meaning two copies of the rare allele may be protective from vertebral fracture. 16/54 variants in LRP5 may also be associated with SDI scores. The SDI odds ratio for having two copies of the minor allele (11.1% in the genetic cohort) for rs671191 was 1.68-1.90 (CI's 1.15-2.76, unadjusted p = 0.0038), meaning two copies of the rare allele may be associated with risk of vertebral fracture. One of the LRP5 variants, rs638051, may be associated with lumbar spine and femoral neck BMD (unpublished results). These findings suggest there may be value in investigating the genetic determinants of fracture in carefully phenotyped clinical trial patients and that variants of genes in the Wnt and RANK pathways might be associated with risk of vertebral fractures. Additional research including replication of these findings is required.

SA0277**Skeletal Responsiveness to Cold Exposure: Implications for Age-Related Osteoporosis.** Casey Doucette*¹, Katherine Motyl¹, Clifford Rosen².¹Maine Medical Center Research Institute, USA, ²Maine Medical Center, USA

The sympathetic nervous system (SNS) regulates homeostatic systems including the skeleton such that activation can cause bone loss. Cold exposure is a potent stimulus for SNS activation and, in turn, an inducer of brown-like adipose tissue (BAT). In this study, we hypothesized that acute cold exposure stimulates inducible BAT in fat depots including the marrow but negatively impacts bone. To explore the role of cold exposure, we capitalized on skeletal differences between C3H/HeJ (C3H) and C57BL/6J (B6), as well as mice with a global knockout of the cold receptor (*Trpm8*^{-/-}). Male C3H mice have higher bone density and greater marrow adipose tissue (MAT) than B6. In addition, C3H mice have seasonal changes in MAT by MRI with a peak in the fall months. We studied whole bone gene expression in 6-month-old C3H and B6 male mice at 23°C and at 4°C for 6 hours. At 23°C, expression levels of *Runx2* were higher in C3H mice (1.6 fold, $p < 0.03$), consistent with earlier findings that C3H has higher bone formation. With acute cold challenge, expression of *Runx2* was decreased in C3H by 50% but was unchanged in B6. *Rankl* mRNA levels did not differ by genotype or cold exposure, but adiponectin mRNA was 2x greater in C3H at 23°C than B6. *Ucp1* transcripts were approximately 100x higher at 23°C ($p = 0.0003$) in C3H and rose further (250x, $p = 0.0007$) with cold exposure vs B6 which did not change at 4°C. *Pgc1 α* mRNA did not differ by strain at 23°C and did not increase in B6 but rose 8x in C3H at 4°C ($p = 0.0005$), suggesting that C3H marrow has thermogenic properties. *Pdk4* and *Fabp4* expression levels were also increased with cold exposure in both C3H and B6 ($p < 0.05$). Interestingly, *Adrb2* expression was higher in C3H vs B6 at 23°C, but at 4°C there was a significant increase only in B6 ($p < 0.05$). Next, we phenotyped *Trpm8*^{-/-} mice at 16 weeks. These mice lack the cold receptor globally, have reduced SNS tone, and are more susceptible to diet-induced obesity. We found slightly higher femoral areal BMD in *Trpm8*^{-/-} vs +/+ ($p < 0.08$) and significantly higher femoral %BV/TV in *Trpm8*^{-/-} (4.5%) vs +/+ (3.2%, $p = 0.04$) due to greater trabecular thickness ($p = 0.01$). Taken together, these results indicate that activation of sympathetically-mediated pathways of thermogenesis via the cold receptor affect bone mass in a strain-dependent manner. Changes in ambient temperature in the elderly may contribute to age-related bone loss. NIH AG040217, NIDDK092759

SA0279**Plasma Sphingosine 1-phosphate Levels and Risk of Vertebral Fracture in Postmenopausal Women.** Seung Hun Lee*¹, Beom-Jun Kim², Jung-Min Koh², Sun-Young Lee³, Young-Sun Lee⁴, Kyeong-Hye Lim⁵, Tae-Ho Kim⁶, Shin-Yoon Kim⁷, Ghi-Su Kim⁵.¹Asan Medical Center, University of Ulsan College of Medicine, South Korea, ²Asan Medical Center, South Korea, ³Asan Institute for Life Sciences, South Korea, ⁴Asan Institute for Life Sciences, South Korea, ⁵Division of Endocrinology & Metabolism, Asan Medical Center, University of Ulsan College of Medicine, South Korea, ⁶Kyungpook National University School of Medicine, South Korea, ⁷Kyungpook National University Hospital, South Korea

Background: Although sphingosine 1-phosphate (S1P) can play diverse roles in bone metabolism, the main effect seems to augment bone resorption. To investigate the possibility of S1P as a predictor for the risk of osteoporotic vertebral fractures (VFs), we performed a case-control study in postmenopausal Korean women.

Methods: Among 460 women not taking any drug and not having any disease that could affect bone metabolism, we could find 69 cases defined as subjects with radiological VFs. The controls were randomly selected from the remaining 391 subjects and matched 1:1 to cases on age and body mass index. Lateral thoracolumbar radiographs, bone mineral density (BMD), bone turnover markers, and plasma S1P levels were obtained from all subjects.

Results: S1P levels were markedly higher in subjects with VF ($7.49 \pm 3.44 \mu\text{mol/L}$) than those without VF ($5.58 \pm 2.01 \mu\text{mol/L}$; $P = 0.001$), and increased in a dose-response manner across increasing number of VF (P for trend < 0.001), even after adjustment for lumbar spine BMD as well as potential confounders. The odds ratios (ORs) for VF were marked higher in subjects in the highest S1P quartile category compared with those in the lowest S1P quartile category after adjustment for confounders (OR = 9.33, 95% CI = 2.68 – 32.49). S1P levels were inversely correlated with BMD at various sites ($P = 0.015$ to 0.044), whereas they had positive correlation with bone resorption markers ($P = 0.016$ to 0.098). **Conclusion:** These findings suggest that plasma S1P may be a potential biomarker for the risk of VFs, independent of BMD, in postmenopausal women.

SA0282**Bone Microstructure Analysis of Femoral Head in Osteoporosis: Ex vivo HR-pQCT Study.** Ko Chiba*¹, Andrew Burghardt², Makoto Osaki³, Sharmila Majumdar². ¹Nagasaki University Hospital, Japan, ²University of California, San Francisco, USA, ³Nagasaki University, Japan

Purpose: High Resolution peripheral Quantitative CT (HR-pQCT) is a clinical high-resolution CT for peripheral skeletal sites. It is also useful as an experimental CT which can image intact bone specimens with a high spatial resolution (41 μm), sufficient to analyze trabecular bone microstructure. We imaged the femoral heads extracted from osteoporosis (OP) patients using HR-pQCT, to investigate regional differences of bone microstructure and the correlation between the OP progression and bone microstructure.

Method: Femoral heads specimens extracted from 15 OP patients with femoral neck fracture (average 85, 67-94 y.o. all female) were scanned using HR-pQCT (XtremeCT, Scanco medical) with a 41 μm voxel size. The image orientation of all femoral heads was adjusted by anatomical landmarks. The femoral head was divided into 3 longitudinal regions (superior, center, and inferior), and then 5 axial subregions (center, medial, lateral, anterior, posterior) for a total of 15 regions. Fracture regions were excluded with a 2.5 mm margin from the fracture line. As a result, 5 regions were excluded from the analysis. Thus, in 10 regions (Sup-Cen, Sup-Med, Sup-Lat, Sup-Ant, Sup-Post, Cen-Cen, Cen-Med, Cen-Ant, Cen-Post, and Inf-Med) cancellous bone microstructure was measured (TRI/3D-BON, Ratoc System Engineering, Japan). Microstructural parameters were compared between regions, and correlations between bone volume fraction and microstructural parameters were analyzed.

Results: In Sup-Cen, Sup-Post, and Cen-Cen, bone volume fraction, trabecular thickness, and trabecular number were greater, with a plate-like structure, higher connectivity, and higher anisotropy. The plate-like bone was oriented supero-inferiorly and antero-posteriorly. As bone volume fraction decreased, trabecular thickness and number decreased, with more rod-like structure, less connectivity, and higher anisotropy.

Discussion: Inhomogeneous bone microstructure in the femoral head may be derived from the weight bearing pattern in the hip joint. At Cen-Ant and Cen-Post regions, where a fixation screw is sometimes inserted erroneously, bone volume fraction was almost half of Cen-Cen region. Supero-inferior plate-like structure at central regions might be due to vertical weight bearing. In addition, daily hip flex-extension movements might cause its antero-posterior structural alignment. With the increasing severity of OP, this plate-like structure changed to rod-like structure with a loss of connectivity. Loss of horizontal connectivity and the preservation of vertical trabeculae are likely reflected by the increase anisotropy.

SNPs in 3'UTR RANK Gene Determine Site-Specific Low Trauma Fractures Independently of Bone Mineral Density. Natalia Garcia-Giralto¹, Guy Yoskovitz¹, Daniel Prieto-alhambra², Maria Rodriguez-Sanz³, Roser Urreizti⁴, Daniel Grinberg⁵, Robert Güerri⁶, Leonardo Mellibovsky⁷, Xavier Nogues⁸, Susana Balcells⁹, Adolfo Diez-Perez¹⁰. ¹IMIM, Spain, ²Institut Municipal D'Investigació Mèdica, United Kingdom, ³IMIM-Parc de salut Mar, Spain, ⁴Departament de genètica, Universitat de Barcelona, Spain, ⁵The University of Barcelona, Spain, ⁶Hospital Universitario Del Mar.Institut Municipal D'Investigació Mèdica, Spain, ⁷Internal medicine, Parc de salut Mar, Spain, ⁸Institut Municipal D'Investigació Mèdica, Spain, ⁹University of Barcelona, Spain, ¹⁰Parc De Salut Mar, Spain

Introduction: Bone remodelling is regulated by the RANK/RANKL/OPG system. Hence, this system would be involved in the determination of bone mineral density (BMD) and/or bone microarchitecture. In the light of the raise of miRNAs as epigenetic regulatory elements, we studied SNPs in the *RANK* 3'UTR region, which may affect miRNAs binding; secondly, we tested for an interaction between these and a previously defined BMD-related RANKL SNP (rs9594738).

Methods: Seven genetic variants were genotyped in the BARCOS cohort, and multivariable regression models were fitted to assess the association between the genotyped SNPs and both BMD and fractures.

Results: None of genotyped SNPs were significantly associated with either femoral neck or lumbar spine BMD. Two SNPs were significantly associated with clinical fractures in our cohort but even stronger evidence for an association was found when these were related to either spine or wrist/forearm fractures separately: SNP1 appeared associated with wrist/forearm fractures (Log-additive OR 3.12, (95%CI 1.69-5.75); $p = 7.16 \times 10^{-4}$), while SNP2 was related to spine fractures (Recessive OR 4.05 (1.59-10.35); $p = 8.24 \times 10^{-3}$). These associations stood for Bonferroni correction, and remained significant after further adjustment for BMD. Finally, interaction analyses between RANKL SNP rs9594738 and SNP1 on fracture produced significant results ($p = 0.039$). Accordingly, an analysis of the effect of compound genotypes of rs9594738 and SNP1 was carried out, which pointed towards increasing fracture prevalence in subjects with a higher number of unfavourable alleles, with corresponding adjusted OR 2.76 (1.30-5.81; $p = 0.007$) and OR 5.14 (1.37-15.67; $p = 0.007$) for 2 and ≥ 3 unfavourable alleles respectively compared to none/1.

In conclusion, two genetic variants in 3'UTR of RANK gene predispose to low trauma fracture in a site-dependent manner. Although this fracture association was independent of BMD, an interaction with the BMD-associated RANKL SNP rs9594738 suggests an additive effect of BMD and bone strength.

Space Radiation-Induced Bone Loss - Radiation Quality Response In Mice. Laura Bowman¹, Eric W. Livingston², Gregory A. Nelson³, Ted Bateman⁴. ¹University of North Carolina at Chapel Hill, USA, ²University of North Carolina at Chapel Hill, USA, ³Loma Linda University, USA, ⁴University of North Carolina, USA

Astronauts on exploratory missions will be exposed to a mixture of radiation types from solar and cosmic sources. We have shown that spaceflight relevant doses and types of radiation may cause bone loss in excess to what is already lost due to microgravity. While protons account for the majority of space radiation fluence, particles with high linear energy transfer (LET, a measure of radiation quality) are predicted to have a greater relative biological effectiveness (RBE), causing more damage. We examined bone loss of modeled space radiation representing a range of LET (protons, oxygen, silicon and iron). **Methods:** Twenty-week-old, female BALBc mice were assigned to one of four ion types: 150 MeV/amu Protons (LET = 0.6 keV/μm), 600 MeV/amu ¹⁶O (LET = 15 keV/μm), 600 MeV/amu ²⁸Si (LET = 51 keV/μm), and 600 MeV/amu ⁵⁶Fe (LET = 181 keV/μm). They were then subdivided into either irradiated (IRR) or non-irradiated (NR) groups within each ion type (n=24/group, different NR group for each ion). Irradiated animals were exposed to 50 cGy of whole body irradiation of the appropriate ion type at the NASA Space Radiation Laboratory (NSRL) at Brookhaven National Laboratory. Animals were then shipped to the University of North Carolina where they were maintained until euthanasia 14 days after irradiation. Tibiae were harvested for analysis of trabecular microarchitecture using micro-computed tomography (μCT, SCANCO Medical μCT-80). **Results:** Significant changes ($p < 0.05$) in bone trabecular volume (BV/TV) and volumetric bone mineral density (vBMD) occurred in oxygen (BV/TV, -11.1%; vBMD, -9.6%), silicon (BV/TV, -21.8%; vBMD, -18.3%) and iron (BV/TV, -11.4%; vBMD, -10.1%) irradiated groups. Connectivity density (Conn.D) and trabecular number (Tb.N) were also significant for both silicon (Conn.D, -22.6%; Tb.N, -6.4%) and iron (Conn.D, -20.1%; Tb.N, -5.2%). Silicon was the only radiation type to cause a change in trabecular thickness (Tb.Th, -4.9%) and iron caused the only change in trabecular separation (Tb.Sp, +6.1%). Proton was the only radiation type for which no significant changes were observed. **Conclusions:** Skeletal effects were observed following exposure to all ion types except proton and the changes were greatest with silicon ions. It appears LET is important in predicting the deterioration of trabecular bone and further studies should be performed with radiation species with an LET between 50 and 180 keV/μm.

Higher Strontium Consumption is Anabolic in Goats. Zhiqiang Xu¹, Dahai Gu², Zhenhui Cao², Xiaobo Chen², Hua Rong³, Guozhou Liao⁴, Qichao Huang³, Xi Zhang⁵, Shizheng Gao⁶, Qiuye Lin³, Changrong Ge⁷, Junjing Jia⁸, Wei Yao⁸. ¹Yunnan Agricultural University, China, Peoples Republic of China, ²Yunnan Provincial Key Laboratory of Animal Nutrition & Feed, Yunnan Agricultural University, China, ³Yunnan Provincial Key Laboratory of Animal Nutrition & Feed, Yunnan Agricultural University, China, ⁴Yunnan Provincial Key Laboratory of Animal Nutrition & Feed, Yunnan Agricultural University, China, ⁵Yunnan Agricultural University, Peoples Republic of China, ⁶Yunnan Provincial Key Laboratory of Animal Nutrition & Feed, Yunnan Agricultural University, China, ⁷Yunnan Agricultural University, China, Peoples Republic of China, ⁸University of California, Davis Medical Center, USA

Previous studies have reported that strontium (Sr+) plays an important role in regulating bone remodeling, and has been used as a newly drug for the treatment in osteoporosis. In 2006, our research group discovered a special goat group in a closed village (Dongshan Village) in Mile County of Yunnan Province. These goats have bright red bone including teeth and therefore are named as "red-boned goats". We performed some preliminary studies in these goats and found they had 3 folds higher strontium content and significant low calcium content in their cortical bone. The circulating alkaline phosphatase (ALP) levels were 2-fold higher than the aged-matched regular goats. The aim of study is to investigate how environmental Sr+ composition would alter bone metabolism.

Method: We collected soil, water and nature pastures samples from the Dongshan Village, in where are red-boned goats grazing. The control samples were collected from three different counties, in where are normal bone goats grazing area. Mineral compositions were measured by inductively coupled plasma mass spectrometry. Six-month-old red-boned lambs (n=10) were fed in Dongshan Village with nature pasture grazing (group I). Ten other age-matched red-boned lambs were transported to other goat farm and fed with normal pasture (group II). Total experimental period was one year. Serum ALP and bone-specific alkaline phosphatase (BSAP) were measured at 6, 12 and 18 months and femur mineral compositions were measured at 18 months.

Results: The samples of soil, water and nature pasture from Dongshan Village showed around 2-4 fold higher strontium and calcium concentration than other samples from normal bone goats grazing area. The red-boned goats in group I showed significantly higher serum ALP concentrations at three time points, and significantly higher BSAP concentrations at 6 and 12 months. Moreover, red-boned goats showed 3 fold higher strontium contents and low calcium contents in the femur at 18 months compare to group II and Control. It is interesting to note that the bone redness have dispersed from group II. There were no significant differences for serum ALP, BALP concentrations, strontium and calcium contents in the femur between group II and Control.

Conclusion and implication: Environmental strontium consumption could alter bone metabolism significantly. Higher Sr+ consumption had an anabolic action on bone.

Iron Overload and Radiation Exposure Cause Oxidative Damage and Reduce Bone Density. Evelyn Yuen¹, Jennifer Morgan², Sara Zwart³, Estela Gonzalez¹, Kaleigh Camp⁴, Brandon Macias⁵, Scott Smith⁶, Susan Bloomfield⁴. ¹Texas A&M University, USA, ²ORAU, USA, ³USRA, USA, ⁴Texas A&M University, USA, ⁵Texas A&M University, USA, ⁶Wyle/nasa Jsc, USA

Astronauts on long duration space flight missions to the moon or mars are exposed to increased iron (Fe) stores and galactic cosmic radiation, both of which independently induce oxidative stress. There is growing evidence that links oxidative stress to bone loss with aging and estrogen deficiency. We hypothesized that iron overload (induced by feeding a high Fe diet) and γ radiation exposure would independently increase markers of oxidative stress and result in loss of bone mass, with the combined treatment having additive or synergistic effects.

Male Sprague-Dawley rats (3-mo-old, n=32) were randomized to receive an adequate (45 mg Fe/kg diet) or high (650 mg Fe/kg diet) Fe diet for 4 weeks and either 3 Gy (8 fractions, 0.375 Gy each) of ¹³⁷Cs radiation (γ RAD) or sham exposure every other day for 16 days starting on day 14. Serum Fe and catalase and liver Fe and glutathione peroxidase (GPX) were assessed by standard techniques. Immunostaining for 8-hydroxy-2-deoxyguanosine (8OHdG, marker of DNA adducts) quantified number of cells with oxidative damage in cortical bone. *Ex vivo* pQCT quantified volumetric bone mineral density (vBMD); bone mechanical strength (ultimate load) was assessed by 3-pt bending (midshaft tibia) and compression of the femoral neck.

High Fe diet increased serum catalase 31%, liver Fe 20%, and liver GPX 17%; high Fe diet and γ RAD increased serum Fe 20% and 25%, respectively. Preliminary data show Fe diet and γ RAD increased number of osteocytes with extensive 8OHdG staining (24% and 33%, respectively), with the combined treatment exhibiting 26% of osteocytes positively stained. γ RAD and high Fe diet lowered proximal tibial cancellous vBMD (by -15% and -12%, respectively); high Fe diet produced a small decrease in femoral neck total vBMD (-4%, $p = 0.07$). Cortical vBMD at midshaft tibia

was lower after high Fe diet, but not after γ RAD. Higher serum Fe levels were associated with lower proximal tibial cancellous vBMD ($r = -0.61$); higher liver GPX was associated with lower proximal tibial cancellous vBMD ($r = -0.60$); higher serum catalase was associated with lower vBMD at the 3 different bone sites ($r = -0.52$). No significant differences in ultimate load at mid-shaft tibia or femoral neck were detected.

High dietary iron and fractionated γ RAD cause oxidative damage in bone and are associated with decreases in bone density.

Effect of Glucocorticoid Treatment on Wnt Signaling Antagonists (sclerostin and Dkk-1) and their Relationship to Bone Turnover and Bone Mass. Lai Gifre¹, Pilar Peris², Silvia Ruiz-Gaspà³, Ana Monegal⁴, Benet Nomdedeu⁵, Nuria Guanabens⁶. ¹Hospital Clinic Barcelona, Spain, ²Hospital Clínic of Barcelona, Spain, ³CIBERhed, Hospital Clinic of Barcelona, Spain, ⁴Rheumatology Department, Hospital Clinic of Barcelona, Spain, ⁵Hematology Department, Hospital Clinic of Barcelona, Spain, ⁶Universitat De Barcelona, Spain

Wnt-b-catenin signaling and its antagonists (sclerostin and Dkk-1) play an important role in the regulation of bone mass and osteoblastogenesis. Glucocorticoid (GCC) treatment is a well known factor related to decreased bone formation and osteoporosis development. Therefore, the aim of this study was to analyze the effect of GCC treatment on Wnt signaling antagonists (sclerostin and Dkk-1) and their relationship to bone mass and bone turnover.

Methods: Patients with recent initiation of GCC treatment were prospectively included (≥ 7.5 mg/day and ≤ 6 months on GCC treatment). Patients with associated metabolic bone diseases or on antiosteoporotic treatment were excluded. Bone turnover markers (Bone formation: PINP, bone AP; Bone resorption: CTx), Wnt antagonists (serum sclerostin and Dkk-1, determined by ELISA, Biomedica Gruppe, Austria) and bone mineral density (BMD) were assessed in all patients. The results were compared with 20 healthy individuals of similar age and sex.

Results: 21 patients (11M/10F) with a mean age of 48 ± 20 yrs and a mean GCC daily dose of 66 ± 16 mg/day were prospectively included. Idiopathic thrombocytopenic purpura (76%) and hemolytic anemia (14%) were the most frequent associated conditions. Patients on GCC treatment showed a significant decrease in bone formation compared to controls (PINP: 20 ± 9 vs. 48 ± 19 ng/ml, $p=0.001$) and an increase in bone resorption (CTx: 0.60 ± 0.23 vs. 0.35 ± 0.1 ng/mL, $p=0.006$); 20% had densitometric osteoporosis. Patients on GCC had decreased Dkk-1 levels compared to controls (31.1 ± 28.6 vs. 51.5 ± 18.2 pmol/L, $p=0.013$) with a trend to higher sclerostin values (38.6 ± 21.2 vs. 29.8 ± 13.4 pmol/L, $p=0.119$). Sclerostin levels correlated positively with GCC doses ($r=0.511$, $p=0.018$) and lumbar BMD ($r=0.573$, $p=0.008$), and negatively with bone AP ($r=-0.476$, $p=0.034$). Dkk-1 levels correlated positively with total BMD ($r=0.533$, $p=0.016$).

Conclusion: The effect of GCC treatment on the serum levels of the Wnt signaling parameters differs depending on the antagonist evaluated. Dkk-1 levels were decreased shortly after the initiation of GCC therapy whereas sclerostin values tended to increase and showed a relationship to the dose of GCC and bone formation parameters. Long-term evaluation of these parameters in this process as well as their relationship to bone turnover and bone mass evolution is clearly indicated.

A New Protective Function of Nell-1 Against Osteoporosis by Activation of Wnt/ β -Catenin Signaling. Aaron James^{*1}, Jia Shen¹, Mari Kim², Xinli Zhang¹, Khoi Le², Alan Nguyen², Todd Rackohn², Greg Asatrian², Donna Soffer², Cymbeline Culiati², John Adams¹, Kang Ting¹, Chia Soo². ¹University of California, Los Angeles, USA, ²University of California, Los Angeles, USA

Introduction: NELL-1 is a secreted differentiation factor, first identified to have osteogenic properties by its overexpression in human craniosynostosis. We recently described an osteoporotic phenotype of *Nell-1* haploinsufficient mice (ASBMR, 2011). While skeletally normal during development, senile *Nell-1* haploinsufficient mice manifest osteoporotic bone loss with age, with a reduction in bone-formation and concomitant increase in bone-resorption.

Methods: This study expands on this association between NELL-1 and bone maintenance. First, bone marrow mesenchymal stem cells (BMSCs) and hematopoietic stem cells (HSCs) were isolated from both wildtype and *Nell-1* haploinsufficient mice. Osteogenic differentiation or bone resorption assays were performed with BMSCs and HSCs, respectively, in the presence or absence of added recombinant NELL-1. Similar studies were performed with human BMSCs, derived from both osteoporotic and non-osteoporotic donors, assaying the effects of NELL-1 on Wnt/ β -catenin signaling.

Results: *Nell-1*^{+/-} BMSCs showed a significant reduction ($p < 0.037-0.007$) in markers of osteogenic differentiation, including alkaline phosphatase staining, Alizarin red accumulation in bone nodules and gene markers of osteogenesis (*Runx2*, *Opn*, *Ocn*). In contrast, *Nell-1*^{+/-} HSCs showed a significant increase ($p < 0.0013$) in uncoupled bone resorption, including quantification of Toluidine Blue staining, resorption 'roughness' as measured by SEM and an increase in mean resorption pit depth. These metrics of formation and resorption were all reversed by conditioning cells with recombinant NELL-1. NELL-1 dose-dependently and significantly ($p < 0.039-0.007$) increased osteogenesis and reduced bone resorption ($p < 0.026-0.0001$) in wildtype mouse BMSCs and HSCs, respectively. In human BMSCs, NELL-1-induced-osteogenesis was associated with a significant increase ($p < 0.002$) in Wnt/ β -catenin signaling. These data suggest that interaction of NELL-1 with the cellular precursors of osteoblasts and osteoclasts leads to a net increase in bone formation.

Conclusions: This study now confirms the dual roles of NELL-1 as both pro-osteogenic and anti-resorptive in bone. This new finding suggests that NELL-1 protein or *Nell-1* pathway manipulation may potentially be a future local or systematic agent for the treatment of osteoporosis.

Effects of Aging on Bone Turnover Markers and Bone Density Regulating Hormones in Rats. Rana Samadfam^{*}, Susan Y. Smith. Charles River Laboratories, Canada

Baseline values for bone turnover markers and hormones regulating bone density, including parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D3 (VD3) in rats can vary significantly depending on diet, kit manufacturers, rat strain, time of sample collection, and/or gender. The aim of this study was to investigate the effect of aging on bone turnover markers and hormones in female and male rats of the same strain using the same time of sample collection, kit manufacturer for each analyzed parameter, and fed the same diet. Sprague Dawley rats from Charles River were fed certified rodent diet 5002. Serum and urine samples were collected from females at Months 2, 3, 7, 9, 10, 12, 13 and/or 14 for measurement of bone formation markers (total alkaline phosphatase, osteocalcin and/or PINP), PTH and/or VD3, and urinary and serum bone resorption markers (C telopeptide (CTx) and Deoxyypyridinolin (DPD)). Serum and urine was collected for males at Months 2, 3, 5, 9 and 12 for bone resorption and bone formation markers. Serum was collected from fasted animals in the morning and urine was collected overnight. Although the same manufacturers were used for each kit, the lot number was different depending on availability. The analyses for each parameter were carried out on separate occasions, months or years apart. In addition to bone turnover markers and hormones, selected serum biochemistry parameters were also evaluated. Osteocalcin and total ALP (surrogate bone formation marker) decreased with age with the sharpest declines between 2 to 6

months. Similar decreases were also noted for the bone resorption markers. PTH levels did not decline with age, however, decreases were noted for VD3. Aging had no effect on serum calcium levels, although a trend for a decline was noted for serum phosphorous. In general, the bone turnover markers and VD3 levels were higher in males compared to females, consistent with the greater bodyweight and size. In conclusion by eliminating variables the age-related decreases in serum and urinary bone turnover markers, serum phosphorous and VD3 were clearly noted for Sprague Dawley rats.

Patients with Low-Energy Distal Radius Fracture Have Similar Bone Strength of the Femoral Neck Compared to Healthy Individuals, but Some Deviation in the Levels of Biochemical Markers of Bone Turnover. Shigeharu Uchiyama¹, Shota Ikegami², Mikio Kamimura³, Toshihiko Imaeda⁴, Kiichi Nonaka⁵, Hirovuki Kato². ¹Shinshu University, School of Medicine, Japan, ²Department of Orthopaedic Surgery, Shinshu University, School of Medicine, Japan, ³Kamimura Clinic, Japan, ⁴Department of Food & Nutritional Environment, College of Human Life & Environment, Kinjo Gakuin University, Japan, ⁵Elk Corporation, Japan

Introduction: Low-energy distal radius fracture occurs relatively earlier in life than other osteoporotic fractures, and patients with these fractures are considered to be at high risk for hip fractures. Although osteoporotic treatment for such patients is highly recommend, routine DXA examinations show that they do not always have low bone mineral density (BMD). We hypothesized that compared with age-matched healthy controls, patients with such fractures should have some risk factors for hip fractures, other than DXA-derived BMD of the proximal femur.

Methods: We enrolled 31 female patients (average age, 71 years) with a history of low-energy distal radius fracture and 82 age-matched healthy postmenopausal women without any history of fracture (controls). The BMD of the femoral neck was obtained using DXA. Data regarding geometrical parameters (hip axis length, femoral neck width, cross-sectional area, and cortical thickness), biomechanical indices (cross-sectional moment of inertia, section modulus, and buckling ratio), and bone mineral density of the femoral neck were obtained using quantitative CT and were analyzed using the Mindways QCT-PRO BIT software. The levels of biochemical markers and hormones associated with bone metabolism were compared between the patients and controls by using an unpaired t-test or Mann-Whitney U test, depending on data distribution.

Results: No significant differences were observed in the geometrical parameters and biomechanical indices between the 2 groups. DXA-derived BMD of the proximal femur; serum and urinary levels of pentosidine; and the bone alkaline phosphatase, osteocalcin, homocysteine, parathyroid hormone, and 1,25-(OH)₂ vitamin D levels did not significantly differ between the 2 groups. The patients had significantly lower serum 25-(OH) vitamin D levels, higher deoxypyridinoline levels, or lower trabecular bone mineral density (derived from quantitative CT) of the total proximal femur than the controls (p < 0.05) (Table).

Discussion: The bone strength of the femoral neck in patients with low-energy distal radius fractures may not differ much from age-matched healthy individuals. From the known risk factors for hip fracture, abnormal results for 25-(OH) vitamin D and urine deoxypyridinoline are more important risk factors for hip fractures in patients with distal radius fracture. To develop effective strategies for preventing hip fractures in such patients, further studies are required to clarify whether addressing these risk factors would be effective in such cases.

Short-Term Effects of Anti-Catabolic and Anabolic Treatments on Bone Turnover Markers in Ovariectomized Rats. Jukka Morkko*, ZhiQi Peng, Katja Fagerlund, Mari Suominen, Jukka Rissanen, Jussi Halleen. Pharmatest Services Ltd, Finland

Short-term effects on bone turnover markers predict long-term effects on bone parameters such as bone mineral density in clinical studies and osteoporosis animal models. We have studied short-term effects of anti-catabolic and anabolic treatments on markers of bone resorption and formation in the rat ovariectomy (OVX) model. Study groups included a sham-operated group receiving vehicle, an OVX group receiving vehicle, and OVX groups receiving *s.c.* injections of 10 µg/kg/d 17β-estradiol (E2), 10 µg/kg/d alendronate (ALN), 10 µg/kg/wk zoledronate (ZOL) and 40 µg/kg/d human (1-34) parathyroid hormone (PTH). Each group contained 12 animals that were 3 months of age at the time of the operations. Dosing was started the next day after OVX and continued for 2 weeks. Procollagen I N-terminal propeptide (PINP), N-terminal mid-fragment of osteocalcin (OC), C-terminal cross-linked telopeptides of type I collagen (CTX), and tartrate-resistant acid phosphatase 5b (TRACP 5b) were determined in serum before the start of treatment and at 2 weeks. Uterine weight was decreased by OVX, demonstrating that the operations were performed successfully. OVX increased PINP values by 110%, OC values by 21% and CTX values by 49% (all with p<0.001), and decreased TRACP 5b values by 26% (p<0.01). PINP values increased 22% by PTH (not significant, ns) and decreased 72% by E2 (p<0.001), 21%

by ALN (ns) and 9% by ZOL (ns). OC values increased 29% by PTH and decreased 20% by E2, 17% by ALN and 23% by ZOL (all with $p < 0.001$). CTX values increased 5-8% by PTH, ALN and ZOL (all ns) and decreased 33% by E2 ($p < 0.001$). TRACP 5b values increased 10% by E2 (ns) and decreased 25% by PTH, 38% by ALN and 54% by ZOL (all with $p < 0.001$). We conclude that all markers showed the expected results caused by OVX and treatment by E2. Although serum CTX is a sensitive marker for monitoring efficacy of bisphosphonate treatment in clinical studies, it did not show significant effects on ALN and ZOL treatments in the rat OVX model. On the contrary, TRACP 5b showed similar significant responses to ALN and ZOL treatments as in clinical studies. Although PINP was the most sensitive marker for detecting changes by OVX and treatment by E2, it did not show significant results on PTH, ALN and ZOL treatments in this study performed in young animals. Although the changes in OC were relatively small, OC was the only marker that demonstrated significant effects on all tested therapies.

Bone Shock Absorbance (BSA) Complements DXA BMD for More Accurate Discrimination of Elderly Women with and without Arm and Wrist Fractures.

Nelson Watts*¹, David Ralph², Diane Busch-James², Cyndy Cox³, Ron Schultheis², Amit Bhattacharya³. ¹Mercy Health Osteoporosis & Bone Health Services, USA, ²OsteoDynamics, USA, ³University of Cincinnati, USA

Bone Shock Absorbance (BSA) is a noninvasive and painless diagnostic technology being developed to complement dual-energy x-ray absorptiometry (DXA) determinations of bone mineral density (BMD) for more accurate evaluation of osteoporotic fracture risk. The output of a BSA test is a bone "damping value".

Arm and wrist fractures are a common type of major osteoporosis-related fragility fractures in elderly women. We report on the results of a study of 73 ambulatory white women ages 65 to 80; 30 had suffered an arm or wrist fracture in the previous 2 years (fracture cases) and 43 had no fracture at any site within 15 years (controls). The mean ages (SD) of the fracture cases and controls were 71.5 (4.2) and 71.0 (4.1) respectively. All had DXA BMD and BSA damping value determinations. DXA BMD values were evaluated as T-scores. The mean (SD) T-score at the femoral neck for the fracture cases was -1.73 (0.80) and for the fracture-free controls was -1.35 (0.75) ($p = 0.062$). Four of the fracture cases and 3 of the controls had T-scores ≤ -2.50 , indicating that they met the diagnostic criterion for osteoporosis. These DXA-derived results were consistent with expectations that while BMD is inversely correlated with osteoporotic fractures, most fractures occur in patients who do not have osteoporosis as determined by BMD. BSA-determined bone damping values were also inversely correlated with fractures. The mean (SD) bone damping values measured above the right knee for the fracture cases was 4.88 (2.33); by contrast, the mean (SD) bone damping value in the fracture free controls was 13.11 (14.38) ($p = 0.018$). Analyses with ROC curves returned AUCs of 0.65 for both T-scores ($p = 0.047$) and BSA damping values ($p = 0.040$). Interestingly and importantly, T-scores and BSA damping values were not highly correlated (Pearson Correlation Coefficient = .172; $p = .164$), suggesting that they contain independent information about fracture association. BSA damping values and DXA-derived T-scores were combined in a logistic regression model with arm and wrist fractures as the dependent variable. The output of the logistic regression model more accurately discriminated between fracture cases and controls (ROC curve AUC = 0.70, $p = .008$) than either DXA or BSA alone.

If confirmed in follow-on studies, combining BSA and DXA results may provide an improved means to identify individuals at high risk of experiencing an osteoporosis-related fragility fracture.

Can Fracture Risk Calculators Help Determine Bone Density Testing Intervals in Men? Kaniksha Desai*¹, Valentina Petkov¹, Robert Adler².

¹Virginia Commonwealth University, USA, ²McGuire VA Medical Center, USA

Objectives: 1. To determine if fracture risk calculators FRAX and GARVAN can predict which men will progress from osteopenia (low bone mass by dual energy x-ray absorptiometry, DXA) to osteoporosis (OP) or have a significant decrease in bone mineral density (BMD). 2. To determine if osteopenic men should have a repeat DXA in 2-3 years.

Methods: Older men were screened for OP by DXA (of spine, hip, and forearm) in a primary care clinic program. Reports for men with osteopenia included a recommendation for a repeat DXA in 2 years. Risk factors including age, weight, alcoholism, tobacco use, previous fracture, parental hip fracture, glucocorticoid use, rheumatoid arthritis, and number of falls were assessed using CPRS (electronic medical record) and a questionnaire at DXA testing. Risk factors were used to calculate FRAX and GARVAN scores, 2 validated methods to determine 10 year fracture risk. Logistic regression models were used to determine if FRAX or Garvan at baseline can predict change in diagnosis or significant BMD loss.

Results: Osteopenic men ($n = 118$, mean age 70) had a repeat DXA 3.2 ± 0.8 years later. Only 6 had a change in diagnosis to OP, but 101 had a significant BMD loss at

one or more sites. On review of the 6 men, 2 had elevated FRAX and 4 had elevated GARVAN score at baseline. Two men were started on androgen deprivation therapy, which may have led to OP. Similar to a recent study in women, 5 out of 6 men who changed to OP had a T score worse than -2 (severe osteopenia). Overall, 14% of men with severe osteopenia progressed to OP. However, at baseline FRAX and Garvan were no different in the 14% compared with those that did not progress to OP.

Discussion: While many osteopenic men lose bone over 3 years, a repeat DXA is unlikely to show a diagnosis change. In a recent study (ML Gourlay, NEJM 366:225, 2012), older women with more severe osteopenia were more likely to develop OP than younger women with milder osteopenia. Our data in men appear to be consistent because the more severe the osteopenia, the more likely progression to OP. However, longer studies are needed to determine the appropriate DXA interval for most men. Although GARVAN and FRAX scores did not predict which men would progress, they can be used in conjunction with clinical judgment and assessment of new risks (such as androgen deprivation therapy) to determine timing of repeat DXAs.

Normative Data for Bone Mineral Density and Calcaneal Ultrasound in 25-year-old Swedish Women: The Peak-25 Cohort of 1061 Women. Mattias Callréus*¹, Fiona McGuigan², Kristina Akesson³.

¹Skåne University Hospital, Sweden, ²University of Lund, Malmö, Skåne University Hospital, Malmö, Sweden, ³Skåne University Hospital, Malmö, Sweden

As bone mass later in life is largely dependent on peak bone mass achieved in young adulthood, normative values of bone mass at this age are imperative in identifying women at risk of osteoporosis. Using a population-based sample of premenopausal Scandinavian women aged 25, the aim of this study is to provide normative DXA and QUS information at an age closely representing peak bone mass.

Subjects and Methods: 1061 women were included in the Peak-25 cohort evaluating determinants of bone health. DXA (Prodigy, GE) was used to assess bone mass. Bone mineral density (BMD) and bone mineral content (BMC) were measured at; total body (TB), femoral neck (FN), trochanter (TR) and lumbar spine (LS) and Z-scores and T-scores were obtained. Quantitative ultrasound of the calcaneus (QUS) (Lunar Achilles) was also assessed: bone ultrasound attenuation (BUA), speed of sound (SOS) and stiffness index (SI). Statistical analysis (descriptives, Pearson's correlation) was performed using SPSS (SPSS Inc., Chicago, Illinois).

Results: At baseline the women were 25.5 ± 0.2 years of age, 168 ± 6 cm tall and weighed 65 ± 11 kg. DXA BMD values (g/cm^2) were 1.17 ± 0.07 (TB-BMD), 1.053 ± 0.123 (FN-BMD), 0.830 ± 0.108 (TR-BMD) and 1.217 ± 0.128 . The corresponding Z-scores were 0.63 ± 0.81 (TB), 0.54 ± 0.98 (FN), 0.38 ± 0.95 (TR) and 0.32 ± 1.03 (LS). Comparing Z-scores and T-scores, femoral neck Z-score was significantly lower in our cohort, whereas other sites showed no differences. QUS values were: BUA (117.4 ± 10.5 db/MHz), SOS (1574 ± 32 m/s) and SI (98.9 ± 14.6 %). The correlation between DXA and QUS was modest (0.44 - 0.52 ; $p < 0.001$) for SOS and SI and lower for BUA.

Conclusion: This very large cohort of exactly 25-year old women provides normative bone mass and QUS values for premenopausal young adult Swedish women and demonstrates the correlation between DXA and QUS. Interestingly, BMD values are considerably higher than those expected for age (Z-score), whereas the FN T-scores suggest that contrary to common assumption, at age 25, peak bone mass has still not been reached at the FN. How this should be interpreted is unclear; it could suggest that FN peak bone mass is reached much later in Swedish women alternatively, the reference population provided in the machine is not applicable for a Scandinavian population.

Predictions of Vertebral Strength using QCT and Intra-Vertebral Heterogeneity Density vs. DXA. Amira Hussein¹, Stacyann Morgan², Glenn Barest³, Elise Morgan¹. ¹Boston University, USA, ²Boston University, USA, ³Boston University School of Medicine, Radiology, USA

Trabecular bone density and architecture are highly non-uniform throughout the vertebra. This intra-vertebral heterogeneity has often been proposed as a main reason why average measures of bone mineral density (BMD) explain only ~60% of the variance in vertebral strength. Given that spatial variations in trabecular density can be assessed non-invasively via quantitative computed tomography (QCT), the goal of this study was to determine the influence of the intra-vertebral heterogeneity in density on strength predictions.

Fresh-frozen, human, L1 functional spine units (age: 79.8+/-11.2, 15 female, 16 male) were scanned via QCT (in-plane resolution: 0.3125mm/pixel, slice thickness: 0.625mm). The volume computed tomography dose index was 96.5mGy. The vertebrae were then compressed to failure to measure the ultimate force (maximum force sustained). BMD was calculated for 5mm contiguous cubes distributed throughout the centrum. The inter-quartile range (IQR) of the cube BMD values was used as the measure of intra-vertebral variation. Average BMD and cross-sectional area (CSA) were calculated for the largest elliptical cylinder that would fit within the vertebra. The images were also used to calculate areal BMD, simulating lateral DXA (BMD_{DXA}), and to obtain an estimate of the axial rigidity (EA), the resistance to axial loading. Linear regressions were used to determine the dependence of ultimate force on each of the following combinations of explanatory variables: 1) BMD*CSA; 2) BMD*CSA and IQR; 3) BMD_{DXA}; 4) EA. A restricted vs. full F-test was used to compare regression models 1 and 2. J-tests were used to rank the four regression models from best to worst predictive performance.

Accounting for the intra-vertebral variation in density in addition to mean density significantly improved strength predictions. Including IQR in addition to BMD and CSA in the regression model improved the R² value from 0.43 (p=0.001) to 0.58 (p=0.002; F-test: p=0.038), resulting in the best regression model. Model 3 (R²=0.22, p=0.033) was inferior to model 2, and model 4 was not significant (p=0.729).

These findings show that non-invasive assessments of the intra-vertebral heterogeneity in density improve predictions of vertebral strength compared to current clinical standards that use only average BMD from QCT or DXA. The higher radiation dose incurred with QCT may thus be acceptable for certain indications when seeking more accurate assessment of bone strength and fracture risk.

Short Term Caloric Restriction Does Not Reduce Bone Mineral Density in Early Type 2 Diabetic Rats. Yun Kyung Jeon¹, Min Jung Bae², WON JIN Kim², YANG SEON Yi³, Sang Soo Kim², Bo Hyun Kim², Soo Hyoung Lee⁴, Yong Ki Kim⁵, In Joo Kim². ¹Pusan National University Hospital, South Korea, ²Pusan National University Hospital, South Korea, ³Pusan National University Hospital, South Korea, ⁴Kim Young Ki clinic, South Korea, ⁵Kim Yong Ki clinic, South Korea

The aim of this study is to determine short term caloric restriction (CR) alters bone mass and bone metabolism in early type 2 diabetic rat model, OLETF rats. The rats were divided into 4 groups (n=5, each): OLETF with ad libitum (AL), OLETF with CR, LETO with AL, LETO with CR. CR was practiced in male rats at 24weeks of age by 40% restriction for 4weeks until the study was terminated. The effect of CR on bone mineral density (BMD) of total femur was assessed using Dual energy X-ray absorptiometry. Serum markers were determined using immunoassay. After 4 wk CR, body weight was decreased in both species. The BMD at total femur were decreased after CR in LETO rats, but not in OLETF rats. After adjustment of body weight, BMD was still lower in LETO rats (p = 0.029), but not in OLETF rats (p = 0.262). Bone specific alkaline phosphatase decrease in LETO rats (p = 0.009), but not in OLETF rats (p=0.347). Serum leptin were lowered by CR in both species, but hyperleptinemic status maintained in OLETF rats (5.348 vs 11.770, p = 0.009). 25(OH)D were significantly increased in CR group of OLETF rats (p = 0.009), but not in LETO rats (p = 0.117). IL-6 and TNF- α were significantly decreased in OLETF rats (p=0.009), but not in LETO rats (p = 0.042) by CR. Short term caloric restriction and its related weight reduction were associated with marked decreases of BMD at femur in LETO rats, but not in OLETF rats with early type 2 diabetic status. Short term CR may not alter bone mass and bone metabolism in early type 2 diabetes.

Thoracic and lumbar regional differences in associations between vertebral deformity, BMD, and age in postmenopausal women. Eual Phillips¹, Chamith Rajapakse², Michael Wald³, Felix Werner Wehrli³. ¹University of Pennsylvania, USA, ²University of Pennsylvania School of Medicine, USA, ³University of Pennsylvania Medical Center, USA

Bone mineral density (BMD) is widely used to assess vertebral fracture risk. However, nearly 50% of patients with vertebral fractures have normal BMD. The goal

of this study is to examine the predictability of MRI-based vertebral deformity measures from BMD and age in the lumbar and thoracic spine.

The study comprised of 32 postmenopausal women (mean age: 71.8 years, $\sigma = 7.0$). Multi-slice sagittal MR images of the midline spine were acquired at 1.5-T (Siemens Sonata) scanner using the manufacturer's surface array coil and a turbo spin-echo sequence. Acquired spine images were taken as input to a custom software tool for quantitative VMA. Anterior, middle, and posterior heights vertebral heights were computed by taking the Euclidian distance between landmark points. Wedge (W), biconcavity (B), and crush (C) vertebral deformities were calculated for each vertebra by adapting an approach developed by Eastell. A continuous mean of each deformity class was computed for the thoracolumbar vertebral column (T4-L5). Adapted from Diacinti, vertebral height summation (VHS) was computed in the anterior (AVHS), middle (MVHS), and posterior (PVHS) regions. Genant's criteria were applied to measure for vertebral fracture frequency (FxN) and severity (FxS). Finally, intervertebral disc space summation (DSS) was also calculated for the anterior (ADSS) and posterior (PDSS) spine.

Associations between vertebral deformity, BMD, and age were found to be different in the lumbar and thoracic regions. LS-BMD demonstrated an inverse relationship with lumbar PDSS (-0.42, p < 0.05). Patient age did not express a predictive relationship with lumbar vertebral deformity. Hip BMD positively correlated with thoracic MVHS (r = 0.43, p < 0.05). Patient age conveyed an inverse relationship with thoracic MVHS (r = -0.43, p < 0.05) and a positive correlation with biconcave (r = 0.37, p < 0.05) and crush deformities (r = 0.41, p < 0.05). Age also exhibited a predictive relationship of biconcave FxN (r = 0.38, p < 0.05) and FxS (r = 0.37, p < 0.05) in the thoracic column. BMD prediction of lumbar vertebral deformity may require further investigation due to the unique shape of the lumbar spine. In conclusion, MRI-based vertebral morphometry may provide information about vertebral fracture susceptibility in addition to BMD and age.

Severities of Vertebral Fractures Evaluated with Semiquantitative Analysis (SQ) in Glucocorticoid-induced Osteoporosis (GIO). Mari Ushikubo¹, Ikuko Tanaka², Shigenori Tamaki³, Harumi Kuda¹, Keisuke Izumi¹, Kumiko Akiva¹, Hisaji Oshima⁴. ¹Department of Connective Tissue Diseases, Tokyo Medical Center, Japan, ²National Center for Geriatrics & Gerontology, Japan, ³Nagoya Rheumatology Clinic, Japan, ⁴Tokyo Medical Center, Japan

Background: Although vertebral fracture is one of the major problems in treatment with glucocorticoids, severities of fractures have not been well evaluated.

Purpose: To clarify situation of severities of vertebral fractures and correlation with clinical variables.

Patients and Methods: 137 patients with connective tissue diseases other than rheumatoid arthritis were recruited and observed for 2 years (age: 61+/-15yo (mean+/-SD), disease duration; 12+/-11ys, total prednisolone (PSL) dosage: 34+/-34g, daily PSL dosage during the study period; 8+/-6mg/day). Grading with the SQ method

(Gerant et al. JBMR, 1993) was used for evaluation of severities of vertebral fractures. Bone mineral densities (BMD) were measured with DXA at the distal radius.

Results: 1) At the beginning of the observation, 42 (31%), 15 (11%), and 6 (4%) patients revealed the grade (G)1, G2, and G3, respectively. 2) Deteriorated grades during 2 years were seen in 47% of the patients. Eighty three percent of patients with incident fractures showed one-grade deterioration. In 8% and 9% of the patients, however, two- and three-grade deteriorations were detected. 3) In patients with more than the two-grade deterioration, the age and the SQ grade at the beginning were higher and the BMD was lower than those in less than one-grade deteriorated patients. Multivariable analysis with logistic regression revealed an age as a risk factor.

Conclusions: Evaluation of severities of vertebral fractures with the SQ method was suggested to be an important aspect in pathogenesis and prevention of GIO.

Evaluating the Effect of Osteoporosis on Femoral Cartilage Thickness using Ultrasonography in Female Patients with Knee Osteoarthritis. Levent Tekin*¹, Alparslan Bayram Çarlı², Selim Akarsu², Mehmet Zeki Kırıl².
¹Gulhane Military Medical Academy Haydarpaşa Training Hospital, Turkey, ²GMMA Haydarpaşa Training Hospital, Turkey

Introduction and Aim: Osteoarthritis (OA) and osteoporosis (OP) are diseases that significantly decrease health quality by functional loss in affected individuals and are among the most important health issues especially in the elderly population. Especially in the past 50 years, these two disorders which cause chronic pain and disability in the elderly have become a public health problem as a result of the increase in mean lifetime. Whether these two diseases affect each other is controversial in the studies that have been conducted since today. We aimed to investigate whether there is a relationship between the presence of OP and OA evaluating the femoral cartilage thickness using ultrasonography. As our knowledge, this is the first study in literature that uses ultrasonography in investigating this relationship.

Material and Methods: 80 female patients aging between 50-75, that were diagnosed as knee OA by history, physical examination and imaging methods with grade 1-3 gonarthrosis (using Kellgren-Lawrence grading Scale) were included into the study. Patients in group 1 (n=40) had a diagnosis of OP (BMD total T score lumbar or femoral <-2.5) and group 2 (n=40) had no OP (BMD total T score lumbar or femoral >-2.5). All the patients received knee joint ultrasonography. Femoral cartilage thickness was measured from three points (mid, medial and lateral femoral epicondyle) and the mean value was calculated.

Results: The mean femoral cartilage thickness in group 1 was significantly higher than in group 2 (p<0.05).

Conclusion: OP seems to be a protective factor from having OA. Nevertheless, we do not know that if this is due to the new bone formation or spurs which counts as bone mass and elevates the BMD scores in OA patients. We consider that our study will enlighten the arguments on the relationship between OP and OA and create a new horizon on this issue.

Noninvasive Prediction of Principal Trabecular Orientation Using Quantitative Ultrasound and Finite Element Analysis. Liangjun Lin*¹, Wei Lin², Yi-Xian Qin¹. ¹State University of New York at Stony Brook, USA, ²Stony Brook University, USA

Introduction: Trabecular structural alignment is heavily influenced by the particular mechanical milieu applied to it and closely related to risk of fracture¹. Quantitative ultrasound (QUS) propagation has potential to predict trabecular structural orientation and anisotropic mechanical properties². The objective of this study is to use QUS to non-invasively predict the principal structural orientation of trabecular bone, and correlate with finite element analysis (FEA) determined mechanical property.

Materials and methods: 7 trabecular bone balls (Ø 25mm) were machined from bovine femurs. Rotational QUS scanning with increment of 10° was performed around 3 anatomical axes of superior-inferior (SI), antero-posterior (AP), and medio-lateral (ML) to measure the fast wave ultrasound velocity (UV) and attenuation (ATT) (Fig. 1). The QUS data was reconstructed in a 3-D Cartesian coordinates system to predict the principal structural orientation (Fig. 2). µCT with resolution of 36.9 µm was performed on all the bone balls. Mean intercept length (MIL) tensor was calculated from the µCT images. The µCT images were then converted into mesh model of tetrahedral elements for FEA (Fig. 3). Young's modulus of 10.9 GPa and Poisson ratio of 0.3 were used in FEA. Displacement controlled loading of 1,000 µstrain was applied to each model along 6 directions: SI, AP, ML, longest vector of MIL tensor, the principal structural orientations predicted by UV and ATT.

Results: QUS was able to pick up the angle-dependent change of the trabecular structure (Fig. 4). The average angle difference between the principal structural orientations predicted by UV and the longest vector of MIL tensor is $4.45 \pm 2.20^\circ$, and the difference between ATT and MIL is $11.67 \pm 6.83^\circ$. The difference between ATT and UV is $8.96 \pm 7.48^\circ$ (Table 1).

Conclusion: The presented non-invasive QUS method was able to predict the principal structural orientation of the trabecular bone with an angle difference smaller than 10° compared to the µCT data. The ongoing FEA can validate these results and potentially predict the trabecular mechanical strength in associated orientations. These data may provide insight of the mechanism of ultrasound predictions for the structural orientation with multiple QUS parameters.

Geographic Disparities in BMD Testing and Osteoporosis Treatment for Manitoba, Canada. William Leslie*¹, Patricia Caetano². ¹University of Manitoba, Canada, ²University of Manitoba, Canada

Background: Geographic disparities in healthcare are well documented, and have recently been noted for DXA testing in the United States. The Province of Manitoba, Canada (1.2 million) has a centralized DXA testing program with testing centres in two southern urban areas (Winnipeg and Brandon). To examine regional disparities in osteoporosis care, we analyzed DXA testing and osteoporosis treatment rates for 5 fiscal years (2005/06 to 2009/10) as part of a provincial patient care initiative.

Methods: Health services are provided to virtually all Manitoban residents through a single public health care system. Manitoba Health maintains computerized databases for all residents eligible to receive health services. DXA testing was identified in a database that contains all clinical BMD results for the Province of Manitoba, Canada. Non-estrogen osteoporosis treatment (1 or more dispensations for the fiscal year) was identified in a comprehensive retail pharmacy database for the Province. Rates per 1,000 (averaged for 2005/06 to 2009/10) were computed for each of 10 provincial regional health authorities (RHAs), and for the 12 community areas (CAs) comprising the urban capital of Winnipeg. Spearman correlation coefficients were determined between the rate of BMD testing, rate of osteoporosis treatment rates, and median household income (2006 census data).

Results: BMD testing rates varied by more than two-fold between provincial RHAs (28.2 per 1,000 in Brandon to 10.3 per 1,000 in the Northern-Manitoba RHA), with a slightly smaller variation in osteoporosis treatment rates (116 per 1,000 in Brandon to 58 per 1,000 in the northern Burntwood RHA). Within Winnipeg, BMD testing rates varied by more than two-fold (maximum 32.5 per 1,000 versus minimum 12.5 per 1,000), with a large variation in osteoporosis treatment rates (maximum 116 per 1,000 versus minimum 35 per 1,000). There was a significant positive correlation between BMD testing and osteoporosis treatment rates by provincial RHA (Spearman rho=0.66, p<.05) and Winnipeg CA (Spearman rho=0.80, p<.01), but neither of these showed a significant correlation with median household income.

Conclusions: Large geographic disparities in osteoporosis care were identified in the public health care system of Manitoba, Canada. The northern regions of Manitoba, which are most distant from the DXA testing centres, have the lowest DXA testing and osteoporosis treatment rates. Targeted strategies will be required to address these disparities.

Calcium and Vitamin D Intakes in a Prospective Population-based Study: the Canadian Multicentre Osteoporosis Study. Wei Zhou^{*1}, Claudie Berger¹, Lisa Langsetmo², David Goltzman¹, Suzette Poliquin³, Stephanie Kaiser⁴, Robert Josse⁵, Jerilynn Prior⁶, Tanveer Towheed⁷, Tassos Anastassiades⁸, K. Shawn Davison⁹, Christopher Kovacs¹⁰, Emmanuel Papadimitropoulos¹¹, Nancy Kreiger¹². ¹McGill University, Canada, ²Canadian Multicenter Osteoporosis Study, Canada, ³Institut national d'excellence en santé et services sociaux, Canada, ⁴Dalhousie University, Canada, ⁵St. Michael's Hospital, University of Toronto, Canada, ⁶University of British Columbia, Canada, ⁷Queen's University, Canada, ⁸Queen's University, Canada, ⁹Laval University, Canada, ¹⁰Memorial University of Newfoundland, Canada, ¹¹Lilly, Canada, ¹²University of Toronto, Canada

Calcium and vitamin D are nutrients essential for overall health, accrual of optimal bone mass, and prevention of osteoporosis and fractures in adulthood. Our objective was to estimate calcium and vitamin D intakes and their change over ten years among an adult Canadian population.

Participants in the Canadian Multicentre Osteoporosis Study (CaMos) were randomly selected from a 50 km radius of 9 cities across Canada. A short interviewer-administered semi-quantitative food frequency questionnaire was completed at baseline and Year10. Calcium intake from both diet and supplements, and vitamin D intake from milk, beverage fortification, yogurt and supplements, were estimated cross-sectionally and longitudinally, by categories of age (25-50, 51-70 and 71+) and by sex.

At baseline, the study sample included 6518 women (mean age 63 yr) and 2864 men (mean age 60 yr). Detailed intakes of calcium and vitamin D at baseline and Year 10 are shown in the Table, along with comparisons to 2010 Institute of Medicine (IOM) dietary reference intakes. The prevalence of those with intakes below the Estimated Average Requirement (EAR) ranges from 47% to 69% at baseline and 32% to 52% at Year 10 for calcium, and ranges from 72% to 83% at baseline and 42% to 76% at Year 10 for vitamin D. The calcium intake increased in all groups over 10 years with a mean change of 315 (95% confidence interval (CI): 290, 340) mg/day in women and 190 (95% CI: 154, 226) mg/day in men. Vitamin D intake increased in women, the mean change was 10.1 (95% CI: 8.7, 11.5) µg/day [405 (349, 461) IU/day] in those aged 51+ and 5.3 (95% CI: 4.2, 6.5) µg/day [214 (169, 259) IU/day] in the 25-50 group. Vitamin D intake increased by 5.3 (95% CI: 4.3, 6.4) µg/day [213(172, 254) IU/day] in men aged 51 and older, but the change was not significant in men aged 25-50. The percentage of participants reporting calcium supplements increased from 38.3% at baseline to 58.8% at Year 10, and the percentage who supplemented with vitamin D increased from 29.6% to 57.5%.

We observed a high prevalence of Canadian adults that did not meet the EAR established by the IOM for calcium and vitamin D intake. With reference to the new IOM guidelines, the present intakes are substantially below optimal intakes for bone health.

| Age (year) | n | Calcium (mg/day) | | | Vitamin D (µg/day) | | | |

Dietary Patterns in Men and Women Aged 25 Years and Older: Relationship with Body Mass Index, 25-hydroxyvitamin D Levels, Fasting Glucose, and Risk of Diabetes Mellitus. Lisa Langsetmo^{*1}, Claudie Berger², Jerilynn Prior³, David Hanley⁴, Jacques Brown⁵, Jonathan Adachi⁶, Sophie Jamal⁷, Robert Josse⁸, Christopher Kovacs⁹, Suzanne Morin², Susan Barr¹⁰, K. Shawn Davison¹¹, David Goltzman², Nancy Kreiger¹². ¹Canadian Multicenter Osteoporosis Study, Canada, ²McGill University, Canada, ³University of British Columbia, Canada, ⁴University of Calgary, Canada, ⁵CHUQ Research Centre Laval University, Canada, ⁶St. Joseph's Hospital, Canada, ⁷The University of Toronto, Canada, ⁸St. Michael's Hospital, University of Toronto, Canada, ⁹Memorial University of Newfoundland, Canada, ¹⁰University of British Columbia, Canada, ¹¹Laval University, Canada, ¹²University of Toronto, Canada

We have previously shown younger adults are choosing a more energy-dense and less nutrient-dense diet than older adults, and that the associated dietary patterns are related to body mass index (BMI). Objectives: To determine potential relationships between dietary patterns (Nutrient-Dense and Energy-Dense) and incident diabetes mellitus, and to assess possible mediation of this relationship by BMI, fasting glucose, and/or 25-hydroxyvitamin D (25OHD).

Design: We performed a secondary analysis of a longitudinal study, the Canadian Multicenter Osteoporosis Study—a randomly selected population-based cohort. Dietary patterns were assessed by self-administered food-frequency questionnaires in year 2 (1997-99). We used principal components to derive two dietary pattern factor scores: Energy-Dense and Nutrient-Dense. Exclusion criteria were missing/incomplete questionnaires or prevalent diabetes at year 2; 3868 women and 1545 men were eligible. Clinical assessment at year 5 (2000-02) included measured height and weight. A subsample (749 women and 318 men) also had fasting serum samples analyzed at that time. Our primary outcome was self-reported diagnosis of incident diabetes (assumed to be type 2) before the 10th annual follow-up (2005-07). Regression models (Cox and multivariate) were adjusted for age, education, alcohol, smoking, physical activity, comorbidities, menopausal status, and hormone therapy.

Results: The Nutrient-Dense dietary pattern was strongly associated with intakes of fruit, vegetables, and whole grains while the Energy-Dense pattern was strongly associated with intake of soft drinks, potato chips, french fries, meats, and desserts. The Energy-Dense dietary pattern was associated with higher risk of incident diabetes, HR=1.15 (95% CI: 1.00-1.32), with this effect mediated in part by higher BMI, higher fasting glucose, and lower serum 25OHD levels. The Nutrient-Dense dietary pattern was associated with lower risk of diabetes, HR=0.85 (95% CI: 0.74-0.98), with this effect mediated in part by lower BMI values, lower fasting glucose, and higher serum 25OHD levels.

Conclusion: A diet high in vegetables, fruit, and whole grains and low in soft drinks, potato chips, french fries, meats, and desserts is associated with lower BMI, lower fasting glucose, and higher serum 25OHD values, and lower risk of incident diabetes. These results support public health measures to mitigate impact of dietary patterns prevalent in younger adults.

Disclosures: Lisa Langsetmo, None.

Effect of Gamma-glutamyl Carboxylase gene Polymorphism on the Association between Serum Vitamin K and Gamma-carboxylation of Osteocalcin in Young Adults. Mavu Haraikawa^{*1}, Naoko Tsugawa², NATSUKO SOGABE³, Rieko Tanabe⁴, Yuka Kawamura¹, Toshio Okano⁵, Takayuki Hosoi⁶, Masae Goseki-Sone⁷. ¹Department of Food & Nutrition, Faculty of Human Sciences & Design, Japan Women's University, Japan, ²Kobe Pharmaceutical University, Japan, ³KOMAZAWA WOMEN'S UNIVERSITY, Japan, ⁴Department of Food & Nutrition, Faculty of Human Sciences & Design, Japan Women's University, Japan, ⁵Kobe Pharmaceutical University, Japan, ⁶National Center for Geriatrics & Gerontology, Japan, ⁷Japan Women's University, Japan

Osteoporosis results from complex interactions between genetic and environmental factors. Nutrition is one of the most important environmental factors in the prevention of osteoporosis. Vitamin K acts as a cofactor for gamma-glutamyl carboxylase (GGCX), which is an essential enzyme for the gamma-carboxylation of vitamin K-proteins such as osteocalcin (OC). OC is produced in osteoblasts, and fully carboxylated osteocalcin binds to the calcium ions of hydroxyapatite. The amount of OC which is not carboxylated (undercarboxylated OC: ucOC) is considered a sensitive index of the vitamin K status of bone, and an elevated ratio of ucOC to intact OC is thought to be associated with low dietary intakes of vitamin K. Recent studies demonstrated that a significantly higher association between the single nucleotide polymorphisms of GGCX (R325Q, 974G>A) is associated with the bone mineral density among postmenopausal women. In this study, we investigated the effect of GGCX polymorphism on the correlations among vitamin K intake, the level of serum vitamin K, and the ratio of ucOC to intact OC. Serum biochemical parameters, such as serum phylloquinone (PK), menaquinone-7 (MK-7), intact OC, ucOC, and bone-

type alkaline phosphatase, were measured in healthy young males (n=97, age: 22.3 ± 1.7 y, mean ± standard deviation) and females (n=92, age: 21.8 ± 1.8 y). Dietary nutrient intakes were measured based on 3-day food records before the day of blood examinations. All subjects were genotyped for polymorphism (R325Q) presence. Dietary vitamin K intake from vegetables was significantly correlated with the level of serum PK, and vitamin K intake from fermented beans, natto, was also significantly correlated with the level of serum MK-7. The ratio of ucOC to intact OC showed a negative association with the total vitamin K intake and serum MK-7 in both male (r=-0.333, p=0.001) and female (r=-0.549, p<0.001) subjects. Interestingly, on grouping by the GGCX genotype, a significant interaction between the ratio of ucOC to intact OC with serum MK-7 was observed in 325R homozygotes (r=-0.411, p=0.007, r=-0.552, p<0.001) and heterozygotes (r=-0.358, p=0.015, r=-0.540, p<0.001), but not in 325Q homozygotes in both male and female subjects. These results suggest that there is an effect of the GGCX gene polymorphism on the correlation between the levels of serum MK-7 and gamma-carboxylation of serum OC.

Low Vitamin D Status is Prevalent among Aboriginal and Younger Women and is Related to Number of Milk Servings Consumed. Nihal A Natour*¹, John Krahn², Hope Weiler³, William Leslie⁴. ¹McGill University, Canada, ²University of Saskatchewan, Canada, ³McGill University, Canada, ⁴University of Manitoba, Canada

Background: Health disparity is a well-recognized problem among Aboriginal people in North America. Canadian Aboriginal women and men have a 2-3 fold increase in major osteoporotic fractures. The Canadian Health Measures Survey (CHMS) of plasma 25-hydroxyvitamin D [25(OH)D] concentration in white and non-white people failed to capture enough information to enable assessment according to Aboriginal ethnicity.

Data and Methods: Data from culturally appropriate surveys, a food frequency questionnaire (FFQ) and plasma 25(OH)D concentration (RIA, Diasorin) were collected from 147 urban dwelling white women and 204 urban and rural dwelling Aboriginal, First Nation (FN), women 27-75 y. Descriptive statistics (means, medians and frequencies) were used to evaluate plasma 25(OH)D concentration, according to age, ethnicity, month of blood sample collection, and servings of milk consumed. The prevalence of vitamin D deficiency and percent that met various 25(OH)D concentration cut offs were evaluated. Data was analyzed using SAS 9.2 software.

Results: First Nation women had significantly lower median plasma 25(OH)D concentration than white women (47.0 vs. 65.0 nmol/L, p<0.0001; Table 1). Plasma concentration of 25(OH)D lower than 27.5 nmol/L was present among 9.8% of FN women and 4.1% of white women. Also, plasma concentrations lower than 37.5 nmol/L were present among 20.6% of FN women and 14.9% of white women. Similar to CHMS report, our results indicate that median (IQR) of plasma 25(OH)D concentration was lower in November- March than in April-October (48.0 (13.0-83.0) vs. 57.0 (13.0-111.0) nmol/L, p=0.04). Race and number of milk servings were significant contributors to plasma 25(OH)D concentration (Table 2).

Conclusion: There is higher prevalence of vitamin D deficiency (25(OH)D <27.5 nmol) and inadequacy (25(OH)D <37.5 nmol/L) among Aboriginal FN women, and younger women 25-39 y which could have detrimental consequences to bone health.

Table1. Plasma 25(OH)D concentration (nmol/L) based on ethnicity and age

| Age | FN | | Non-FN | |
|---------|------------------|-----|-------------------|-----|
| | Median (IQR) | n | Median (IQR) | n |
| Total | 47.0 (17.0-77.0) | 204 | 65.0 (28.0-102.0) | 147 |
| 25-39 y | 46.0 (15.0-77.0) | 100 | 54.0 (1.0-107.0) | 69 |

Bisphosphonate Use and Increased Incidence of Subtrochanteric Fracture in South Korea: Results from the National Claim Registry. Young-Kyun Lee*¹, Yong-Chan Ha², Chan Soo Shin³, Hyun-Koo Yoon⁴, Deog-Yoon Kim⁵. ¹Seoul National University Bundang Hospital, South Korea, ²Chung-Ang University Hospital, South Korea, ³Department of Internal Medicine, Seoul National University College of Medicine, South Korea, ⁴Cheil General Hospital & Women's Healthcare Center, South Korea, ⁵Kyung Hee University Hospital, South Korea

Background: Recently, atypical hip fractures in the subtrochanteric region have been reported among patients on bisphosphonate. However, the association between atypical hip fracture and bisphosphonate is controversial. We evaluated trends in the incidences of typical and atypical hip fracture in relation bisphosphonate use in Korea from 2006 to 2010, using nationwide data obtained from the Health Insurance Review and Assessment Service (HIRA)

Methods: All new visits or admissions to clinics or hospitals for a typical and atypical hip fractures were recorded nationwide HIRA using the ICD-10 code classification. To identify hip fractures, selected ICD-10 codes and a minimum cut-off value of 50 years were used. Typical hip fracture cases were defined as those requiring hospitalization with a primary diagnosis of femoral neck fractures or intertrochanteric fracture, and atypical hip fractures as those requiring hospitalization with a primary diagnosis of a subtrochanteric fracture. We limited the cohort to those patients that underwent one of the following 7 procedures; open reduction of fractured extremity-femur, closed pinning-femur, external fixation-pelvis/femur, closed reduction of fractured extremity-pelvis/femur, bone traction, skin traction, or hemiarthroplasty-hip. To determine trends in fracture incidences, the patients were categorized by age, gender, and fracture site (typical and atypical hip fracture). Annual Percentage Change for trends was used to determine whether fracture incidences changed from 2006 to 2010. (Joinpoint Regression Program, Version 3.5.2, Statistical Research and Applications Branch, National Cancer Institute, Bethesda, USA) Age-adjusted and gender-specific incidences from 2006 to 2010 were used in this analysis.

Results: The absolute number of typical and atypical hip fracture increased during the study period. Although age-adjusted incidence rates of typical hip fractures were stable in men and women, those of atypical hip fractures in women increased 4.1 % per year during the study period (95% CI, 0.5 to 7.9) (figure 1). Nationally, the annual numbers of prescriptions of bisphosphonate also increased during the study period (figure 2).

Conclusions: The results of this study suggest a possible causal relationship between bisphosphonate use and the increased incidence of atypical hip fracture in Korea.

SA0329

Changes in Health Related Quality of Life (HRQoL) after non-traditional fractures. Yu Zhang*¹, Kerrie Sanders², Julie Pasco³, Mark Kotowicz⁴.
¹University of Melbourne, Australia, ²The University of Melbourne, Australia, ³Deakin University, Australia, ⁴Deakin University School of Medicine, Australia

To date studies have focused mainly on HRQoL associated with hip, spine and distal forearm fractures. HRQoL at other fracture sites have been grossly under-investigated. The aim of this study was to investigate the HRQoL related to non-traditional fractures including ribs, pelvis, clavicle, humerus, forearm (other than distal), hand, femur, tibia/fibula (other than distal), ankle (including distal tib/and fib) and foot.

Participants were recruited from the Geelong Hospital (GH), the sole provider of emergency services in a city with a population of approximately 220,000, between June 2010 and November 2011. Those aged 50+yr who had sustained a radiologically confirmed low trauma fracture (e.g. fall from standing height or less) were invited to take part. High trauma (e.g. motor vehicle accident), multiple and pathological fractures were excluded (n=92). We also excluded people with cognitive disabilities (n=65), those who were unable to understand the questionnaire (n=37) and others (n=65). Using EQ5D questionnaire within 2 weeks of fracture, HRQoL immediately before and at the time of interview was measured. EQ5D repeated 4 months post fracture. Confidence intervals were estimated using bias-corrected accelerated bootstrap. Using multiple ordinary least square regression analysis, the impact of variables on HRQoL after fracture (age, gender, fracture-related hospital admission, fracture sites, time between first interview and fracture, and pre-fracture HRQoL) was assessed.

Among the 217 participants, there were 48 humerus, 64 ankle, and 60 weight-bearing (15 pelvis, 10 femur, 18 proximal and mid tibia/fibula, 17 foot) and 45 non weight-bearing (17 rib, 8 clavicle, 16 forearm, 4 hand) fractures. Impact of fractures on HRQoL is shown in table 1. Pre-fracture HRQoL (coefficient: -0.47, p<0.01) and hospital admission (coefficient: 0.08, p<0.01) had a significant impact on loss of HRQoL 4 months after fracture.

HRQoL declines immediately after fracture. Pre-fracture HRQoL had a negative impact upon HRQoL 4 months after fracture whereas hospital admission improves the HRQoL. These short term changes in HRQoL are comparable to those reported with hip, spine and distal forearm fractures.

Table 1: Mean HRQoL (95%CI) immediately before and after fracture, and 4 months after fracture

Gender-Specific Hip Fracture Risk In Community-Dwelling And Institutionalized Seniors Age 65 Years And Older. Eduard Sidelnikov*¹, Michael Finsterwald², Robert Theiler³, Andreas Egli Linder⁴, Andreas Platz⁵, Hans-Peter Simmen⁶, Christian Meier⁷, Daniel Grob⁸, Sacha Beck⁹, Hannes B. Stähelin¹⁰, Heike Bischoff-Ferrari¹¹.
¹University of Zurich, Switzerland, ²Centre on Aging & Mobility, University Hospital Zurich & City Hospital Waid, Switzerland, ³Stadtspital Triemli, Switzerland, ⁴Centre on Ageing & Mobility, Switzerland, ⁵Department of Traumatology, Triemli City Hospital, Switzerland, ⁶Department of Emergency Medicine & Traumatology, University Hospital Zurich, Switzerland, ⁷Div. of Endocrinology, Diabetes & Metabolism, University Hospital Basel, Switzerland, ⁸Centre on Aging & Mobility, University Hospital Zurich & City Hospital Waid; Acute Geriatric Care, City Hospital Waid, Switzerland, ⁹Acute Geriatric Care, City Hospital Waid, Switzerland, ¹⁰Department of Geriatrics, University Hospital Basel, Switzerland, ¹¹University of Zurich, Switzerland

Background: Differences in gender-specific hip fracture risk in community-dwelling versus institutionalized seniors have not been well established.

Methods: In our primary analysis, we included 1084 hip fracture patients age 65 and older admitted to one large hospital center in Zurich, Switzerland between January 2005 and March 2010 (Triemli City Hospital). Official population statistics from the same time frame was obtained from the Statistical Bureau of the City of Zurich. Information on living conditions prior to the hip fracture (community-dwelling versus institutionalized), age, sex, body mass index (BMI), season, cognitive function, and comorbid conditions was obtained in all patients. For a sensitivity analysis, we extended to de-personalized data from 1265 hip fracture patients from the other two large hospital centers (City Hospital Waid and Zurich University Hospital) within the same time frame (2005-2009) and available data on age, living conditions, and fracture date.

Results: Hip fracture patients of the primary sample were on average 85.1 (SD = 7.1) years old and 78% of them were women. Among community-dwelling seniors, the risk of hip fracture was more than twice as high for women compared to men (RR = 2.11; 95% C.I.: 1.65 – 2.70). Among institutionalized seniors, the risk of hip fracture was 35% higher for men compared to women (RR = 1.35; 95% C.I.: 1.06 – 1.72) independent of age, BMI, season, comorbidities, and cognitive function. Consistent with the literature, age was a strong predictor of hip fracture risk: compared to seniors age 65 – 74 years, the risk of hip fractures increased more than 5 times for age 75 – 84 (RR = 5.55; 95% C.I.: 4.33 – 7.12), and 12 times for age 85-94 (RR = 12.39; 95% C.I.: 9.57 – 16.05), and more than 20 times for seniors age 95+(RR = 20.77; C.I.: 14.61 – 29.51). In the sensitivity analysis among 2349 patients of all 3 hospitals, community-dwelling women had a 67% higher risk of hip fracture than community-dwelling men (RR = 1.67; 95% C.I.: 1.43 – 1.97); and institutionalized men had 40% higher risk than institutionalized women (RR = 1.40; 95% C.I.: 1.00 – 1.85) independent of age and season.

Conclusion: It is widely believed that women have greater risk of hip fractures than men. Based on our data, that is the case for seniors living in the community, however, among nursing home patients men may be at higher risk.

Occurrence of Previous Depression in Patients with Femoral Fracture in Pre-operative Phase. Fabiana Fonseca*¹, Ana Elisa Sena Klein Rosa², Segantin Bianca Isis², Priscila Primo Cáo², Thaise Arruda².
¹PUC - SP, Brazil, ²PUC-SP, Brazil

The relationship of the body in old age is very particular to each be. the objective of this study was to highlight the prevalence of depression in elderly 40 (thirty-one females and nine males) with fracture of femur in indication of surgical treatment in pre-operative stage, diagnosed with depression progresso serviced by the Hospital's Orthopedic Service of the São Paulo State Public Server. This is an observational study of cross-section. Data collection occurred with visit to patient records files and interviews structured way during the period October 2010 to February 2011. All statistical analyses were made by software Statistical Package for the Social Sciences for Windows, version 15.0. The survey was submitted to the Committee of ethics in research of Hospital Sao Paulo State civil servant and approved in April 2010. The age varied from 62 to 97 years, averaging equal to 78.9 years, dp of 9.5 years and median of 79 years, with the intention of crossing factors that concern the process of human aging, we got six seniors (15%) with a diagnosis of depression. For Gerontology, old age should be understood under different looks. With this study, we were able to note that a policy of Public Health is required to develop actions that are intended to identify situations that may be harmful to the elderly in relation to the increased risk of falls.

Prevalence of Fractures in Women with Rheumatoid Arthritis or Systemic Lupus Erythematosus on Chronic Glucocorticoid Therapy in Spanish Population. Maria Luz Rentero¹, Encarnación Amigo², Nicolás Chozas³, Manuel Fernández⁴, Susana Sarnago⁵. ¹Medical Department Lilly, Spain, ²Hospital de Lugo, Spain, ³Hospital Puerta del Mar, Spain, ⁴Hospital Sanitas La Moraleja, Spain, ⁵Eli Lilly & Company, Spain

Purpose: To determine the prevalence of vertebral and non-vertebral fractures in the Spanish population of women with diagnosis of rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE) on chronic glucocorticoid (GC) therapy.

Methods: This is a cohort, open-label, multicentric, non-drug interventional, descriptive and cross-sectional study to assess the prevalence of vertebral and non-vertebral fractures in women ≥ 18 yrs with ≥ 1 year diagnosis of RA or SLE, on chronic GC therapy ≥ 2.5 mg of prednisone [or equivalent] for at least 3 months. Information regarding the disease, time and dose of GC treatment, prevalent vertebral and non-vertebral fractures and patients quality of life (SF-36 questionnaire) was collected. All patients had a thoracic-lumbar spine radiography and FRAX evaluation.

Results: 39 sites in Spain participated in the study (n=605 women screened from those attending the rheumatologist's office for any reason and 592 enrolled), obtaining complete data for 575 women with a mean age of 59.6+15 yrs, BMI 26.8+4.8 and 73% were postmenopausal. 83.3% (n=480) were diagnosed of RA and 16.7% (n=95) of SLE. Only 6.4% of the study population referred prevalent vertebral fractures, but in fact we confirmed by X-ray their existence in up to 18.9% of the total of patients. 9% of them stated to have suffered at least one non-vertebral fragility fracture located mainly at the distal radius and proximal femur. Mean dose of GC was 5.6 mg+3.3 of prednisone [or equivalent] for a median of 6.3 yrs. FRAX evaluation revealed the presence of any previous fracture increased by ≥ 2.5 fold the risk of ten-year probability of major osteoporotic fracture [mean (SD)=22.7+14.50 vs 8.7+8.40 respectively] or hip fracture [mean (SD)=14.8+14.1 vs 3.9+6.7 respectively]. The scores of physical component and functioning SF-36 domains were significantly lower for patients with prevalent vertebral or any fractures vs those without previous fractures. The 66.7% of the studied population was on osteoporosis treatment, out of which 43.4% were on antiresorptive therapy and 2.1% were taking anabolic treatment (49% were on calcium or Vit D). **Conclusions:** Prevalence of vertebral fractures in this setting is 3-fold greater than doctors and patient assume, so it would be very important to increase the awareness in order to enhance diagnosis and fracture prevention. AR and SLE patients with prior fractures have worse quality of life and increased risk of fracture.

SA0334

Risk of Fracture among Treated and Untreated Men with Osteoporosis. Karen Smoyer Tomic¹, Joanne LaFleur², Liisa Palmer³, David M. Smith⁴, Carly Paoli⁵, Irene Agodoa⁶, Nicole Yurgin⁷. ¹Thomson Reuters, USA, ²University of Utah, USA, ³Thomson Reuters, USA, ⁴Thomson Reuters, USA, ⁵Amgen, USA, ⁶Amgen, USA, ⁷Amgen Inc., USA

Purpose: Osteoporosis (OP) affects an estimated 2 million men in the United States. The relationship between treatment and fracture outcomes has been reported from clinical trial populations, but little is known about the impact of treatment on fracture risk among men with OP in the real-world setting.

Methods: The *MarketScan*® Medicare Supplemental and Coordination of Benefits Database was used to identify treated (received an OP medication) and untreated (had an OP diagnosis or fragility fracture but no OP medication) men with OP between 1/1/04 and 4/30/10 and at least 12 months pre-period and 3 months post-period follow-up in the database. Patients were matched on pre-period fracture and age (± 2 years). Follow-up time was variable and ended with fracture, inpatient death, end of health plan eligibility, or on 4/30/10, whichever came first. Fracture incidence rates and time to fracture were reported. A Cox proportional hazards model was used to assess whether treated men had a lower risk of fracture compared to untreated men after controlling for demographic and clinical characteristics.

Results: Of the 3,072,696 men ≥ 65 years in the database, a total of 31,696 men met the inclusion and match criteria (15,848 in each cohort). In both cohorts, the mean age was 78 years and 55% had a pre-period fracture. 1,990 treated men had a follow-up fracture [incidence = 5.98/100 person-years (p-y)] over 33,274 p-y of follow-up, compared to 2,231 untreated men with a follow-up fracture (incidence = 8.03/100 p-y) over 27,785 p-y. Treated men also had longer mean time to fracture (588 days, SD 426) than untreated men (401 days, SD 372, $p < 0.001$). The adjusted risk of fracture was lower among treated men compared to untreated men (adjusted hazards ratio = 0.83, 95% CI: 0.78 to 0.89). Other pre-period factors associated with an increased risk of fracture were urban residence, no bone mineral density test, use of benzodiazepines, and a higher number of comorbidities and concomitant medications.

Conclusion: The fracture incidence rate was lower and time to fracture was longer for men with OP who received treatment than for those without treatment. After

controlling for prior fracture and other risk factors, treated men had a lower adjusted risk of fracture. To better characterize the benefit of OP treatment, more research is needed into the role of medication adherence and risk of fracture among men with OP.

SA0335

Sex Steroid Hormones and Fracture in a Multi-ethnic Cohort of Women: The Women's Health Initiative (WHI). Jane Cauley¹, Michelle Danielson², Robert Boudreau³, Tanushree Prasad³, Douglas Bauer⁴, Rebecca Jackson⁵, Jean Wactawski-Wende⁶, Rowan Chlebowski⁷, Kristine Ensrud⁸. ¹University of Pittsburgh Graduate School of Public Health, USA, ²University of Pittsburgh, USA, ³University of Pittsburgh, USA, ⁴University of California, San Francisco, USA, ⁵The Ohio State University, USA, ⁶University at Buffalo, USA, ⁷University of California, Los Angeles, USA, ⁸Minneapolis VA Medical Center / University of Minnesota, USA

Sex steroid hormones have been linked to the risk of hip fracture. To our knowledge, however, all of these studies have been carried out in White women. The objective of the current analysis was to test the hypothesis that sex steroid hormones influence the risk of fracture across race/ethnicity. We performed a nested case-control study within the prospective WHI Observational Study. Fractures were self-reported except for hip fractures. We excluded spine, facial and digit fractures. Incident fractures were identified in 381 Black, 192 Hispanic, 112 Asian, and 46 Native American women over an average of 8.6 years. A random sample of 400 White women who fractured was chosen. One control was selected per case and matched on age, race/ethnicity, and blood draw date. Serum bioavailable estradiol (BioE₂), testosterone (BioT) and sex hormone-binding globulin (SHBG) were measured using baseline fasting serum. Conditional logistic models were used to calculate the odds ratio (OR) and 95% confidence interval (CI). Tertile cutoffs were determined in the total sample of controls. The mean age of the women across ethnicity ranged from 63-66 yrs. Comparison of median sex hormones among controls showed that BioE₂ (pg/ml) levels were lowest in Asian women (5.3) and highest in Black and Native American women (8.1). Median BioT (ng/dL) levels were also lowest in Asian women (9.5) and highest in Black women (12.1). Median SHBG (nmol/L) levels were lowest in Black women (37.9) and highest in White women (48.1). In multivariable adjusted models, higher BioE₂ was associated with a decreased risk of fracture among White and among Black women. Higher BioT was associated with a lower risk of fracture in Black women but it was not significant in White women. Increasing SHBG was associated with a lower risk of fracture in Whites but a higher risk of fracture in Blacks (p race x SHBG interaction = 0.004). There was no association between sex steroid hormones and fracture in the other ethnic groups except higher BioT was associated with a lower risk of fractures in Native American women; OR per 1 standard deviation increase in BioT = 0.20(0.05, 0.76). In conclusion, serum E₂ is an important biomarker for fracture risk in both White and Black women. Testosterone levels appear to have greater influence on fracture risk in Black and Native American women. The differential association between SHBG and fracture in Whites and Blacks needs replication.

Table: Odds ratio (95% CI) of fracture across tertiles of sex steroid hormones

| | White ^{1,2,3} | | | | | | Black ^{1,2,3} | | | | | |

The Contributions of First Nations Ethnicity, Income, and Delays in Surgery on Mortality Post-fracture: A Population-based Analysis. William Leslie¹, Sharon Brennan², Heather Prior³, Lisa Lix⁴, Colleen Metge¹, Brenda Elias⁵. ¹University of Manitoba, Canada, ²The University of Melbourne, Australia, ³University of Manitoba, Canada, ⁴University of Saskatchewan, Canada, ⁵University of Manitoba, Canada

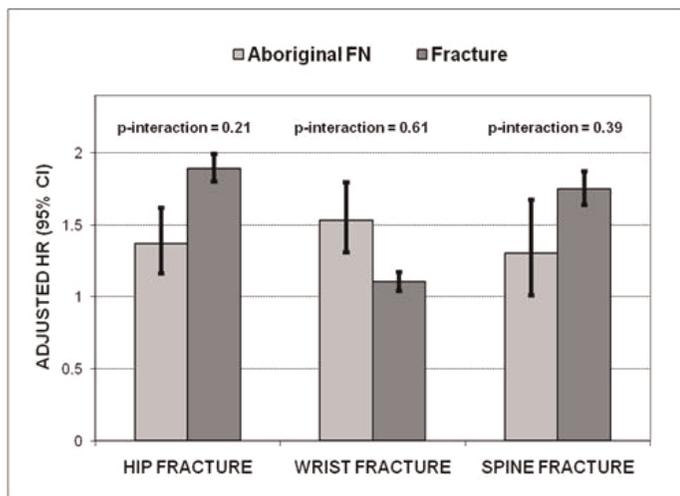

Purpose: Social determinants may influence post-fracture mortality risk. First Nations peoples are the largest group of Aboriginal (Indigenous or Native) peoples in Canada, and have a greater risk of fracture, and of mortality, than non-First Nations peoples. The purpose of this study was to examine the independent contributions of First Nations ethnicity and income to post-fracture mortality, and the association with time to surgery following hip fracture.

Methods: We used a retrospective case-control design in which non-traumatic fracture cases and fracture-free controls from Manitoba, Canada, aged ≥ 50 years

were matched for sex, age (within 5 years of birth), First Nations ethnicity, and number of co-morbid conditions. We examined differences in mortality after fracture of (i) the hip, wrist or spine between the years of 1996-2004 (Study Population 1), and (ii) the hip between the years of 1987-2002 (Study Population 2). Cox proportional hazards regression was used to model time to death. For hip fracture, logistic regression analyses were used to model the probability of death within 30 days and one year of fracture.

Results: In Study Population 1, First Nations ethnicity was associated with an increased mortality risk of 30-53% for each type of fracture, but there was no statistically significant interaction between fracture status (case-control), and First Nations ethnicity for any of the fracture types (all $p > 0.2$, Figure). Lower income was associated with an increased mortality risk of 18% for both hip and vertebral fracture, and of 26% for wrist fracture. In Study Population 2, lower income predicted mortality overall (OR 1.15, 95%CI 1.07-1.23) and for hip fracture cases (OR 1.18, 95%CI 1.05-1.32), as did older age, male sex, diabetes and >5 co-morbid conditions (all $p \leq 0.01$). Higher mortality was also seen for a pertrochanteric fracture (OR 1.14, 95% CI 1.03-1.27), surgery times of 2-3 days (OR 1.34, 95%CI 1.18-1.52) or ≥ 4 days (OR 2.35, 95%CI 2.07-2.67) after fracture.

Conclusion: Given that First Nations peoples have a higher baseline mortality compared to non-First Nations peoples, a similar relative increase in mortality associated with fracture appears to translate into a larger absolute increase in post-fracture mortality. Lower income and surgery times of >2 days are predictors of an increased mortality risk post-fracture. These data have implications regarding the prioritization of health care delivery.

No interactions between fracture status (case-control) and First Nations ethnicity

Genome-Wide Association Study Identifies the Chromosome 1q23 Gene UHMK1 as a Novel Bone Mass Density Susceptibility Gene. Hyung Jin Choi¹, Ye An Kim², Joo-yeon Hwang³, Lei Zhang⁴, Yu-fang Pei⁴, Jian Li⁵, Qing Tian⁵, Hong-Wen Deng⁶, Ah Reum Khang⁷, Jung Hee Kim⁸, Sang Wan Kim⁹, Jong-Young Lee¹⁰, Bok-Ghee Han¹⁰, Seong Yeon Kim⁷, Nam H Cho¹¹, Chan Soo Shin². ¹Chungbuk National University Hospital, South Korea, ²Department of Internal Medicine, Seoul National University College of Medicine, South Korea, ³Republic of Korea, ⁴Center of System Biomedical Sciences, University of Shanghai for Science & Technology, China, ⁵Tulane University, USA, ⁶Tulane University, USA, ⁷Department of Internal Medicine, Seoul National University College of Medicine, South Korea, ⁸Seoul National University College of Medicine, South Korea, ⁹Seoul National University Boramae Hospital, South Korea, ¹⁰Center for Genome Science, National Institute of Health, South Korea, ¹¹Department of Preventive Medicine, Ajou University School of Medicine, South Korea

Most large-scale genome-wide association studies (GWAS) of bone mineral density (BMD) have been focused on Caucasian populations. Caucasians and Asians are two distinct ethnic groups, with appreciable ethnic difference in genetic background and osteoporosis related phenotypes. To identify genetic variants that influence BMD in East Asians, we performed a quantitative trait analysis of total hip, femoral neck and lumbar spine BMD in 2729 unrelated subjects from population-based cohorts in Korea. Then, in silico replication of promising GWAS signals were performed in a Chinese Han population and two Caucasian populations (1547, 2250 and 987 subjects, respectively). We identified three BMD loci that reached

genome-wide significance ($P < 5 \times 10^{-7}$), of which one locus on 1q23 (UHMK1, rs16863247, $P = 4.1 \times 10^{-7}$ for femoral neck BMD and $P = 3.2 \times 10^{-6}$ for total hip BMD) was novel, not previously associated with bone phenotypes. Interestingly, the minor allele frequency (MAF) of rs16863247 was very low in Caucasian populations (MAF < 0.01), indicating that this association could be specific to East Asians. Two SNPs (rs9371538 and rs1856859) in the known BMD region on 6q25 (C6orf97/ESR1) were associated with lumbar spine BMD ($P = 5.6 \times 10^{-9}$ and $P = 9.4 \times 10^{-9}$, respectively). One SNP (rs7776725) in the known BMD region on 7q31 (FAM3C) was associated with total hip BMD ($P = 8.6 \times 10^{-9}$) and femoral neck BMD ($P = 1.3 \times 10^{-6}$). In gender specific analysis, one SNP (rs1160574) on 1q32 (KCNH1) was associated with femoral neck BMD ($P = 2.1 \times 10^{-7}$) and total hip BMD ($P = 2.2 \times 10^{-7}$) in female subjects. UHMK1 encodes a serine/threonine protein kinase KIS (Kinase Interacting with Stathmin). Interestingly, a recent report demonstrated that Stathmin plays an important role in the maintenance of bone mass by regulating osteoblast and osteoclast functions. Our results identify the UHMK1 gene as a candidate for East Asian specific BMD loci.

The Influence of Educational Interventions on Modifiable Risk Factors for Osteoporosis After a Fragility Fracture. Louis Bessette¹, Claudia Beaudoin², Sonia Jean³, Louis-Georges Ste-Marie⁴, Jacques Brown⁵. ¹Centre Hospitalier De L'Universite Laval, Canada, ²Crchuq Research Centre-chul, Canada, ³INSTITUT NATIONAL DE SANTÉ PUBLIQUE DU QUÉBEC, Canada, ⁴CHUM, Canada, ⁵CHUQ Research CentreLaval University, Canada

Purpose: To investigate the effect of educational interventions on modifiable risk factors for osteoporosis in women (>50 old) after a fragility fracture (FF).

Methods: This study was part of the Recognizing Osteoporosis and its Consequences in Quebec (ROCQ) programme. Women who recently suffered a FF were recruited from hospitals and from an administrative database-generated list (Quebec Ministry of Health). Six to eight months after FF, women were contacted to complete questionnaires and were randomized into the control group (usual care group) or the intervention groups (written materials or videocassette + written materials). The written materials consisted of information for both the patient and their respective primary care physician regarding osteoporosis, FF and the need for treatment following FF. The 15-minute video consisted of similar information as the written materials, but went into greater depth. Women in the usual care group were told that their fracture was related to osteoporosis but did not receive the educational tools. Twelve months following randomization, follow-up questionnaires were completed. The proportion of women who improved their behavior for dietary calcium, physical activities, and alcohol and caffeine consumption 12 months after randomization were compared between usual care and intervention groups. Both intervention groups were combined for this analysis.

Results: In this analysis, we included 1,175 women (387 control, 788 interventions) with neither a diagnosis nor treatment for osteoporosis at randomization. No statistically significant difference was detected between the two groups (table).

Conclusions: When comparing the usual care group to the intervention groups, we cannot conclude that the interventions lead to statistical significant changes in the women's behavior. Therefore, a simple educational intervention on osteoporosis is not sufficient to influence life style in women who have recently suffered a FF.

| Outcome | Randomization group | % improving their behavior | P-value |
|--|---------------------|----------------------------|---------|
| Increase in dietary calcium consumption (mg/day) | Control | 45.9 | 0.142 |
| | Interventions | 50.6 | |
| Increase in time spent walking (hours/week) | Control | 24.2 | 0.686 |

Abdominal Aortic Calcification is Associated with Vertebral Fractures Independent of Bone Mineral Density in Patients with Type 2 Diabetes. Noriko Ogawa-Furuya^{*1}, Masahiro Yamamoto², Masayuki Shinohara³, Toru Yamaguchi⁴, Toshitsugu Sugimoto⁵. ¹Shimane University Faculty of Medicine, Japan, ²Shimane University Faculty of Medicine, Japan, ³Hosogi Hospital, Japan, ⁴Shimane University Faculty of Medicine, Japan, ⁵Shimane University School of Medicine, Japan

Introduction: Meta-analyses study shows that hip fracture risk of type 2 diabetes mellitus patients (T2DM) is higher than that estimated by bone mineral density (BMD). We also reported that T2DM have an increased risk of vertebral fractures (VFs) despite increased their BMD. These results suggest that it is difficult to assess fractures risk by BMD in T2DM. Thus, investigation of other risk factors for VFs in T2DM is needed. Vascular calcification is known to be associated with osteoporosis in non-T2DM subjects. However, association between the presence of vascular calcification and VFs in T2DM still remains unclear. The aim of this study is to investigate whether or not the abdominal aortic calcification is involved in VFs in T2DM.

Methods: A total of 163 Japanese men and 196 postmenopausal women with T2DM (average age: 65 and 66; HbA1c: 8.9% and 8.9%; number of vertebral fracture: 66 and 61, respectively) were recruited. All subjects were over age 50, and whose creatinine levels were within normal range. We measured BMD at the lumbar spine, femoral neck, and radius 1/3, and evaluated VFs by thoracic and spinal radiographs. The abdominal aortic calcification scores (ACS) were assessed on lateral 1st to 4th lumbar spine radiographs by semiquantitative method of Frye et al. We analyzed a cross-sectional association between the presence of ACS and VFs.

Results: ACS of the VFs group in each sex were significantly higher than those of non-VFs group (Men: 2.7 ± 3.3 vs. 1.5 ± 2.3 , $P < 0.01$; Women: 3.1 ± 5.7 vs. 1.1 ± 2.6 , $P < 0.01$). ACS 3 or more was significantly increased risk for VFs in both genders compared with AAC 2 or less after adjustment for age, BMI, creatinine, HbA1c, duration of T2DM, LDL-cholesterol, Neck BMD, calcium, phosphate, BAP, and smoking [Men: odds ratio (OR) 2.67 (95% confidential interval (CI) 1.23-5.77), $P < 0.05$; Women: OR 2.80 (95% CI 1.14-6.87), $P < 0.05$].

Conclusions: These findings showed that ACS were associated with VFs independent of BMD in T2DM in both sexes, suggesting that abdominal aortic calcification may be linked to deteriorating bone quality and become a risk factor for VFs in T2DM.

Mortality of Non-respondents in a Population-based Cohort (OSTPRE) Study. Risto Honkanen^{*1}, R. Sund², Marjo Tuppurainen³, Heli Koivumaa-Honkanen⁴, Heikki Kröger⁵. ¹University of Eastern Finland, Finland, ²National Institute for Health & Welfare, Finland, ³Kuopio University Hospital, Finland, ⁴Kuopio University Hospital, lapland Hospital district, Finland, ⁵University of Eastern Finland, Finland

Nonresponse is a menace to the representativeness of a study. The Kuopio Osteoporosis Risk Factor and Prevention (OSTPRE) Study targeted to recruit all women (14220) born in 1932-41 and living in a defined geographic area in Eastern Finland in 1989. A high response (91 %) was achieved: 13100 responded. The cohort has now been followed for 20 years 1989-2009.

The purpose of this study was to compare the 20-year mortality of the non-respondents to that of the respondents. The Kaplan-Meier survival analysis was used.

A total of 1975 women died during the follow-up. The mortality of the non-respondents was double compared to that of the respondents (Figure). The most common causes of death were cancer 706 (42.9 %) vs. 89 (27.1 %), cardiovascular disease 533 (32.4 %) vs. 140 (42.7 %) and injury 110 (6.7 %) and 20 (6.1 %) for the respondents vs. non-respondents, respectively.

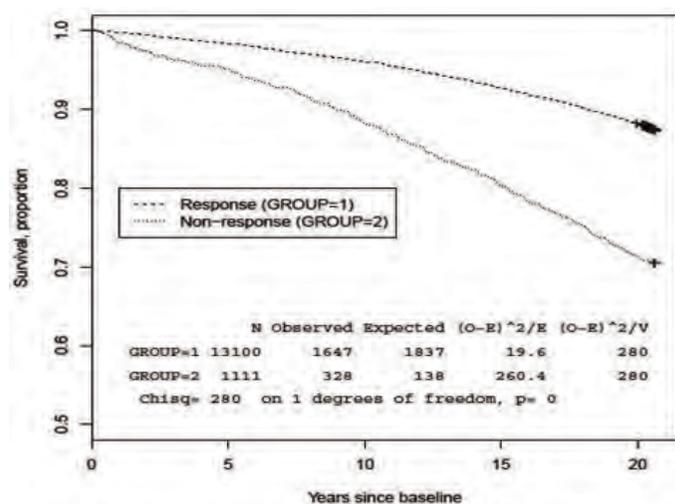

Figure 1.

Conclusions. Morbidity and mortality of non-respondents are higher than those of respondents. This may affect prevalence and risk factor effect estimates.

Trabecular Bone Micro-Architecture during SSRI Treatment Using Multi-Detector CT Imaging and Topological Analysis on a Continuum between Plates and Rods. Punam K. Saha^{*1}, CHADI CALARGE¹, Cheng Li¹, Yinxiao Liu², Jessica Fishbaugher², Bille Tyler², Nichole Baker², Trudy Burns², Kathleen Janz¹, James Torner², Steven Levy¹. ¹University of Iowa, USA, ²University of Iowa, USA

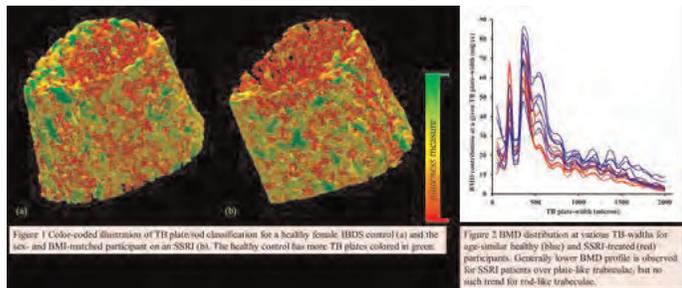

Background: Recent evidence has implicated serotonin in bone metabolism and selective serotonin reuptake inhibitors (SSRIs) in bone-loss and increased fracture-risk. Trabecular bone (TB) micro-architecture is a strong determinant of bone-strength and fracture-risk, yet, to our knowledge, it has not been characterized in SSRI-treated patients. We recently developed a peripheral high-resolution multi-detector CT (MD-CT)-based algorithm that generates unique TB micro-architectural measures by classifying individual trabeculae on a continuum between plates and rods. This algorithm was applied in a pilot study exploring TB micro-architecture in young adults receiving long-term SSRI treatment.

Methods: Seven patients (18-23 years, 2 male/5 female) on continuous treatment with an SSRI for at least one year were recruited (mean treatment duration: 3.3 ± 3.0 years; mean fluoxetine-equivalent dose: 36 ± 13 mg/day); seven sex- and body mass

index (BMI)-matched age-similar controls were selected from the Iowa Bone Development Study (IBDS) cohort. MD-CT scans of the distal tibia were acquired on a 128 slice Siemens Flash scanner at 120kV, 200mAs, pitch: 1, 0.3mm slice-thickness and 10cm scan-length (total effective dose: 0.17mSv \approx 20 days of environmental radiation). A Gammex calibration phantom was used to transform CT Hounsfield unit into BMD (mg/cc).

Results: Figure 1 compares color-coded TB plate/rod classification for a healthy female IBDS control and the matched citalopram-treated participant. It suggests that the healthy control has more TB plates (green). Figure 2 depicts BMD distribution at various TB-widths for healthy (blue) and SSRI-treated (red) participants, showing a generally lower BMD profile for SSRI patients at plate-widths greater than 400 μ m, i.e., plate-like trabeculae, but no such trend at lower plate-widths representing rod-like trabeculae. In fact, a pairwise comparison between healthy controls and matched SSRI-treated participants showed 1.7% ($p=0.017$) lower total BMD in the SSRI-treated participants. In particular, compared to controls, mean TB plate-width was 5.5% ($p=0.164$) lower and BMD at plate-like trabeculae was 24.5% ($p<0.002$) lower in the SSRI group.

Conclusion: Long-term SSRI treatment may be associated with magnified TB micro-architectural alterations. Our preliminary findings require confirmation in a larger sample, where the potential confounding skeletal effect of psychopathology is accounted for.

Bone Health in CHARGE syndrome. Leila Khan^{*1}, Mariam Stevens², Krupa Doshi¹, Susan Williams³, Angelo Licata³. ¹Cleveland Clinic, USA, ²Cleveland Clinic, USA, ³Cleveland Clinic Foundation, USA

CHARGE syndrome first recognized in 1979 is a cluster of congenital abnormalities characterized by coloboma, heart defects, choanal atresia, growth retardation, genital hypoplasia, and ear anomalies (1). It has an estimated population-based incidence of 1/9,000 live births (2). The clinical diagnosis is made from identification of the major features of syndrome described above. Although several genetic abnormalities have been documented, a mutation on the CHD7 gene on chromosome 8q12 represents the likely cause for most affected patients (3, 4).

A 25 year old woman with CHARGE syndrome presented to endocrine clinic for evaluation of amenorrhea. Her evaluation revealed absent puberty with primary amenorrhea, complete vision loss in left eye, bilateral hearing loss, and history of surgically corrected congenital heart defects. She denied fractures and back pain, and she used no vitamin or mineral supplements. She was Tanner stage two, had scoliosis, and was short statured compared to other family members. Laboratory evaluation revealed hypogonadotropic hypogonadism with low levels of FSH and estradiol, and normal parathyroid, 25 OH vitamin D, and electrolyte levels. Calcium phosphorus product was 40 mg/dL. Bone density z-score was less than -1.5 in lumbar spine and both bilateral hips, and pelvic ultrasound revealed hypoplastic uterus and absent ovaries. Gene testing was positive for heterozygous mutation in the CDH7 gene. Other biochemical indices were normal. Treatment plan includes initiation of oral contraceptive, calcium and vitamin d replacement, and weight bearing exercise.

Individuals with CHARGE syndrome are at increased risk of developing low bone mass. In a longitudinal cohort study, questionnaires were collected from caregivers of 30 individuals with CHARGE. Results indicated that most had delayed or absent puberty with the majority not receiving hormone replacement therapy, receiving diets markedly deficient in calcium and vitamin D, and performing in less weight bearing physical activity as compared to controls (5). It is important to recognize the skeletal consequences of CHARGE since many are unaware of the risks towards poor bone health.

Hypophosphatasia Diagnosed in Adults: Differential Features Based on Sex, Presence of Fractures, and Symptoms at Presentation. Kathryn Berkseth¹, Peter Tebben², Matthew Drake³, Robert Wermers^{*4}. ¹University of Washington, USA, ²Mercy Clinic, USA, ³College of Medicine, Mayo Clinic, USA, ⁴Mayo Clinic, USA

Introduction: Adult hypophosphatasia (HPP) is a rare disorder characterized by low serum alkaline phosphatase (AP) levels. Limited data exists regarding the clinical presentation of HPP diagnosed in adults.

Aim: To evaluate the clinical and biochemical characteristics of adult HPP based on sex, presence of fractures, and symptoms at presentation.

Methods: Mayo Clinic Rochester patients diagnosed with HPP as adults from 1976 through 2008 were identified by diagnostic code or the medical record. Inclusion criteria were: age \geq 18 years at diagnosis; low serum AP without bisphosphonate therapy; and one additional supporting element including elevated pyridoxal 5'-phosphate (PLP) or urine phosphoethanolamine (PEA), evidence of osteomalacia (pseudofracture or stress fracture), family history, or positive genetic testing.

Results: Over the 33 year period reviewed, 22 unrelated adults were diagnosed with HPP. Median age at diagnosis was 49 years; 68% were female. Most patients (68%) were symptomatic at presentation with primary features including musculoskeletal pain (41%) or fracture (18%). Overall, 54% of patients had a history of fracture as an adult: hip/femoral neck (23%), feet (23%, all women), wrist (18%), and spine (9%, all men). Nine patients (36%) had multiple fractures, while four (all women) had subtrochanteric femur fractures. Femoral pseudofractures were observed in 2 patients; one each in a male and female. Chondrocalcinosis was only identified in women (40%). Symptomatic subjects had more fractures and chondrocalcinosis, lower median alkaline phosphatase and PLP levels, and higher median PEA levels, compared to asymptomatic patients. Clinical features seen more commonly in fracture patients included the presence of symptoms at presentation, a history of childhood rickets, dental abnormalities, lower median alkaline phosphatase levels, and higher median urine PEA levels. Conversely, median PLP levels were higher in subjects without a history of fracture.

Conclusion: Adult HPP demonstrates a wide spectrum of clinical manifestations including musculoskeletal pain, fractures, chondrocalcinosis and dental anomalies. Some overlap in laboratory characteristics exists in relationship to disease severity. In addition to genetic and environmental factors, sex may influence the clinical expression of HPP.

System-level Approaches to the Secondary Prevention of Osteoporotic Fractures: A Systematic Review and Meta-analysis. Kirtan Ganda¹, Markus Seibel^{*2}, Michele Puech³, Jian Sheng Chen⁴. ¹Concord Hospital, Australia, ²Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, ³Public Health Unit, Hornsby Ku-ringai Hospital, Australia, ⁴Institute of Bone & Joint Research, The University of Sydney, Australia

Introduction: Despite the availability of effective treatments that reduce re-fracture and mortality rates in patients presenting with incident osteoporotic fractures, the majority of these patients are not being assessed or treated for osteoporosis. In the past, numerous clinical care pathways have been trialed to close this treatment gap. We evaluated the effectiveness of published system-level care approaches for the secondary prevention of fractures in patients with osteoporosis.

Methods: We searched eight medical literature databases using relevant key words to identify reports published between 1996 and 2011, describing clinical or system-level care models for secondary fracture prevention. The following information was extracted from each publication by two independent researchers: Study design, patient characteristics, identification strategies, assessment and treatment initiation strategies and outcome measures (rates of BMD testing, anti-resorptive treatment initiation, re-fractures, and cost-effectiveness). The outcomes within each model of care were analysed in two ways: Firstly, we conducted meta-analyses of studies with valid control groups for two outcome measures, BMD testing and anti-resorptive treatment initiation. Secondly, we described the outcomes of studies not included in the meta-analysis, stratified by the model of care.

Results: The literature search identified 43 studies and re-grouped them into four general models of care: Type A, where patients are identified, assessed and treated as part of a fully integrated service; Type B, as in A, but the service only makes treatment recommendations (no initiation of therapy); Type C, which consists of patient education plus alerting the primary care physicians to the need for further assessment and treatment; Type D, consists of patient education only. The meta-analyses showed a trend towards better rates of BMD testing and treatment initiation with increasing intensity of intervention (table). Only five studies examined re-fracture rates but only one Type A had a control group and enough power to show a significant decrease in

re-fractures at 4 years follow-up. Type A & B services have been shown to be cost-effective.

Conclusions: Fully co-ordinated system-level approaches to secondary prevention of osteoporotic fractures appear more effective in improving patient outcomes than approaches involving alerts and/or education only, whilst still being cost-effective.

| Intervention Type | Risk Difference | 95% Confidence Interval |
|---------------------------|-----------------|-------------------------|
| Model of care 'A' (n = 8) | 0.29 | 0.19 - 0.40 |
| Model of care 'B' (n = 5) | 0.21 | 0.05 - 0.37 |
| Model of care 'C' (n = 7) | 0.16 | 0.07 - 0.25 |
| Model of care 'D' (n = 1) | 0.03 | 0.00 - 0.07 |

Serum Sclerostin Levels Positively Correlate with the Expanded Disability Status Scale in Ambulatory Women with Multiple Sclerosis. Vit Zikan^{*1}, Ivan Raska Jr¹, Michaela Tyblová², Maria Luchavova¹, Eva Havrdova², Dana Michalska¹. ¹Department of Internal Medicine III- Department of Endocrinology & Metabolism, First Faculty of Medicine, Charles University in Prague & General University Hospital in Prague, Czech Republic, ²Department of Neurology, First Faculty of Medicine, Charles University in Prague & General University Hospital in Prague, Czech Republic

Background: The progressive immobilization, namely walking impairment is one of the most life-limiting consequences of multiple sclerosis (MS) and the most important risk factor for osteoporosis and fractures. Sclerostin, a major inhibitor of Wnt signaling and bone formation, is regulated by mechanical strain and may play a role in the pathogenesis of disuse bone loss. The aim was to evaluate the relationship between serum sclerostin levels and motor disability (assessed by Expanded Disability Status Scale, EDSS), bone mineral density (BMD) and biochemical markers of bone remodeling in ambulatory women with MS. Methods: We measured serum sclerostin levels in 120 ambulatory MS women with EDSS \leq 6.5, aged 25 to 68 years and in healthy controls. Carboxy-terminal telopeptide of type I collagen, N-terminal propeptide of procollagen type I (PINP) were evaluated by ECLIA. Sclerostin was evaluated by ELISA. Results: The ambulatory women with motor disability (EDSS $>$ 3.5) had significantly higher serum sclerostin levels than fully ambulatory women with EDSS \leq 3.5. The serum sclerostin levels correlated positively with EDSS when controlled for age in both pre- and postmenopausal women with MS ($p < 0.001$) and negatively with serum PINP ($p < 0.01$) in premenopausal women. There was no relationship between serum sclerostin and BMD after controlling for age or EDSS. Conclusion: Our results represent the first study of circulating sclerostin levels in MS. The motor disability in ambulatory women with MS is associated with a higher sclerostin levels and with reduced bone formation. Further studies are needed to evaluate the role of sclerostin on bone remodeling and bone mass in this population.

Disclosures: Vit Zikan, None.

New Onset Diabetes Mellitus After Liver Transplantation. Relationship With 25-hydroxyvitamin D Levels And Serum Osteocalcin. Fernando Sotillo¹, Guillermo Martinez Diaz-Guerra^{*2}, Raquel Sánchez-Windt¹, Mercedes Aramendi¹, Elena García¹, Federico Hawkins³, Enrique Moreno¹. ¹University Hospital 12 de Octubre, Spain, ²University Hospital 12 Octubre, Spain, ³Hospital Universitario, Spain

Liver transplantation (LT) patients are at high risk of developing new-onset diabetes after transplantation (NODAT), but risk factors are still unknown. Experimental data have shown that Vitamin D receptors are present in pancreatic beta cell, and low levels of vitamin D have been linked with insulin resistance and metabolic syndrome. In addition, osteocalcin-deficient animals are hyperglycaemic, hyperinsulinaemic, and have decreased insulin sensitivity and increased fat mass.

The objectives of our study are firstly to investigate the prevalence of NODAT and abnormal glucose tolerance in LT patients followed up in our hospital and secondly to analyze serum osteocalcin and 25-hydroxyvitamin levels (25OHD) and their relationship with glucose tolerance and insulin resistance.

Methods: 71 patients (52 males, 19 females) with orthotopic liver transplantation without known diabetes mellitus before this procedure were studied. Mean age was 58.2 ± 11.3 years (range 21-78). Minimum time since LT was 6 months and mean time since LT was 9.2 years. An oral tolerance test with 75 g of glucose (OTTG) was performed, measuring plasma glucose, C-peptide and insulin at baseline, 60 and 120 minutes. Biochemical parameters included glycated hemoglobin (HbA1c), serum osteocalcin (total), and 25-OHD. Insulin resistance index (HOMA-IR) and insulin sensitivity index (Quicki) were calculated.

Results: Diabetes Mellitus (NODAT) was present in 19.7% (n=14), and prediabetes in 33.8% (n=24) (ADA 2011 criteria). 46.5% (n=33) had normal glucose tolerance (NGT) after LT. Vitamin D deficiency (<20 ng/ml) was present in 40%, and 70% had 25-OHD below 30 ng/ml. Serum osteocalcin and 25-OHD were not statistically different across NGT, prediabetes and NODAT patients. HOMA-IR

index was significantly higher in prediabetes ($p < 0.001$) and diabetes ($p = 0.014$) compared with NGT. Insulin sensitivity index was significantly lower in prediabetes ($p < 0.001$) and diabetes ($p < 0.01$) compared with NGT. No significant correlations between osteocalcin, 25OHD and HOMA-IR or Quicki index were found.

Conclusion: The study seems to indicate that diabetes mellitus is more prevalent in patients with liver transplantation (NODAT) than in average Spanish population and that vitamin D insufficiency is also frequent. However, no significant association has been established between serum total osteocalcin and 25OHD with diabetes mellitus or impaired glucose tolerance after liver transplantation.

SA0359

Study of Bone Quality at the Time of Lung Transplant in Cystic Fibrosis Patients Using Rib Specimens. Louis-Georges Ste-Marie^{*1}, Natalie Dion¹, Pasquale Ferraro², Caroline Albert¹, Nathalie Bureau², Audrav Fortin², Valérie Jomphe², Larry Lands³, Genevieve Mailhot⁴. ¹CHUM, Canada, ²CHUM, Canada, ³MUHC-Montreal Children's Hospital, Canada, ⁴Research Center CHU Sainte-Justine/University of Montreal, Canada

Nowadays, the median life expectancy of cystic fibrosis (CF) patients exceeds 45 years of age. As CF patients get older, secondary morbidities superimpose on pre-existing complications thereby worsening the patient's condition. One of the leading complications is thoracic fractures which seriously undermine the patient's quality of life. Despite its high prevalence, pathogenesis of CF related bone disease (CFBD) remains poorly understood and predicting individuals at increased risk of fracture is especially difficult given that bone mineral density (BMD) is considered a poor predictor of fractures in CF. As bone strength is determined by bone quantity and bone quality, it is reasonable to postulate that alterations in bone quality will likely contribute to the propensity to fractures in CF patients. The aim of this pilot study is to use various techniques to assess bone quality in CF patients. During lung transplantation in CF patients as well as in non-CF patients, a 2 cm segment of one rib (either the 5th or 6th) is routinely removed. These specimens were recovered to perform the following analyses: *ex vivo* BMD by DXA, high resolution micro-CT, microcrack detection and bone histomorphometry. In the last 8 months, 12 specimens were collected [6 CF: $30.3 \pm 2.1y$ and 6 non-CF (various non-CF lung diseases): $56.8 \pm 2.3y$]. There was no difference in *ex vivo* BMD (0.17 ± 0.02 vs $0.18 \pm 0.03g/cm^2$) between the two groups. However, micro-CT data in CF patients showed a significant greater BV/TV (8.79 ± 0.8 vs non-CF: $5.58 \pm 0.65\%$; $p = 0.01$) Tb.N (0.51 ± 0.06 vs non-CF: $0.3 \pm 0.03/mm$; $p = 0.007$) and Conn.D (2.76 ± 0.4 vs non-CF: $1.64 \pm 0.28/mm^3$; $p = 0.04$) whereas Tb.Sp was lower (1.06 ± 0.11 vs non-CF: $1.67 \pm 0.14mm$; $p = 0.007$). No major differences in other microstructure indices (SMI, Tb.Th) or in cortical parameters were found between CF and non-CF patients. The differences observed in trabecular bone density and microstructure are, among other factors, due to the younger age of the CF group. With a greater number of CF patients, correlations between bone parameters (density, microstructure, microcracks, bone remodeling) and clinical parameters of CFBD (fractures, BMI, bisphosphonates and glucocorticoids use) as well as biochemical indices will be investigated and data will be presented. This exploratory study has shown the feasibility of using rib specimens to assess bone quality in patients undergoing lung transplantation.

Evaluation of the Densitometric Response at 12 and 24 Months after Strontium Ranelate (SR) Treatment, in Patients Previously Treated with Bisphosphonates (BP). Laura Maffei¹, Maria Valeria Premrou^{*2}, Carolina Pelegrin². ¹Consultorios Asociados De Endocrinologia, Argentina, ²no, Argentina

Introduction: Many patients with severe osteoporosis need a long treatment, and frequently it is necessary to change the scheme of treatment to minimize side effects. We have already published a densitometric improvement after one year of treatment with SR in patients previously treated with BP.

Objectives: To evaluate the densitometric response after 12 and 24 months of treatment with SR. And then, if there is any difference in densitometric response between 12 and 24 months.

Material and methods: Postmenopausal patients who had received more than 3 consecutive years of BP treatment, with worsening or maintenance of bone mineral density (BMD) and requiring to continue the treatment, were studied. BMD of spine and femoral neck were performed at the baseline, 12 and 24 months after SR treatment.

Results: 63 patients were included, with a mean age of 64.83 (48-86 years). The results are expressed in the followings tables 1 and 2.

Conclusions: Spine and femoral BMD increased significantly at 12 and 24 months after SR treatment; more significant at 24 than at 12 months.

The bone turnover is very inhibited after a long use of BP; the SR would be deposited more easily in new bone. This fact could explain the improvement of the parameters with a longer treatment time.

Usually patients under a long BP treatment should make a drug holiday, however they should continue the osteoporosis therapy. This study shows that SR could be a very useful and effective alternative for these patients.

| | Baseline | | 12 months | | 24 months | |

Beneficial Effects of Zoledronate versus Placebo on Lumbar Spine Bone Mineral Density (BMD) and Microstructural Parameters (TBS) in Postmenopausal Women with Osteoporosis. A 3-Year Study. Albrecht Popp^{*1}, Helene Buffat², Olivier Lamy³, Romain Perrelet², Didier Hans⁴, Kurt Lippuner¹. ¹Osteoporosis Policlinic, University of Bern, Switzerland, ²Osteoporosis Policlinic, University of Bern, Switzerland, ³University Hospital, Switzerland, ⁴Lausanne University Hospital, Switzerland

Objective(s): The Trabecular Bone Score (TBS) is an index of bone micro-architecture that predicts osteoporosis fracture risk independently of bone mineral density (BMD). It is calculated from antero-posterior DXA scans of the spine. The aim of this study was to compare the effects of yearly intravenous zoledronate (ZOL) versus placebo (PLB) on spine BMD and TBS in postmenopausal women with osteoporosis.

Materials and Methods: The HORIZON trial was a randomized, double-blind, placebo-controlled study comparing the effects of once-yearly intravenous ZOL and PLB over 3 years in postmenopausal women with osteoporosis. All subjects also received adequate calcium and vitamin D3. In a subset of 98 patients (n = 49 on ZOL, 49 on PLB) retrospective analysis was performed to assess changes in lumbar spine BMD and TBS during 3 years vs. baseline. BMD was measured by DXA and TBS

parameters were assessed by TBS iNsite™ (v1.9) at baseline and 6, 12, 24, and 36 months after treatment initiation.

Results: Baseline characteristics (mean ± SD) were similar between groups in terms of age, 76.5 ± 5.1 years; BMI, 24.4 ± 4.1 kg/m²; L1-L4 T-score, -2.55 ± 1.44; and TBS 1.200 ± 0.12. ZOL induced an early and sustained significant increase in spine BMD relative to both baseline and placebo (+3.2% and +9.4% change in spine BMD with ZOL vs. corresponding -0.2% and +2.1% changes with PLB at 6 and 36 months, respectively; p < 0.01). Change in TBS was significantly greater with ZOL than with PLB at 36 months (+1.6 vs. -1.4%, respectively; p < 0.05). Spine BMD and TBS were weakly correlated (r² = 0.11), and there were no correlations between changes in BMD and TBS from baseline at any visit.

Conclusions: In postmenopausal women with osteoporosis, once-yearly intravenous ZOL therapy significantly increased lumbar BMD relative to PLB and prevented bone microarchitecture decay, as assessed by TBS, over three years. Changes in BMD and TBS were not correlated, confirming that TBS reflects bone properties other than BMD.

Early Initiation of Bisphosphonate Does Not Affect Healing and Outcomes of Volar Plate Fixation of Osteoporotic Distal Radius Fractures. Hyun Sik Gong^{*1}, Kee Jeong Bae², Jeong Hwan Kim², Jung Eun Lee². ¹Seoul National University Bundang Hospital, South Korea, ²Seoul National University Bundang Hospital, South Korea

Background: Bisphosphonates can adversely affect fracture healing because they inhibit osteoclastic bone resorption. Given this, it is unclear whether bisphosphonate medication can be initiated safely in patients sustaining an acute distal radius fracture. The purpose of this randomized study was to determine whether the early use of bisphosphonate affects fracture healing and outcomes of osteoporotic distal radius fractures treated by volar locking plate fixation.

Methods: Fifty women older than 50 years of age who underwent volar locking plating of distal radius fractures and were diagnosed with osteoporosis were randomized to Group I (n=24, initiation of bisphosphonate at 2 weeks after operation) or Group II (n=26, initiation of bisphosphonate at 3 months). Patients were assessed for radiographic union and radiographic parameters (radial inclination, radial length, and volar tilt) at 2, 6, 10, 16, and 24 weeks, and for clinical outcomes at 24 weeks which included disabilities of the arm, shoulder, and hand (DASH) scores, wrist ranges of motion, and grip power. The two groups were compared for time to radiographic union, radiographic parameters and clinical outcomes.

Results: No significant differences were observed between the two groups with respect to radiographic or clinical outcomes. All patients achieved fracture union and mean times to radiographic union in groups I and II were similar (6.7 weeks vs. 6.8 weeks, respectively; p=0.65). Furthermore, time to radiographic union was not found to be related to osteoporosis severity or fracture type in patients treated by volar locking plate fixation.

Conclusions: In patients with an osteoporotic distal radius fracture treated with volar locking plating, the early initiation of bisphosphonate was not found to affect fracture healing or clinical outcomes. Future investigation should focus on whether the immediate initiation of medication actually results in increased osteoporosis treatment rate.

Effects of Bisphosphonate Alone or Combined Treatment of Bisphosphonate and Vitamin K2 on Serum Undercarboxylated-osteocalcin (ucOC) or Osteocalcin (OC) in Osteoporotic Women. Yuji Kasukawa^{*1}, Naohisa Miyakoshi¹, Toshihito Ebina², Toshiaki Aizawa³, Yoichi Shimada⁴. ¹Akita University Graduate School of Medicine, Japan, ²Dept. of Orthopedic Surgery, Kakunodate General Hospital, Japan, ³Dept. of Orthopedic Surgery, Kita-Akita General Hospital, Japan, ⁴Dept. of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan

Purpose: Serum undercarboxylated osteocalcin (ucOC), which is a marker of vitamin K2 deficiency, has been considered as also a marker of bone quality

independent of bone mineral density. Its cut-off value for osteoporotic fracture is 4.5 ng/ml, however the value of uOC has been changed under treatment with bisphosphonates. The purpose of the present study was to evaluate the effects of bisphosphonate alone or combined treatment of bisphosphonate and vitamin K2 on serum uOC, osteocalcin (OC) level and the other bone metabolic markers prospectively.

Methods: Ninety-five osteoporotic women were randomly stratified into two groups: Bis-group (mean age 74-year-old, n=48), which was treated with risedronate alone (17.5 mg/week), and Bis+K2-group (mean age 76-year-old, n=47), which was treated with risedronate and menatetranone (45 mg/day). Serum uOC, OC, cross-linked N-telopeptide of type 1 collagen (NTx), and bone alkaline phosphatase (BAP) were measured before, 6-month, and 12-month after treatment, and then the change rates of these markers were evaluated.

Results: Persistence rates of treatment at 6-month and 12-month were 83% and 75% in Bis group and 74% and 68% in Bis+K2 group, respectively. The decreasing rates of uOC at 6-month and 12-month were not statistically significant between the groups (31% and 51% in Bis-group, and 34% and 56% in Bis+K2-group). However, the decreasing rates of OC in Bis-group at 6-month and 12-month (25% and 36%, respectively) were significantly higher (p<0.01) than those in Bis+K2-group (0.4% and 17%, respectively). The change rates of uOC/OC in Bis-group at 6-month and 12-month (9.3% and 23%, respectively) were significantly lower (p<0.05) than those in Bis+K2-group (36% and 48%, respectively). The decreasing rates of NTx and BAP were not statistically significant between the groups at both time points.

Conclusions: Although the decreasing rate of serum uOC level was not different between mono-therapy of bisphosphonate and combined treatment with vitamin K2, the decreasing rate of serum OC in combined treatment was significantly lower than that in mono-therapy of bisphosphonates.

Exploration of Prognostic Factors on BMD Percent Change in Patients Administrated Risedronate -A Pooled Analysis of Clinical Trials in Japan- Ryoichi Muraoka¹, Ryo Okazaki^{2*}, ¹Ajinomoto Pharmaceuticals Co, Ltd., Japan, ²Teikyo University Chiba Medical Center, Japan

Objective : Risedronate (RIS) has been shown to inhibit osteoporotic fractures and widely used in the world. However, there are some non-responsive patients to RIS in terms of BMD increase. We performed post-hoc analyses of RIS Phase III trials conducted in Japan to explore prognostic factors associated with responsiveness to RIS.

Subjects and methods : 465 subjects whose lumbar spine BMD data were available both at the baseline and after 48 weeks of RIS treatment in Phase III trials were analyzed. In those trials vitamin D supplementation was not given. Subjects were divided into responders (N=418) by BMD percent change from baseline equal to or above 0% and non-responders (N=47) with negative BMD change. Analyses on bone turnover markers between groups were performed. Logistic regression analysis was performed in which positive BMD response to RIS as an event. Comorbid complications, demographic profiles, BMI, drug adherence, existing vertebral fracture, basal levels of serum 25(OH)D and bone turnover markers were considered as prognostic variables.

Results : In non-responders, serum bone-specific alkaline phosphatase (BAP) levels were lower at baseline (26.1 +/- 9.1U/L vs. 31.1 +/- 10.2U/L, P=0.0022) and at 4-week. The BAP value at 12, 24, 36, 48-week showed no significant differences (at 48-week, 18.2 +/- 5.6U/L vs. 19.3 +/- 6.0U/L, p=0.2773). BAP percent changes from baseline in non-responders at 12, 24, 36, 48-week were significantly lower than responders (at 48-weeks, -25.4 +/- 21.6% vs. -34.5 +/- 19.9%, p=0.0106). Compared with responders, non-responders showed blunted decreases in bone resorption markers (urinary CTX and NTX) as well. In logistic regression analysis, existing vertebral fracture, higher basal serum 25(OH)D level [above 20ng/mL (median)], and higher serum BAP level [above 28.6U/L (median)] were significantly associated with positive BMD response to RIS. Estimated odds ratio were 2.441 (P=0.0387), 2.458 (P=0.0070) and 2.310 (P=0.0092), respectively.

Conclusions : These results suggest that serum 25(OH)D level should be adequately increased prior to RIS treatment in order to ensure positive BMD response to RIS. In terms of BMD, patients with higher bone turnover markers and/or existing bone fractures are more likely to respond to RIS, suggesting RIS may be more effective in severer osteoporotic patients.

SA0373

Identifying Factors Involved in Predicting Response to Intravenous Zoledronic acid in Elderly Patients with Osteoporosis. Najia Siddique^{*1}, Ng Kin Cheung², Kevin McCarroll², Nessa Fallon², Miriam C.Casey³, JB Walsh². ¹St James University Hospital, Ireland, ²St.James's Hospital, Ireland, ³Stjames's Hospital, Ireland

Introduction: IV Zoledronic acid (Zol) has been proven to increase spinal BMD in osteoporosis. However some patients may not respond to this therapy. There is limited data in the literature to identify the factors which might predict treatment

failure. This study looks at the baseline characteristics of patients who have inadequately responded to IV Zol. It also considers any significant correlation among these characteristics when compared to BMD.

Methods: This was a retrospective study. A cohort of 192 patients with post menopausal osteoporosis who were treated with IV Zol was analysed. Patients were followed up for 12-18 months after their 1st dose. From this cohort, 43 patients who had their dexa scans performed at 12-18mths post Zol infusion were selected for further analysis. All these patients were on Calcium/VitD supplements at time of infusion. These patients were divided into two main groups as Responder Vs Non responder. Patients who failed to achieve a gain of 3% or more in BMD at their lumbar spine at 12-18mth were considered as non responders. The differences in baseline characteristics between the 2 groups were compared and correlations among these characteristics were looked at. Statistical analysis was performed using T-test and Logistic regression model. A p value ≤0.05 was considered as significant.

Results: Table 1 shows baseline characteristics and lab parameters of the cohort. There was no significant difference in the general characteristics of both groups i.e. age, medical history, previous bone or other medical treatment. There was also no significant difference in their GFR, Bone markers: Ctx,P1NP, OC (table1), PTH, Vitamin D, Serum calcium and 24hr Urinary calcium. A significant difference in BMD was observed between Responders(0.76 SD ±0.13) Vs NonResponders(0.87 SD±0.19) (p0.03). A significant trend towards an increase in response with lower baseline BMD was also observed (p 0.04). Also, higher baseline BMD was observed in patients with higher baseline BMI (p0.03), higher osteocalcin p 0.029, CTX (p0.00).

Conclusion: Although this analysis couldn't identify the predictors of response, it enabled us to establish that patients who have a lower BMD at baseline show a better response to treatment and ViceVersa - so the magnitude of the response to IV Zol is increased for subjects with relatively severe osteoporosis compared to patients with less severe disease.

Table 1: General characteristics and lab results of the population at baseline.

Oral Sequestration Not Associated With Bisphosphonate Use. Aliya Khan^{*1}, Ed Peters², Neili Sifelddeen³. ¹McMaster University, Canada, ²University Of Alberta, Canada, ³University of Alberta, Canada

The incidence of bisphosphonate related osteonecrosis of the jaws (BRONJ) in patients taking oral bisphosphonates has been variably estimated between 0.0004% and 0.06%. The case definition in these incidence studies typically has required the presence of exposed bone for greater than 8 weeks in patients who have been treated with bisphosphonates and with no history of radiotherapy. The objective of this preliminary study was to assess the presentation profile of BRONJ type cases in the absence of bisphosphonate use. All sequestration cases, which were submitted for histopathologic exam during a 3 year period before bisphosphonates were approved for clinical use, were reviewed. 55 cases were identified. 48 cases had clinical histories indicating the suspected cause and clinical presentation and were included in the study. 34 of these cases (71%) could be attributed to a range of etiologic factors (post-surgical complication, infection, trauma, radiation, eruption) and did not match the BRONJ type profile. A further 14 cases (29%) were characterized by prolonged bone exposure in the absence of a clinically evident initiating factor. 7 of these latter cases involved idiopathic bone exposure in the posterior lingual mandible, 4 cases occurred in association with developmental exostoses and 3 cases were associated with persistent recessed gingiva. In 7 of these exposed bone cases, there was definitive information regarding lesion duration before surgical management. 3 cases (2 lingual mandible and 1 recessed gingiva) had persisted for over 8 weeks before surgical management. Thus, a minimal 6% of BRONJ type presentations could be identified from the total sequestration cases. These preliminary results indicate that studies attempting to assess BRONJ incidence need to account for the unknown incidence or "background noise" associated with BRONJ type sequestrations that occur in the absence of bisphosphonate use.

Pre-existing Hyperparathyroidism Affects the Anti-fracture Efficacy of Oral Alendronate in Long-term Kidney Transplantation Survivors. Atsushi Suzuki*¹, Sakura Yamamoto², Hitomio Sasaki³, Hiroyuki Hirai⁴, Yoshiteru Maeda⁵, Sahoko Sekiguchi-Ueda¹, Yasumasa Yoshino⁶, Shogo Asano⁶, Megumi Shibata⁷, Masaki Makino⁸, Nobuki Hayakawa⁹, Kiyotaka Hoshinaga³, Mitsuvasu Itoh⁵. ¹Fujita Health University, Division of Endocrinology, Japan, ²Fujita Health University, Division of Endocrinology, Japan, ³Department of Urology, Fujita Health University, Japan, ⁴Fujita Health University Division of Endocrinology, Japan, Japan, ⁵Division of Endocrinology, Fujita Health University, Japan, ⁶Toyokawa City Hospital, Japan, ⁷Fujita Health University Division of Endocrinology, Japan, ⁸Division of Endocrinology, Fujita Health University, Japan, ⁹Faculty of Pharmacy, Meijo University, Japan

Background: Post-transplantation bone diseases negatively affect the quality of life of solid organ recipients. Secondary or tertiary hyperparathyroidism is a frequent complication in kidney transplantation (KTx) recipients. Treatment with immunosuppressive agents including glucocorticoids can lead to deterioration in bone metabolism in these patients. In the present study, we explored the effects of a three-year treatment period with oral alendronate (ALN) in long-term KTx survivors.

Subjects: Post-KTx recipients were recruited (n=24, M/F=12/12, mean age 52.0 ± 7.8 years) into this study. All patients were prescribed methylprednisolone (4.07 ± 0.86 mg/day) with various immunosuppressive agents.

Results: Before treatment with oral ALN (35 mg/week), the mean concentrations of intact parathyroid hormone (iPTH) and 25-hydroxyvitamin D (25-OHD) were 139.2 ± 71.4 pg/mL and 20.8 ± 4.1 ng/mL, respectively. After 36 months of ALN treatment, mean iPTH levels increased slightly (+20.9%). Treatment with ALN reduced bone-specific alkaline phosphatase (BAP) (-35.4%), serum type I collagen N-terminal telopeptide (NTx) (-31.2%) and osteocalcin (-55.6%) levels. ALN did not increase bone mass after 24 months. Four patients suffered a clinical osteoporotic fracture during the 36-month ALN treatment period. Higher basal iPTH level and a smaller %decrease in BAP and NTx were associated with the incidence of new clinical fractures during ALN treatment.

Conclusion: Anti-resorptive therapy with ALN can suppress bone turnover even when iPTH concentration is elevated in long-term KTx survivors. Pre-existing hyperparathyroidism and a smaller decrease in bone turnover markers seem to be associated with new clinical fractures during BP treatment.

Gastrointestinal Events and Association with Osteoporosis Treatment Initiation. Ethel Siris*¹, Shiva Sajjan², Srinivasan Rajagopalan³, Shuvayu Sen⁴, Ankita Modi⁵. ¹Columbia University College of Physicians & Surgeons, USA, ²Merck & Company, USA, ³Meddata Analytics, USA, ⁴Merck & Co., Inc., USA, ⁵Merck & Company, USA

Purpose: To examine the association of Gastrointestinal (GI) events with osteoporosis (OP) treatment initiation patterns among women after having a diagnosis of OP.

Methods: A retrospective cohort study using i3 Invision Datamart; a large U.S. claims database records from January 1, 2001 to December 31, 2010 (study period) was conducted. The index date was defined as the date of first diagnosis of OP during study period. Study included women, 55 years or older, with a diagnosis of OP based on ICD-9 codes and enrolled for at least one year before (baseline) and one year after the index diagnosis date (follow-up). Subjects were excluded if they had a diagnosis of Paget's disease, malignant neoplasm or a prescription for an OP medication anytime prior to index date during the study period. OP medications were identified based on NDC codes and included bisphosphonates (BIS) (alendronate, etidronate, ibandronate, risenedronate, zoledronic acid) and non-BIS (calcitonin, raloxifene, teriparatide). Users of estrogen therapy during the one year prior to index date were also excluded. GI events were assessed as having a GI symptom related ICD-9 diagnosis after OP diagnosis and before treatment initiation in the follow-up. The association of any GI event on OP treatment initiation was analyzed using multivariate logistic regression

model controlling for age, comorbidities, OP fracture history, glucocorticosteroid use, gastroprotective agent use and nonsteroidal anti-inflammatory drug history at baseline.

Results: 65,344 patients met the inclusion criteria with a mean age of 66 years. Almost 27.3 % of the patients had a GI event at baseline. 23.7% of patients had a GI event post diagnosis and before treatment initiation. Among patients with GI events at baseline, those who continued to have GI events in the period after OP diagnosis were less likely to be initiated with any pharmacological treatment for OP (OR: 0.20, CI: 0.19-0.22) and were less likely to be initiated with a BIS as compared to a non-BIS (OR: 0.61, CI: 0.53-0.72). Similar association was seen among subjects with no GI events at baseline and those who developed GI problems post OP diagnosis.

Conclusion: Almost 24% of women had GI events prior to treatment initiation and post OP diagnosis. Occurrence of a GI event may be associated with the likelihood of not being treated. Among patients receiving treatment, a GI event increased likelihood of being treated with a non-bisphosphonate as compared to a bisphosphonate.

Disclosures: *Ethel Siris, Amgen, Eli Lilly.; Amgen, Eli Lilly, Merck, 2 This study received funding from: Merck and Company*

SA0380

Osteoporotic Fracture Rate Among Women with at least One Year of Adherence to Osteoporosis Treatment. Adolfo Diez-Peréz*¹, Chun-Po Steve Fan², Shuvayu Sen³, Ankita Modi⁴. ¹Parc De Salut Mar, Spain, ²AsclepiusJT LLC, USA, ³Merck & Co., Inc., USA, ⁴Merck & Company, USA

Purpose: To examine the incidence of osteoporosis-related fractures over 2 years of treatment among women adherent to osteoporosis (OP) therapy for at least 1 year.

Methods: A retrospective analysis using i3 Invision Datamart (Ingenix, Eden Prairie, MN); a large U.S. claims database with records from January 1, 2001 to December 31, 2010 (study period) was conducted. Women ≥50 years old who initiated treatment with oral bisphosphonates (alendronate, risenedronate, ibandronate) during study period and were enrolled in the database for 3 consecutive years, including a baseline year before the index prescription, an adherence year (year 1), and a follow-up year (year 2). Patients were excluded if they had Paget's disease or diagnosis of malignant neoplasm. Adherence to therapy was defined as medication possession ratio (MPR) ≥0.6 during year 1 (MPR = total number of days' supply/365 days). Additional sensitivity analysis was conducted with adherence defined to be MPR ≥0.8. OP fracture incidence rate was computed as number of OP fractures per 1,000 patient-years among women adherent to osteoporosis treatment for at least one year.

Results: Among 62,446 women who met eligibility criteria, 35,737 (57%) were adherent to osteoporosis therapy (based on MPR ≥0.6) during year 1 (mean [SD] age, 60.7 [8.4] years). Among the 1-year adherent patients, OP fractures were recorded during the baseline year (before initiating therapy) for 1,507 (4.2%) patients; during year 1 for 1,397 (3.9%) patients; and during year 2 for 1,173 (3.3%) patients. There were in total 1,851 fractures in year 2 with an incidence rate of 52 per 1,000 patient-years. Hip and other non-vertebral fractures were most common, representing over two thirds of all fractures. Moreover, 2,350 (6.6%) of the 1-year adherent patients experienced a fracture in the baseline or the adherence period. 33,387 did not experience fractures in baseline or adherence period. Among 2,350 patients, 423 (18%) had fractures in the follow-up, in contrast to only 750 (2.2%) of the 33,387 patients without a fracture history had fractures in the follow-up. Similar results were obtained with sensitivity analysis of MPR ≥0.8.

Conclusion(s): Rate of osteoporotic fracture during the second year of follow-up was 3.3% despite having been previously adherent to treatment for one year. Results indicate an unmet need related to level of osteoporosis control and an opportunity for newer therapies to help address this need.

Disclosures: *Adolfo Diez-Peréz, None.*

Outcomes in Patients with a Fractured Neck of Femur following the Establishment of a Fracture Liaison Service. Jude Ryan*¹, Audrey Butler², Sheila Carew³, Tina Sheehy³, Aine Costelloe³, Brian Lenehan², Declan Lyons³, Margaret O' Connor³. ¹Midwest Regional Hospital, Ireland, ²Department of Orthopaedic Surgery, Ireland, ³Clinical Age Assessment Unit, Ireland

Introduction: Fractures of the neck of femur may commonly indicate advanced osteoporosis and therapeutic interventions to slow bone loss and improve fracture risk have been shown to lead to better outcomes. We looked at the outcomes in the first eight months following the establishment of a fracture liaison service in a regional hospital.

Methods: A fracture liaison service was established in July 2011. All patients who were admitted following a fractured neck of femur were assessed in the perioperative period by a geriatric physician with a special interest in bone health and offered investigation and follow-up, excluding patients with advanced dementia. Follow-up investigations included DEXA, laboratory markers of bone health and a falls work-up. Outcome parameters included survival, re-admission rates, length of stay and

compliance with follow up. We compared length of stay to a similar period 2010 in the same unit prior to the establishment of the fracture liaison service.

Results: There were 155 patients admitted with fractured neck of femur during the 8 month study period, 111 (72%) were female. Median age was 81 (53-94) years. Length of stay was 8 (2-40) days, compared with 9 (2-56) days in 2010. The overall mortality was 10/155 and 30-day mortality was 6/155. The 30-day readmission rate was 6.5% (10/155). Follow up was offered to 112 patients to date and of these, 75 patients have attended for bone health and falls investigations (compliance rate 67%).

Conclusion: These results indicate that a fracture liaison service can reduce length of stay for patients following fractured neck of femur. Further work is needed to establish whether this service and improved compliance with follow up can influence longer term outcome measures.

Disclosures: *Jude Ryan, None.*

Persistence With Denosumab Therapy For Postmenopausal Osteoporosis. Christine Simonelli¹, Susan Mehle², Julie Morancey³. ¹HealthEast Osteoporosis Care, USA, ²HealthEast Medical Research Institute, USA, ³HealthEast Osteoporosis Care, USA

Compliance and persistence with oral osteoporosis medications has been notoriously poor, compromising efficacy leading to more fractures and higher healthcare costs. An every 6-month subcutaneous injection option is now available with 60mg. denosumab therapy (ProliaTM) in managing postmenopausal osteoporosis. We report the persistence of this medication use over 18 months of prescribed therapy.

Consecutive patients being treated for postmenopausal osteoporosis who were felt by the clinician to be appropriate for denosumab treatment were monitored for follow-up visits. An index card was created for each patient and filed at the next 6-month time point. Patients were encouraged to set up their follow-up visit at the end of their appointment. The mean age of patients was 70.9 (39-100) and 136 (37.5%) had at least one prior fracture with vertebral fractures most common (63, 17%) and 12 (3.3%) had prior hip fracture, 31 (8.5%) prior wrist fracture. Thirty-nine (10.7%) patients had more than one prior fracture. Most patients (257, 69%) used prior osteoporosis medication with 120 (33%) using a single medication and 137 (38%) using more than one prior medication. Bisphosphonates alone were used by 122 (34%) patients, teriparatide by 36 (10%) and teriparatide and a bisphosphonate by 67 (18%). Survival of patients who had tried a previous osteoporosis medication was 88.4%, compared to 81.5% for those who had no prior osteoporosis medications. The difference was not statistically significant (Log-Rank p-value = 0.335).

Three hundred sixty-three patients received their first Prolia injection between June 2010 and January 2012 and were followed through February 29, 2012. Of 246 patients eligible for a second dose 219 (89%) received their dose and of 121 patients eligible for a third dose, 107 (88%) patients received the final dose. Reasons for using denosumab were BMD decline on prior osteoporosis medication (22.8%), adverse event on prior osteoporosis medication (25.6%), physician and/or patient preference (28.6%), history of GI disease (10.2%) and renal failure (15.4%).

Use of denosumab (ProliaTM) to manage postmenopausal osteoporosis had a high persistence with therapy in an outpatient clinical practice setting and offers an important treatment option.

Primary Care Providers' Management after Receipt of an Osteoporosis Electronic Consult for Patients with Recent Fracture. Richard Lee^{*1}, Karen Barnard², Kenneth Lyles³, Megan Pearson⁴, Cathleen Colon-Emeric⁵. ¹Duke University, USA, ²Duke University Medical Center, Durham VAMC, USA, ³Duke University Medical Center, USA, ⁴Durham VA Medical Center, USA, ⁵Duke University Medical Center, USA

Background: According to the Office of the Inspector General, only 45 percent of patients within the Veterans Health Administration received appropriate osteoporosis management after a fracture. An electronic consult service was implemented at a Veterans Administration Medical Center to facilitate identification of and to recommend management for patients with recent fracture.

Method: The osteoporosis electronic consult service was initiated in October 2011 at a single VAMC. The consult service coordinator identified potential osteoporotic fractures from inpatient and outpatient encounter data drawn from the central data repository. All patients with an ICD9 diagnosis code for fracture (800-829) were screened. Patients were excluded if they were deceased, receiving palliative care, under 50 years, already on treatment for osteoporosis, fracture management had been addressed by primary provider, no primary provider assigned, fracture was located in face or digits, fracture occurred in setting of high-impact trauma, suspected fracture was not seen on radiograph, or insufficient information regarding the fracture in medical record. Eligible patients were referred to a bone specialist who reviewed each medical chart. After chart review, an electronic consult note was sent to the patient's primary provider that provided recommendations for further evaluation and management of osteoporosis, consistent with current guidelines. We report the service's activity in the first 3 months after implementation and the primary providers' subsequent management.

Results: Among 986 potential fractures, 841 were excluded from further evaluation. The most common reasons for exclusion were age under 50 years (38%), fracture of the face or digits (25%), and no primary provider assigned (22%). A total of 88 fractures were reviewed by a bone specialist, and primary providers acknowledged receipt of 85 consults. Twenty seven (31%) consults recommended treatment and 40 (45%) recommended bone density assessments (DXA). The primary providers responded by referring 14 patients (35%) for DXA and prescribing bisphosphonates in 16 patients (59.3%).

Conclusion: An electronic consult service identified a number of patients with a recent fracture, who were eligible but not receiving treatment or evaluation for osteoporosis. After receipt of the consult, primary care providers referred patients for DXA in over a third and prescribed bisphosphonates in over half of the patients.

Association Between Prevalent Osteoporosis (OP) and Total Health Care Costs in Managed Care Members with High Cost Chronic Diseases. Sarah Thayer¹, Gabriel Gomez Rey², Jerald Seare³, Brad Stolshek^{*4}. ¹Optum, USA, ²Optum, USA, ³Optum, USA, ⁴Amgen Inc, USA

Background: Highly prevalent or costly chronic diseases(CD) such as chronic obstructive pulmonary disease(COPD), cardiovascular disease(CVD), depression(-DEP), and diabetes mellitus(DM) and multiple CDs are of significant interest to payers. Little is known about how osteoporosis (OP) in these diseases impacts health care costs. Objective and Purpose: To examine differences in total health care costs among members with CD with or without OP, and OP only. Methods: This was a retrospective study of commercial and Medicare Advantage members aged ≥50 years continuously enrolled in a large US health plan with evidence of prevalent CD and/or OP in the identification(ID) period(01/01/07 - 10/31/09). Evidence of OP was defined as ≥1 medical claim with an ICD-9 CM diagnosis code for OP, ≥2 OP medication fills, or ≥1 medical claim for fragility fracture during the ID period. Members with Paget's disease of bone, hypercalcemia, osteogenesis imperfecta, HIV, or preventive or active breast cancer treatment were excluded. Evidence of CD was disease-specific based on medical and/or pharmacy claim algorithms during the ID period. Members were assigned to one of 11 cohorts: single or multiple CD with or without OP and OP only. Index dates were set as a random service date from medical or pharmacy claims for each disease during the ID period. Each CD with OP cohort was compared with 1) its counterpart without OP and 2) OP only. Total all-cause health care costs in a 12-month follow-up period were examined. For each CD+/-OP pairing, the association between total health care costs was assessed using a generalized linear model with a log link and a gamma distribution controlling for baseline characteristics(age group, gender, region, Quan-Charlson comorbidity score, top AHRQ comorbidities, and resource utilization). Results: A total of 422,862 members were identified with CD with prevalent OP(10.9%), CD only(84.8%) or prevalent OP only(4.3%). Each CD with OP cohort had higher mean actual costs compared with its respective CD only cohort, and the OP only cohort(p<0.001). The presence of OP was associated with higher baseline-adjusted costs in each CD cohort(p≤0.0003). Predicted mean costs were 12%-23% higher in each CD with OP cohort vs. each cohort without OP. Conclusions: Members with CD and OP had significantly higher total health care costs than those with CD only. In these members, OP should be managed closely to improve the quality of care and overall cost.

Mean total all-cause healthcare costs during follow-up by cohort

| Chronic Disease (CD) | COPD | CV | DEP | DM | ≥2 CD |
|-----------------------------------|--------|--------|--------|--------|--------|
| Actual costs US \$/year* | | | | | |
| CD + OP | 15,024 | 10,038 | 13,878 | 12,465 | 17,997 |
| CD only | 11,047 | 8,377 | 9,467 | 8,570 | 12,801 |
| OP only | 5,377 | 5,377 | 5,377 | 5,377 | 5,377 |

Lack of Osteoporosis Treatment in Real World Hip Fracture Patients. Stephen Johnston¹, Yang Zhao^{*2}, Donna McMorow³, John Krege⁴, Kelly Krohn⁵, ¹Thomson Reuters, USA, ²Eli Lilly, USA, ³Thomson Reuters, USA, ⁴Eli Lilly & Company, USA, ⁵Lilly USA, LLC, USA

Purpose: National Osteoporosis Foundation guidelines recommend that postmenopausal individuals age 50 and older presenting with hip fracture should be considered for treatment with pharmacologic osteoporosis (OP) treatment. This study examined patterns of OP treatment strategies among hip fracture (HFx) patients in real world clinical practice.

Methods: Patients aged 50+ with an HFx between 1/1/2002-12/31/2010 (first observed HFx = index) were identified from a large US administrative claims database. Patients included for study had 6+ months of pre-index continuous enrollment (baseline), no baseline evidence of teriparatide (TPTD), cancer, or Paget's disease. Patients were followed for up-to 36 months post-index to observe patterns in pharmacologic OP treatments. Five cohorts were constructed based on pre- and post-index use of OP treatment: patients with no observed evidence of OP treatment pre- or post-index (N/N); new bisphosphonate (BP) initiators with no baseline BP (N/BP); BP continuers with baseline BP (BP/BP); new TPTD initiators with no baseline BP treatment (N/TPTD); TPTD initiators switching from prior BP (BP/TPTD). Demographics, clinical characteristics, and healthcare resource use were compared across the 5 cohorts.

Results: Study included 71,115 patients. The majority of the sample, 53,634 (75% of total) patients, was observed to have no OP treatment (N/N) over a median of 352 days of follow-up; 26,238 of whom had ≥ 1 year of follow-up. New BP initiators (N/BP; 9,187 patients) started BP treatment within a median of 117 days. BP continuers (BP/BP; 7,463 patients) resumed treatment within a median of 58 days. New TPTD initiators (N/TPTD; 346 patients) started TPTD treatment within a median of 138 days. TPTD initiators switching from prior BP (BP/TPTD; 485 patients) switched to TPTD treatment within a median of 64 days. Mean ages ranged from 74.0 (BP/TPTD) to 80.5 (N/N) years. The N/N cohort was the oldest (81 vs. 74-79 years), had the highest proportion of males (39% vs. 8-18%), and the lowest baseline use rates of systemic glucocorticoids (13% vs. 17-30%) and dual energy X-ray absorptiometry scans (2% vs. 5-17%).

Conclusions: In spite of a sentinel event of a hip fracture, which is a known risk factor for future fracture, 75% of patients had no evidence of OP treatment over a median follow-up of 352 days. These data provide further evidence of a substantial gap in the management of OP among patients at very high risk for fractures.

Treatment (Rx) of Post-Menopausal Women with High FRAX Scores may be Cost-Effective without First Performing Bone Densitometry. John Schousboe^{*1}, William Leslie², Brent Taylor³, Steven Cummings⁴, L. Joseph Melton⁵, Margaret Gourlay⁶, Kristine Ensrud⁷. ¹Park Nicollet Clinic/University of Minnesota, USA, ²University of Manitoba, Canada, ³University of Minnesota, USA, ⁴San Francisco Coordinating Center, USA, ⁵Mayo Clinic, USA, ⁶University of North Carolina, USA, ⁷Minneapolis VA Medical Center / University of Minnesota, USA

Background: It is uncertain whether drug Rx prevents non-vertebral fractures in postmenopausal women with femoral neck (FN) BMD T-score > -2.5 and no prevalent vertebral fracture. However, among women ≥ 65 years old, 3 of every 10 meeting FRAX treatment threshold for major osteoporotic fracture and 6 of 10 meeting FRAX treatment threshold for hip fracture have FN T-scores > -2.5 . We used a Markov microsimulation model to estimate lifetime costs, health benefits, and cost-effectiveness of Rx of older US White women with high fracture risk by FRAX without BMD compared to first obtaining a BMD test plus vertebral fracture assessment and Rx of only the subset with either FN T-score ≤ -2.5 or a prevalent vertebral fracture.

Methods: The model had states of hip, morphometric and clinical vertebral, wrist, and humerus fracture, no fracture, and death. Fracture rates, costs, and disutilities were derived from the literature. The prevalence of FN T-score > -2.5 in those with FRAX w/o BMD 10-year hip and major osteoporotic fractures risks $\geq 3\%$ and $\geq 20\%$ were from the Manitoba Bone Density database. The age-specific prevalences of vertebral fracture were from Rochester Epidemiology Project data. Models were run for women age 65, 75, or 85 until death or age 100, assuming a national health payer perspective and willingness to pay of \$75,000 per quality adjusted life year (QALY) gained. For those with FN T-score > -2.5 and no prevalent vertebral fracture, we assumed relative risks of incident clinical vertebral fracture, morphometric vertebral fracture, and non-vertebral fracture on Rx to be, respectively, 0.45, 0.64, and 1.0. (Quandt 2005; Ryder 2008). Sensitivity analyses assumed only 18% reduction of vertebral fractures on Rx in the proportion with T-score > -2.0 (Cummings 1998), or 25% of base case disutility from morphometric vertebral fractures.

Results: Table shows estimated costs per QALY gained for Rx of women with high FRAX without BMD score vs. Rx of only those with prevalent vertebral fracture or FN T-score < -2.5 .

Conclusions: Rx initiation on the basis of high fracture risk estimated by FRAX w/o BMD may be cost-effective, but this is highly sensitive to vertebral fracture disutility and to assumed vertebral fracture reduction on Rx for those with T-score > -2.0 and

no prevalent vertebral fracture. A randomized controlled trial of fracture reduction medication in this subset with preference weighted quality of life assessments is needed.

| Age | Analysis | Fracture Risk Subgroup | Drug Cost \$250/year | Drug Cost \$500/year |
|----------|--|--------------------------------|----------------------|----------------------|
| 65 Years | Base Case | $\geq 20\%$ Major Osteoporotic | \$24,504 | \$62,308 |
| | Base Case | $\geq 3\%$ Hip | \$24,858 | \$60,211 |
| 75 Years | Base Case | $\geq 20\%$ Major Osteoporotic | \$29,993 | \$98,732 |
| | Base Case | $\geq 3\%$ Hip | \$40,295 | \$97,095 |
| | Sensitivity: RR Vert Fx on Drug Rx 0.82 if T-score > -2.0 | $\geq 3\%$ Hip | \$52,162 | \$134,989 |
| | Sensitivity: Morphometric Vertebral Fracture Disutility 25% of Base Case | $\geq 3\%$ Hip | \$65,716 | \$189,907 |
| 85 Years | Base Case | $\geq 20\%$ Major Osteoporotic | \$43,928 | \$122,623 |
| | Base Case | $\geq 3\%$ Hip | \$45,847 | \$122,804 |

Importance of Physician Communication and BMD testing in Management of Glucocorticoid-Induced Osteoporosis. Stuart Silverman^{*1}, Jeffrey Curtis², Kenneth Saag², Julie Flahive³, Adolfo Diez-Perez⁴, Jonathan Adachi⁵, Susan Greenspan⁶, Steven Boonen⁷, Cyrus Cooper⁸, Coen Netelenbos⁹, Nelson Watts¹⁰, Juliet Compston¹¹, for the GLOW investigators¹². ¹Cedars-Sinai/UCLA, USA, ²University of Alabama at Birmingham, USA, ³University of Massachusetts, USA, ⁴Parc De Salut Mar, Spain, ⁵St. Joseph's Hospital, Canada, ⁶University of Pittsburgh, USA, ⁷Center for Metabolic Bone Disease & Division of Geriatric Medicine, Belgium, ⁸University of Southampton, United Kingdom, ⁹VU Medical Center, The Netherlands, ¹⁰Mercy Health Osteoporosis & Bone Health Services, USA, ¹¹University of Cambridge School of Clinical Medicine, United Kingdom, ¹²University of Massachusetts, USA

Purpose: Guidelines recommend bone-mineral density (BMD) testing, and use of calcium (CA), vitamin D (vitD) and antiosteoporosis medication (AOM) in glucocorticoid (GC)-exposed individuals. We have reported less than optimal use of AOM, CA and vitD in such individuals in both the US and Europe (IOF/ECCEO 2012). We hypothesized that GC-exposed individuals who had a BMD test or communicated with their healthcare provider (HCP) about osteoporosis (OP) would be more likely to begin CA, vit D, and/or AOM and would be more "concerned" about their risk of fracture.

Methods: We studied the impact of BMD testing and HCP communication on medical management of GC exposure over 3 years in GLOW, a multinational prospective observational cohort of postmenopausal women (17 sites, 10 countries). Data on self-reported GC use were collected at baseline and at 1, 2 and 3 years. At baseline, participants were asked if they had ever taken GC. At both baseline and at subsequent surveys the women were asked if they had had a BMD test, had discussed OP with their HCP, and if they were taking CA, vit D and/or AOM.

Results: Of the 40,058 women with complete data over the 4 surveys, 27.4% (n=10,978) reported past/current oral GC use. Of these, 893 (2%) were current continuous users (CCU) over the past ≥ 2 years at the 3-year survey. Approximately 45% of nonusers were taking CA and VitD compared to 67% with CCU. AOM use was 22% in nonusers and 45% in CCU. Approximately 48% of nonusers had had a BMD test within the 3 years of the study, with an approximately 50% greater BMD testing in CCU. current intermittent and recent past GC users. BMD testing within the past 3 years doubled combined AOM and CA/VitD use in GC-exposed individuals compared to those who did not have a BMD. BMD testing within the 3 years of the study was associated with a 50% increase in AOM use alone in CU vs nonusers. BMD testing doubled the individual participant rating of being "very concerned" about risk of fracture in both users and nonusers of AOM. There was an almost 3-fold increase

in BMD testing among non-GC users who discussed OP with their HCP vs those who did not, and a 2-fold increase in BMD testing in GC-exposed individuals who spoke with their HCP. AOM use increased from 35% to 54% in CCU who spoke to their HCP about OP.

Conclusions: Our study confirms the importance of BMD testing and communication between patient and HCP in the management of GC-exposed individuals.

The Effect of Vitamin K₂ on Pregnancy-associated Osteoporosis: A Report of Four Patients. Hirovuki Tsuchie*¹, Naohisa Miyakoshi², Michio Hongo², Yuji Kasukawa², Yoshinori Ishikawa³, Yoichi Shimada³. ¹Akita University Graduate School of Medicine, Japan, ²Akita University Graduate School of Medicine, Japan, ³Dept. of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan

Purpose: Pregnancy-associated osteoporosis is a rare disease which causes multiple vertebral compression fractures from the late gestation period to several months after delivery. Although stopping breast-feeding, wearing a corset and calcium and vitamin D intake are common treatments for this disease, there has been no report using vitamin K₂ (menatetrenone), which is one of the medicines for osteoporosis. We herein describe 4 cases showing a favorable course by prescribing vitamin K₂.

Case 1: A 30-year-old woman developed back pain 4 weeks after her first delivery. Because her back pain did not lessen by wearing a corset, we advised against breast-feeding and prescribed a daily intake of 45 mg of vitamin K₂. One year and 3 months after her delivery, her back pain had completely disappeared.

Case 2: A 31-year-old woman developed back pain 2 weeks after her first delivery. Because her back pain did not lessen by stopping breast-feeding, we instructed her to wear a corset and prescribed a daily intake of 45 mg of vitamin K₂. Nine months after her delivery, her back pain had reduced significantly.

Case 3: A second pregnant 31-year-old woman had a past history of vertebral compression fractures after her first delivery 7 years ago, and she was treated by wearing a corset and prescribing a daily intake of 45 mg of vitamin K₂. Although she had continued to take vitamin K₂ for osteoporosis treatment, she stopped to take it when she got second pregnant. We advised against breast-feeding and prescribed a daily intake of 45 mg of vitamin K₂ after her second delivery, and she did not appear any back pain and decrease of bone mineral density.

Case 4: A 30-year-old woman developed back pain 1 week after her first delivery. Because her back pain did not lessen by wearing a corset, against breast-feeding and prescribing a daily intake of nonsteroidal anti-inflammatory drugs (NSAIDs), we prescribed a daily intake of 45 mg of vitamin K₂. Eight months after her delivery, her back pain had completely disappeared.

Conclusion: Vitamin K₂ prevents fractures by improving the bone quality. Vitamin K₂ is administered safely to newborns or pregnant woman for the treatment of melena neonatorum. Although stopping lactation, corset application, and medical treatment which include calcium and vitamin D are the basis of treatment, we should consider vitamin K₂ as a choice of subsidiary treatment, because of its effectiveness and safety.

The Efficacy of Hydroxyapatite for Screw Augmentation in Osteoporotic Patients. Jun Ho Lee*¹, Sang Hoon Jang², Ho Yeon Lee², Sang Ho Lee². ¹Wooridul Spine Hospital, South Korea, ²Wooridul Spine Hospital, South Korea

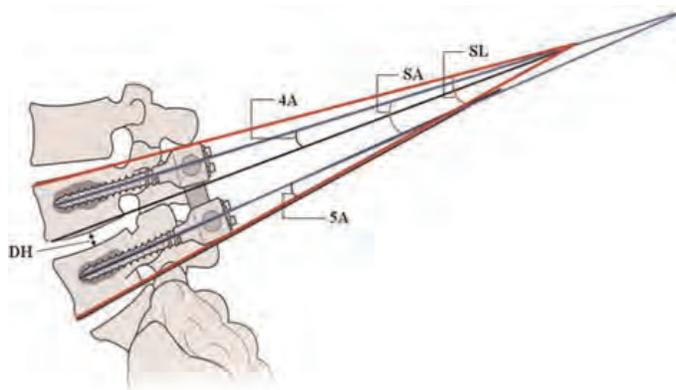

Purpose: Internal stabilization using a pedicle screw system is the gold standard for treatment of an unstable spine. Screw construct stability is of considerable importance in determining outcome, especially in spinal osteoporosis. Polymethylmethacrylate (PMMA) has been proven as an effective material for increasing the pullout strength of pedicle screws inserted into osteoporotic bones. But, it also has several disadvantages; its exothermic properties, the risk of neural injury in the event of

extravasation, and difficulties in performing revision surgery. In the current study, we used hydroxyapatite (HA) for screw augmentation in spinal osteoporosis.

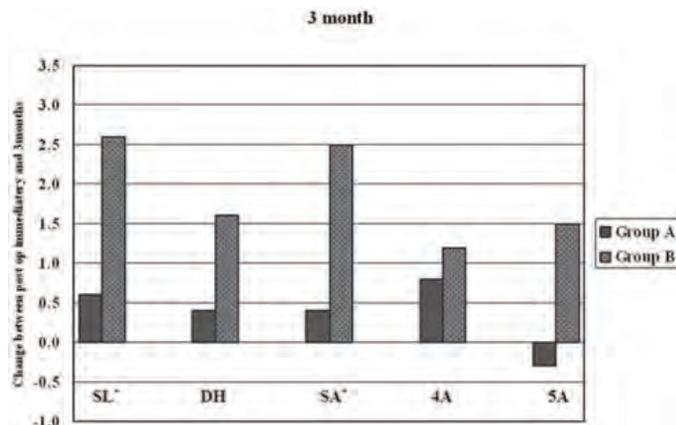

Methods: From March 2002 to December 2005, 34 patients diagnosed as spondylolisthesis grade I or II with osteoporosis (T score < -2.5) underwent one level transforaminal lumbar interbody fusion (TLIF) operation. In group A (screw augmentation group), additional screw augmentation was performed with HA. In group B (control group), conventional TLIF was carried out. Clinical outcome was assessed according to the Visual Analog Scale (VAS). Radiologic outcome was assessed by repeated measurement of standing lateral radiographs obtained at postoperative day 1 and during each follow-up visit (1 month, 3 months, 6 months, and annually). To simplify the results, radiologic parameters were compared between postoperative day 1 and the 3-month follow-up, and between postoperative day 1 and the 2-year follow-up in each group.

Results: The mean age was 67.6 years in group A and 68.2 years in group B. The mean T score was -2.80 in group A and -2.68 in group B. The mean improvement in VAS pain score was 83% for back pain and 85% for leg pain in group A (p < 0.05), and 82% for back pain and 89% for leg pain in group B (p < 0.05). There were no statistically significant changes in radiological parameters in group A. However, in group B, there was a decrease in segmental lordosis (SL) to 2.57 ± 1.03 (p = 0.109) at 3 months and a significant decrease to 2.78 ± 0.67 (p = 0.003) at 2 years. There was also a significant change in screw angle (SA) to 2.50 ± 0.67 (p = 0.005) at 3 months and 3.20 ± 0.84 (p = 0.005) at 2 years in group B.

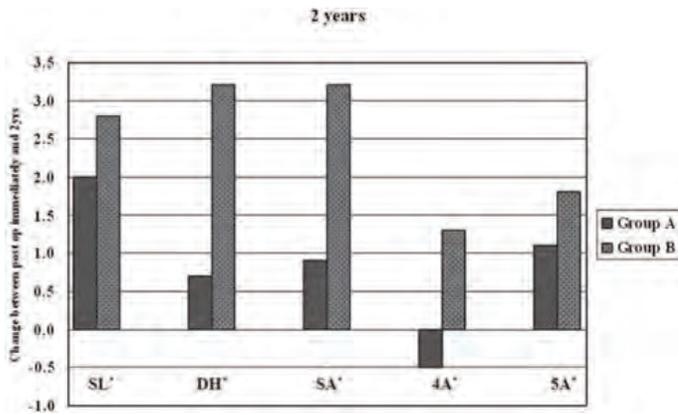

Conclusions: Our results suggest that HA cement is an useful tool for screw augmentation in osteoporotic bone and may play a role as a substitute for PMMA. It can be recommended as a promising alternative during spinal instrumentation in osteoporotic patients.

SA0396

Effects of Calcitonin on Pain, QOL, and Bone Marker in Osteoporosis Patients Suffering Vertebral Compression Fracture. Shinya Tanaka^{*1}, Akira Yoshida², Hiroaki Suzuki³, Manabu Ito⁴. ¹Saitama Medical University, Japan, ²Yoshida Orthopedic Clinic, Japan, ³Asahi Kasei Pharma, Japan, ⁴Hokkaido University Graduate School of Medicine, Japan

Objective: Many elderly individuals decrease activity of daily living (ADL) and require public nursing services due to a vertebral compression fracture associated with osteoporosis. It is important for senior citizens to prevent disuse syndrome in such senior citizens by enabling them to leave their sickbed early after suffering a fragile fracture. In patients with osteoporosis suffering fresh vertebral compression fractures, we assessed whether treatment with calcitonin was effective on improvement of the patient's quality of life (QOL) and on maintenance of bone mass, by comparison with matching patients treated with oral nonsteroidal anti-inflammatory drugs (NSAIDs) combined with an active form vitamin D3 preparation.

Method: A multicenter, open-labeled, randomized parallel-group study was conducted in female patients with primary osteoporosis aged 65 years and over complaining of dorsolumbar pain due to a fresh spinal fragility fracture(s). Patients were randomized to receive either calcitonin at 20 IU once weekly by intramuscular injection (calcitonin group) or oral NSAIDs in combination with an active form vitamin D3 preparation (NSAIDs + VD3 group).

The study treatment period lasted 6 weeks, and patients were assessed as to pain using the visual analog scale (VAS) and with respect to QOL using the Roland Morris questionnaire (RDQ) and EQ-5D. A bone resorption marker (TRACP-5b) was used to evaluate the effect of treatments on bone metabolism.

Results: At week 2 of study treatment, a relief in pain (VAS) and an improvement of QOL (RDQ and EQ-5D) were superior in the calcitonin group than those in the NSAIDs + VD3 group. The values of TRACP-5b also showed decreases at 3 months of study treatment and thereafter in the calcitonin group alone, thus suggesting greater efficacy of the calcitonin therapy as compared to the NSAIDs + VD3 therapy.

Discussion: Nasal and suppository calcitonin is evaluated as having moderate strength of recommendation in the 2010 Guideline on the Treatment Symptomatic Osteoporotic Compression Fractures published by the American Academy of Orthopaedic Surgeons (AAOS). The results of the present study also suggest that the calcitonin injectable preparation is also as effective for this disease.

Calcitonin has a mechanism of analgesic action mediated by central serotonergic neurons with a consequent relatively sustained effect unlike prompts effect of NSAIDs. In this study, the once-weekly regimen of calcitonin was effective for improving QOL and pain relief. Furthermore, since bone resorption becomes augmented after fracture and decreased ADL and sequential disuses also accelerate bone resorption, calcitonin is considered an essential drug in the treatment of early-phase vertebral compression fractures not only for relief of pain and QOL improvement but also in terms of prevention of loss of bone mass.

Unpredictable Spontaneous Fusion after Vertebroplasty and Kyphoplasty in Osteoporotic Compression Fracture. Jin Hwan Kim^{*1}, Jung Hoon Kim², Jae Hyup Lee³. ¹Inje University, Ilsanpaik Hospital, South Korea, ²Inje University, Ilsanpaik Hospital, South Korea, ³Seoul National University, College of Medicine, South Korea

Introduction: We found a spontaneous fusion after percutaneous vertebroplasty (PVP) or kyphoplasty in osteoporotic compression fractures and analyze the radiologic & clinical characteristics.

Materials & Methods: Between January 2000 and January 2011, 555 patients were treated with PVP or kyphoplasty for osteoporotic compression fracture in our department. We classified the spontaneous fusion as two groups. One is absolute spontaneous fusion group with at least three cortical continuity to adjacent vertebrae, the other is partially fusion group which progressed fusion compared to previous radiologic finding. We reviewed the plain film and analyzed the radiologic characteristics of those patients with duration of fusion, location and extent of fused segments. A clinical characteristic by visual analogue score (VAS) compared to our previous report was checked.

Results: Among them, 54 patients (9.7%) had an absolute spontaneous fusion and 43 patients (7.7%) had partially fused on plane image. In absolute fusion group, the average duration of fusion was 19 months ranged of 3 to 48 months. Forty six cases (85%) of absolute fusion patients had occurred with proximal adjacent vertebrae and 7 cases (13%) had proximal with distal adjacent vertebrae. 41 cases (76%) of spontaneous fusion occurred within 1 segment and 13 cases within multiple segments. The most cases of absolute fusion group were occurred at thoracolumbar junction (40 patients, 74%) Mean VAS score of absolute fusion group was 2.0 at final follow-up and were analyzed relatively low score compared to mean VAS of our previous report. (2.0, 2.8 respectively)

Conclusion: After percutaneous vertebroplasty or kyphoplasty in osteoporotic compression fracture, unpredictable spontaneous fusion could develop more than 10% rate, especially with proximal vertebra within 1 segment at thoracolumbar junction in radiologic aspect. Clinically, patients with spontaneous fusion had a tendency of more reduced pain than others.

Are the IOM Vitamin D Guidelines Sufficient for Long Term Care Residents? Marv Anne Ferchak^{*1}, Carroll Lee², Gail Fiorito², Julie Wagner¹, Karen Vujevich², Subashan Perera², David Nace², Neil Resnick², Susan Greenspan¹. ¹University of Pittsburgh, USA, ²University of Pittsburgh, USA

Background: The new Institute of Medicine guidelines for vitamin D suggest a level above 20 ng/dL is sufficient for adults. However, this level may be insufficient for frail residents in long term care (LTC) facilities.

Methods: To examine the impact of vitamin D on falls, function, cognition and mental health status in LTC residents, we examined serum 25-hydroxy vitamin D levels in 181 older women (mean age 85 years) living in LTC (assisted living and skilled) enrolled in an osteoporosis clinical trial. Women were grouped as deficient (< 20 ng/dL), insufficient (20-29.9 ng/dL), or sufficient (≥30 ng/dL). At baseline, deficient women received vitamin D 50,000 IU/week for 8 weeks to achieve a level of 25-hydroxy vitamin D ≥20 ng/dL. All received vitamin D 800 IU/day as maintenance and were followed for 1 year. Outcome measures included falls (obtained from electronic surveillance and reported/document chart reviews), physical activities of daily living (PADL, eat, dress, groom, walk, transfer, bathe, get to bathroom), instrumental activities of daily living (IADL, phone, travel, shop, prepare meals, housework, handle money), physical performance test (PPT, timed sit to stand, timed walk, phone, eat), gait speed (m/sec), time to stand (sec, measure of strength), cognitive status (SPMSQ), and mental health (PHQ-9).

Results: Over 1 year, women who were deficient tended to fall more compared to the other 2 groups, but the results were not statistically significant (Table, mean ± SEM unless otherwise specified). Comparison of the 12-month continuous outcomes across the 3 vitamin D groups adjusting for baseline values using ANCOVA and pairwise comparisons, suggested that women with vitamin D deficiency had lower scores for IADL, PPT and cognitive status (p<0.05) but there was no significant difference between those with insufficiency vs sufficiency. Gait speed, IADL and cognitive status were better in women with insufficiency than deficiency (p<0.05).

Conclusions: Frail women in LTC facilities with vitamin D deficiency are at risk for functional and cognitive status impairment not readily reversed by reaching vitamin D levels above 20 ng/dL and may require levels or doses above the recommended threshold suggested by the IOM. After 1 year of maintenance with the IOM recommended dose of 800 IU/day, LTC residents with insufficient to sufficient levels (≥20ng/dL) have better functional and cognitive status than those who are initially deficient.

| Variable | Deficient (N=40) | Insufficient (N=55) | Sufficient (N=85) | P-value, 3-group comparison |

Effect of Daily 800 IU Versus Single Oral Bolus of 300'000 IU Vitamin D on 25-hydroxyvitamin D Serum Concentration Increase in Postmenopausal Women with Osteoporosis. Heike Bischoff-Ferrari¹, Andreas Egli Linder², Kurt Lippuner³, Albrecht Popp³, Beatrice Günther⁴, Petra Rindova⁵, Robert Theiler⁶. ¹University of Zurich, Switzerland, ²Centre on Ageing & Mobility, Switzerland, ³Osteoporosis Policlinic, University of Bern, Switzerland, ⁴Inselspital Zürich, Switzerland, ⁵Triemli City Hospital, Switzerland, ⁶Stadspital Triemli, Switzerland

Background: Correction of vitamin D deficiency among patients with osteoporosis is challenged by low adherence.

Aim: To test the efficacy of daily versus bolus vitamin D.

Methods: We randomized 99 postmenopausal women with osteoporosis treated with Zoledronate (mean age 77 years) to either daily 800 IU vitamin D3 plus 1000 mg calcium or a single oral bolus of 300'000 IU vitamin D3 plus 1000 mg calcium per day. Follow-up assessments took place at 2 weeks and 6 months.

Results: Baseline 25-hydroxyvitamin D serum concentrations (25(OH)D) did not differ between the daily (mean = 23 ng/ml) and the bolus (mean = 29 ng/ml) group. At 2 weeks, achieved mean 25(OH)D differed significantly between the daily (mean = 24 ng/ml) and the bolus group (mean = 44 ng/ml; p-value < 0.0001). At 6 months, however, achieved mean 25(OH)D were similar between the daily (mean = 29 ng/ml) and the bolus group (mean = 25 ng/ml; p-value = 0.08). At baseline, 60% in the daily and 43% in the bolus group were vitamin D replete (> 20 ng/ml; 50 nmol/l), while 23% in the daily and 28% in the bolus group had desirable 25(OH)D concentrations (> 30 ng/ml; 75 nmol/l). At 2 weeks, 71% in the daily and 96% in the bolus group were vitamin D replete (> 20 ng/ml; 50 nmol/l), while 21% in the daily and 77% in the bolus group had desirable 25(OH)D concentrations (> 30 ng/ml; 75 nmol/l). At 6 months, 61% in the daily and 83% in the bolus group were vitamin D replete (> 20 ng/ml; 50 nmol/l), while 33% in the daily and 22% in the bolus group had desirable 25(OH)D concentrations (> 30 ng/ml; 75 nmol/l).

Conclusion: Postmenopausal women with osteoporosis randomized to either 800 IU vitamin D per day versus a single oral bolus of 300'000 IU vitamin D reached similar 25(OH)D concentrations at 6 months. Notably, at 6 months, daily application leaves 39% and bolus application leaves 17% of patients in the vitamin D deficient range (< 20 ng/ml). Further, daily application shifts only 33% and bolus application shifts only 22% of patients into the desirable 25(OH)D range for fracture reduction (> 30 ng/ml) at 6 month follow-up.

BA058, a Novel Human PTHrP Analog, Restores Bone Density at the Spine and Femur in Osteopenic Sprague-Dawley Rats within 13 Weeks. Elisabeth Lesage¹, Aurore Varela¹, Susan Y. Smith¹, Gary Hattersley². ¹Charles River Laboratories, Canada, ²Radius, USA

BA058 is a synthetic analog of hPTHrP (1-34) currently in Phase 3 of clinical development for the treatment of post-menopausal osteoporosis. The objectives of this study were to determine the effects of BA058 on bone mass as determined by BMD in ovariectomized skeletally mature Sprague-Dawley rats. Six-month old virgin female rats (18/group) were randomly assigned to each of five groups. Four groups were ovariectomized (OVX) and one group underwent Sham surgery (ovaries remained intact). Treatment commenced following a 3-month bone depletion period. Animals received daily subcutaneous injections of vehicle (Sham and OVX controls), or BA058 at 1, 5 or 25 µg/kg/day, for a minimum 26 weeks. Blood and urine samples were analyzed for biochemical markers of bone turnover (P1NP, CTx, OC, DPD). aBMD was measured at the lumbar spine and the femur by DXA whereas vBMD was measured at the proximal tibia metaphysis by pQCT prior to surgery, at the end of the bone depletion period, and after 3 and 6 months of treatment. At the end of the bone depletion period, OVX animals showed a loss in aBMD of 6-8% at the lumbar spine and distal femur sites and a loss of 6% at proximal tibia site. Thirteen weeks of BA058 treatment restored aBMD at the lumbar spine and distal femur sites, to or above pre-OVX values at all doses. After 26 weeks of treatment at 25 µg/kg/day, lumbar and distal femur aBMD were increased by 18% and 27% compared to Sham, respectively, and 26% and 41% compared to pre-OVX,

respectively. After 13 weeks of treatment at 5 and 25 µg/kg/day, total slice vBMD and vBMC at the proximal tibia metaphysis site were restored to, or were above pre-OVX and Sham values. After 26 weeks of treatment, all BA058 treated groups showed increases in metaphyseal total slice vBMD compared to Sham, reaching 18% at 25 µg/kg/day. Increases in biochemical markers of bone turnover were also observed as compared to OVX controls, consistent with the increases in bone mass. In conclusion, BA058 potentially offers a number of important advantages as a new treatment for post-menopausal osteoporosis, including the ability to build new bone rapidly.

Decreased Osteoclastogenesis in Bone Marrow Cells Derived From Ovariectomized Rats Treated With Sclerostin Antibody. Min Liu¹, Pam Kurimoto², Qing-Tian Niu², Kelly S. Warmington², Xiaodong Li², W. Scott Simonet², Hua Zhu Ke¹. ¹Amgen Inc., USA, ²Amgen Inc., USA

Inhibition of sclerostin by treatment with a sclerostin monoclonal antibody (Scl-Ab) in both animal models and humans increases bone formation and decreases bone resorption simultaneously, thereby creating the potential for a larger anabolic window with Scl-Ab treatment than other approved osteoporosis therapies. The mechanism for decreasing bone resorption by Scl-Ab is a topic of ongoing research. In the current study, we examined osteoclastogenesis in bone marrow cells derived from ovariectomized (OVX) rats treated with Scl-Ab.

Six-month-old OVX rats (2 months post-OVX) were treated with vehicle (Veh) or Scl-Ab (Scl-AbVI, 25 mg/kg, SC, 1x/week) for 6, 12, or 26 weeks. Two other groups of OVX rats were treated with Scl-Ab for 6 weeks and then transitioned to Veh for either an additional 6 or 20 weeks. Ex vivo osteoclast cultures were performed with monocytic-enriched bone marrow cells in the presence of m-CSF and RANKL for 7 days. Osteoclast formation was assessed by tartrate-resistant acid phosphatase (TRAP)-positive staining for multinucleated cells and TRAP activity was determined using the cell culture medium.

TRAP-positive cells in OVX rats were increased in size and number compared with sham controls, and these cells were decreased in size and number in OVX rats treated with Scl-Ab at both weeks 6 (Fig. 1) and 12, indicating that in vivo Scl-Ab treatment reduced the osteoclastogenesis capacity of bone marrow cells. TRAP activity in culture medium showed a significant increase in OVX rats compared with sham controls at weeks 6 (Fig. 2) and 12. Scl-Ab treatment in OVX rats for 6 and 12 weeks decreased TRAP activity to the level of sham controls. By week 26, TRAP activity in OVX controls was not significantly higher than that in sham controls, and OVX rats treated with Scl-Ab maintained TRAP activity at the level of sham controls. Discontinuation of Scl-Ab for 6 weeks increased TRAP activity to a level that was not significantly different than OVX controls. The decrease in osteoclastogenesis is consistent with the bone histomorphometric analysis from the current study that showed a decrease in bone resorption indices in vivo by Scl-Ab (data not shown).

In summary, these data suggest that decreased osteoclastogenesis may contribute to the reduction in bone resorption observed with Scl-Ab treatment, although the mechanism of action requires further investigation.

In Vivo Assessment of the Calcitonin Receptor Peptide for the Treatment of Osteoporosis. David Komatsu*¹, Michael Hadjiargyrou², Srinivas Pentylala³. ¹Stony Brook University, Dept. of Orthopaedics, USA, ²State University of New York at Stony Brook, USA, ³Department of Anesthesiology, Stony Brook University, USA

Osteoporosis is the most widespread musculoskeletal disorder with a US prevalence of ~10 million. While several classes of antiresorptive drugs are clinically available to patients with osteoporosis, these agents are only able to slow disease progression. The sole approved anabolic agent, parathyroid hormone, is encumbered by several drawbacks that have limited its widespread utilization. Therefore, the development of new skeletally anabolic agents represents a major clinical need. We previously reported on the *in vitro* osteogenic activity of Calcitonin Receptor Peptide (CRP), a 12 AA-long peptide with homology to the C-terminus of the calcitonin receptor. The present study assessed the *in vivo* efficacy of CRP in normal and ovariectomized (OVX) rats to test the hypothesis that CRP is skeletally anabolic. 36 retired breeders underwent OVX at 6 months of age and after an additional month they were then divided into three groups: OVX Vehicle, OVX 15, and OVX 150. 24 aged-matched ovary intact rats (Intact) were divided into Intact Vehicle and Intact 15 groups. All rats were given 1 mL intraperitoneal injections (IP) of 50% DMSO (Vehicle) or 50% DMSO containing 15 µM (15) or 150 µM (150) 5 days/week for 5 weeks. They were then euthanized and serum, tibiae, femora, and vertebrae were collected. Femora were analyzed by microCT at the midshaft and distal metaphysis followed by 3-point bending tests. Serum samples were used for biomarker analyses. MicroCT analyses revealed significant increases in periosteal volume and periosteal surface at the midshaft, concomitant with increases in polar moment of inertia, maximum principal moment of inertia, and minimum principal moment of inertia for OVX 15 compared to Vehicle. However, subsequent biomechanical testing showed these differences were insufficient to affect femoral biomechanical integrity with no differences seen for stiffness, yield force, ultimate force, or energy to failure. Similarly, biomarker analyses failed to identify differences in bone specific alkaline phosphatase or carboxy-terminal collagen crosslinks. The completed analyses show that IP administration of CRP to rats is safe, though they provide only limited evidence that CRP is skeletally anabolic. However, histomorphometric tibial analyses, as well as microCT and biomechanical vertebral analyses remain to be completed and our hypothesis cannot be conclusively supported or refuted until these outcomes have been determined. Moreover, pharmacokinetic studies designed to establish the optimal dose, route, and frequency of CRP treatment are required for the *in vivo* anabolic potential of this peptide to be definitively assessed. In summary, these studies show that administration of CRP to ovariectomized rats results in modest improvements in midshaft femoral geometry and suggests that further study of CRP may aid in the development of new anabolic treatments for osteoporosis.

Manipulations of Disulfide Bonds in an Amylin Octapeptide: A Mechanism to Modify Bioactivity. Jillian Cornish*¹, Maureen Watson², Karen Callon¹, Renata Kowalczyk², Margaret Brimble². ¹University of Auckland, New Zealand, ²University of Auckland, New Zealand

Amylin, a peptide hormone co-secreted with insulin from the β-pancreatic cells, is active in fuel metabolism. We established amylin is anabolic to osteoblasts, whilst inhibiting osteoclastogenesis *in vitro* and *in vivo* thus suggesting a role in therapy of osteoporosis; although because of the peptide size and its non-osteogenic effects, it is not an ideal therapeutic agent. Previous structure-activity relationships demonstrated that an octapeptide fragment of amylin, amylin-(1-8) a ring-peptide, is inactive on fuel metabolism, but still anabolic to osteoblasts *in vivo* and *in vitro*. This small ring-peptide has thus been used as a model for the creation of orally active, non-peptide analogues, as potential candidates for the therapy of osteoporosis.

The disulfide bond in novel amylin-(1-8) analogues was modified either via macrocyclization or bridging reagent to increase potency and/or stability. A dibromomaleimide linker -analogue 1 (A1), a thiobenzyl linker (A2, A3), a thioalkyl chain of variable length (A5, A6), and a thiol-Michael modification (A7) were used to generate bridged analogues of amylin-(1-8)-NH₂. "Click chemistry" was also used to afford a triazole linked analogue. Importantly, a Nobel Prize-winning Ring Closing Metathesis (RCM) technology was used to afford chemically inert stapled analogues (A8-16).

The analogues were screened for proliferative activity in osteoblasts at physiological concentrations. Six analogues (A2, A8, A12, A13, A15, A16) significantly stimulated increases in mitogenesis (ANOVA, post hoc Dunnett) at a similar level to the native peptide with improved stability. These novel entities could lead to development of stable therapeutic compounds for use in osteoporosis treatment or for promotion of healing fractures.

Further chemical syntheses are needed to optimise these promising analogues. Subsequent synthetic modifications may further improve activity and stability.

Effects of Alfacalcidol and ED-71/eldcalcitol Alone or in Combination with Risedronate in Ovariectomized Rats. Tetsuo Yano*¹, Mei Yamada², Makoto Shiozaki², Daisuke Inoue³. ¹Ajinomoto Pharmaceuticals Co., LTD, Japan, ²Ajinomoto Pharmaceuticals Co., LTD, Japan, ³Teikyo University Chiba Medical Center, Japan

Background/Aim: 1α,25(OH)₂D₃ and its prodrug alfacalcidol (ALF) have been used for treatment of osteoporosis, often combined with antiresorptive agents such as bisphosphonates. ED-71 is a new 1α,25(OH)₂D₃-derivative that improves calcium balance and at the same time suppresses bone resorption, and has recently been approved for treatment of osteoporosis in Japan. ED-71 has been shown to be superior to ALF in decreasing the incidence of vertebral fractures in Japanese postmenopausal women. But its efficacy in combination with bisphosphonates remains unknown. In the present study, we examined effects on BMD and bone architecture of treatment with ED-71 and ALF, each alone or in combination with risedronate using ovariectomized rats.

Methods: Female Sprague Dawley rats at 24 weeks of age were divided into one sham-operated and five ovariectomized groups (1: vehicle, 2: ED-71, 3: ALF, 4: RIS, 5: RIS + ED-71, and 6: RIS + ALF). RIS (3.5 ug/kg, s.c.) and ED-71 (0.2 ug/kg, p.o.) were given twice per week for 12 weeks. ALF (0.4 ug/kg, p.o.) was given three times per week for 12 weeks. BMD, bone architecture and bone turnover makers were measured every 4 weeks by micro CT and ELISA, respectively.

Results: BMD was significantly decreased in vehicle-treated rats compared with sham rats after 4 weeks. At 8 weeks, BMD in RIS + ALF and RIS + ED-71 was significantly increased by 55.6 and 63.9%, respectively, compared with vehicle. At 12 weeks, BMD in RIS + ALF and RIS + ED-71 significantly increased by 94.4 and 97.2%, respectively, compared with vehicle. At 12 weeks, Tb.N of ED-71, ALF, RIS, RIS + ED-71, and RIS + ALF groups significantly increased by 35.2, 42.8, 52.8, 64.8, and 57.9%, respectively, compared with vehicle. Conn.D of RIS, RIS + ED-71 and RIS + ALF significantly increased by 66.9, 68.5 and 78.4%, respectively. Bone turnover makers tended to decrease in RIS + ED-71 and RIS + ALF, but not significantly. Serum calcium concentration significantly increased in ED-71 and ALF, but decreased in RIS alone and combination of RIS + ED-71 or ALF.

Conclusions: Combination therapy with RIS and active vitamin D₃ derivatives significantly improved BMD and bone architecture greater than each alone. RIS + ED-71 was at least as efficacious as RIS+ALF in improving bone architecture, validating the combination of risedronate and the new vitamin D₃ analogue.

Fluorescence Imaging Reveals High Bisphosphonate Delivery to the Mandible Regardless of Bone Turnover Status. Joseph E. Perosky*¹, Adrienne F. Alimasa¹, Laurie McCauley², Kenneth Kozloff³. ¹University of Michigan Department of Orthopaedic Surgery, USA, ²University of Michigan School of Dentistry, USA, ³University of Michigan Department of Orthopaedic Surgery, USA

Osteonecrosis of the jaw (ONJ) is a detrimental condition of exposed bone in the oral cavity. While associated with bisphosphonate (BP) use, it is unknown what role BPs play in the etiology of ONJ. If local BP concentration is responsible for the occurrence of ONJ, then understanding factors that regulate BP localization is of high importance. The purpose of this study was to investigate the role of bone turnover in the local accumulation of BPs at skeletal sites (mandible, femur, and tibia). High and low bone turnover states were induced by parathyroid hormone (PTH) and BP treatment, and compared to a control group (PBS) using fluorescent-labeled BPs to assess local drug concentration. Fourteen week male Balb/c mice were treated with rPTH[1-34] (80µg/kg daily), pamidronate (PAM, 1.07 mg/kg daily), or PBS injection for 1 week (n=14-16/group), after which mice were injected with a single dose of a far-red fluorescent pamidronate (FRFP, 100 nmol/kg). Twenty-four hours after injection, mice were euthanized and femora, tibiae, and mandibles were excised and imaged under fluorescence illumination to quantify average FRFP signal at anatomic sites of interest. Statistical changes were at the level p<0.05 unless otherwise noted. Serum collected at euthanasia from a subset of mice revealed the bone turnover markers, osteocalcin and TRACP5b, increased and decreased after 1 week of PTH or PAM respectively. However significant changes in bone mass or surface area by µCT were not observed at any site. FRFP signal was normalized by bone surface area (FRFP/BS) measured by µCT to compare BP delivery at multiple sites. For all treatment groups, FRFP/BS in the mandible was higher than both femur (PTH=26%, PBS=69%, PAM=39%) and tibia (PTH=99%, PBS=187%, PAM=120%). For femora and tibiae, FRFP delivery in the context of PTH-induced high bone turnover

increased compared to PBS (Femur=37%, Tibia=43%) and increased marginally, but not significantly vs. PAM low turnover groups (Femur=26%, Tibia=29%). Interestingly, mandibles were less sensitive to treatment effects, as FRFP/BS was equivalent across treatment groups. Dynamic histomorphometry revealed FRFP spatially followed calcein and alizarin labels administered 6 and 1 day prior to FRFP. These findings suggest that, at the femur and tibia, local bone turnover regulates local BP delivery, however the mandible may be particularly susceptible to high levels of BP delivery regardless of bone turnover condition.

Effects of Ascorbic Acid on Bone Density and Strength in Ascorbic Acid-deficient ODS Rats. Toyohito Segawa¹, Naohisa Miyakoshi¹, Yuji Kasukawa¹, Hiroyuki Tsuchie², Yoichi Shimada³. ¹Akita University Graduate School of Medicine, Japan, ²Akita University Graduate School of Medicine, Japan, ³Akita University Graduate School of Medicine, Japan

Introduction: The serum level of ascorbic acid (vitamin C) decreases with aging because of the reduction of intestinal absorptive or renal reabsorptive capacities. In recent years, it has been suggested that ascorbic acid deficiency among the elderly causes impairment of bone quality. However, the effects of this deficiency on bone mineral density or strength remain unclear. The objective of this study was to examine the effects of ascorbic acid on bone mineral density and strength in ascorbic acid-deficient rats.

Materials and Methods: Ascorbic acid-deficient rats (Osteogenic Disorder Shionogi rats) were acclimated until 4 months of age with water containing 2 mg/ml ascorbic acid; these rats were then provided with ascorbic acid-deficient water (0.5 mg/ml) for 8 weeks to create ascorbic acid-deficient rats (n = 20). Following the acclimated period, the rats were divided into the two groups (n=10 each group): 1) ascorbic acid-deficient (Aa-) group, which were provided with ascorbic acid-deficient water; and 2) ascorbic acid replenished (Aa+) group, which were given the water containing 2 mg/ml ascorbic acid. After 4 weeks treatment, bilateral femora were harvested. The right femur was used to measure bone mineral density (BMD) at the proximal end, and the left femur was used for femoral neck compression and diaphysis three-point bending tests to evaluate bone strength. BMD measurement and mechanical testing of femora were also performed for 10 Wistar rats of the same age forming the control group.

Results: BMD of the Aa- group was significantly lower than that of the control group (p<0.05). Maximum load, breaking force, and breaking energy of the femoral neck compression and diaphysis three-point bending tests of the Aa- group were significantly lower than those of the control group (p<0.05). Ascorbic acid replenishment significantly increased the parameters of bone strength in the femoral neck compression and diaphysis three-point bending tests (p < 0.05), but not BMD, as compared with those of the Aa- group. [Discussion and Conclusion] Ascorbic acid deficiency resulted in a marked decrease in bone strength rather than in bone density, suggesting that ascorbic acid may be important in maintaining bone quality rather than bone density.

Inhibition of Osteoclastic Resorption and RANKL Expression and Increase of Osteoblastic Differentiation and Extra Cellular Matrix Mineralization by Sulforaphane, a Naturally Occurring Isothiocyanate. Roman Thaler^{*1}, Monika Rumpler², Silvia Spitzer², Matteo Conti³, Klaus Klaushofer⁴, Franz Varga². ¹Ludwig Boltzmann Institute of Osteology, Austria, ²Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling. 1st Medical Department, Hanusch Hospital, Vienna, Austria, Austria, ³Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori (I.R.S.T.), Italy, ⁴Hanusch Hospital, Austria

Sulforaphane (SFN) is abundantly present in cruciferous vegetables like broccoli or cauliflower (1). By various mechanisms SFN can prevent, delay or even reverse carcinogenesis in vivo and in vivo (2). In rheumatoid arthritis, SFN was found to inhibit synovial hyperplasia and T cell activation. Furthermore, SFN was demonstrated to inhibit osteoclastogenesis by inhibiting nuclear factor-kappaB (3).

DMSO was reported to increase differentiation and extra cellular matrix (ECM) mineralization in primary osteoblasts and in MC3T3-E1 cells (4). This may be attributed to the phenotypic shift caused by DMSO via active DNA-demethylation (5). As DMSO shares structural properties with SFN, we evaluated the effect of SFN, on bone cells and tissue.

The cell lines MC3T3-E1, RAW-264.7, MLO-Y4, mouse mesenchymal stem cells (mMSC, cultured in osteogenic medium), mouse pre-osteoclasts (mOC), newborn and adult (7 weeks old) mouse calvaria were treated with increasing concentrations of SFN for up to 6 weeks. Gene expression was measured by qRT-PCR, gene arrays and immunoblots. ECM mineralization was quantified by alizarin red staining. Osteoclastic resorption on ivory was measured and caspases 3/7 and 8 activities were evaluated. DNA hydroxymethylation was visualized by immuno-fluorescence techniques.

After 24 hours, already 3µM SFN inhibited cell proliferation and activated caspases 3/7 and 8 significantly stronger in pre-osteoclastic RAW-264.7 cells as in osteocyte-like MLO-Y4 and pre osteoblastic MC3T3-E1 cells. After 12d of 3µM SFN treatment, resorption of mOC on ivory was significantly inhibited by 40%. After 8 days and 12 days exposure to 3µM SFN, RANKL expression was significantly decreased in MLO-Y4 and in newborn and adult calvaria, respectively. SNF significantly increased the expression of *Bglp2*, *RUNX2*, *Coll1a* and *Lox* in MC3T3-E1 cells after 14 days of treatment. A similar pattern was seen after 20 days in mMSC. In both cases as well as in newborn and adult calvaria a significantly increased ECM mineralization was found after SFN exposure. Similar to DMSO (5), in MC3T3-E1 cells SFN activated genes responsible for active DNA demethylation suggesting this as cause for the effects observed.

SFN serum concentrations in the range as here used are achievable through diet. This suggests SFN as a potential regulator of bone homeostasis.

Raloxifene Prevents Skeletal Fragility in Adult Female Zucker Diabetic Sprague-Dawley (ZSDS) Rats. Kathleen Hill^{*1}, Maxime Gallant¹, Drew Brown², Amy Sato², David Burr¹. ¹Indiana University School of Medicine, USA, ²Indiana University School of Medicine, USA

In type 2 diabetes, fracture risk is increased despite normal or high bone mineral density, implicating poorer bone quality. We previously reported impaired bone material properties in the non-leptin-dependent Zucker Diabetic Sprague-Dawley (ZSDS) rat model of type 2 diabetes. Raloxifene (RAL) improves bone material and mechanical properties independent of bone mineral density, and may serve to prevent bone fragility in those with type 2 diabetes. The purpose of this study was to determine if RAL prevents the negative effects of diabetes on material properties and skeletal fragility.

24 female ZSDS rats and 24 female CD control rats were fed a high-fat diet beginning at 20 weeks of age to induce diabetes. Rats were randomized to receive daily s.c. injections of RAL (0.5 mg/kg/d) or vehicle (VEH, n = 12 ZSDS and n = 12 CD per treatment) for 12 weeks. Blood glucose was measured weekly. Diabetes was defined as blood glucose \geq 250 mg/dL. At the time of sacrifice, bones were harvested for analysis by DXA (femur, LV4), pQCT (femur mid-shaft), microCT (LV4), 3-point bending (femur) and axial compression (LV4).

RAL-treated ZSDS rats had a lower incidence of type 2 diabetes compared with VEH-treated ZSDS rats. Four of the 12 VEH-treated ZSDS rats (33%) became diabetic by study week 4 and remained diabetic throughout the 12 week study. None of the RAL-treated ZSDS rats became diabetic. RAL-treated ZSDS rats had blood glucose levels significantly lower than VEH-treated ZSDS rats that did not become diabetic, and similar to CD control rats.

Material properties were superior in RAL-treated ZSDS rats compared with both diabetic and non-diabetic VEH-treated ZSDS rats. RAL-treated ZSDS rats had greater femoral toughness than diabetic and non-diabetic VEH-treated ZSDS rats. This was due to greater energy absorption in the post-yield region. These differences

between groups were also observed for the structural (extrinsic) mechanical properties of energy-to-failure, post-yield energy-to-failure, and post-yield displacement.

RAL treatment prevented the onset of type 2 diabetes in adult female ZSD rats fed a high-fat diet and controlled blood glucose to levels similar to control rats. Additionally, RAL had beneficial effects on material-level mechanical properties in ZSD rats.

In vivo Measurement of Bone Strontium Accumulation in Rats Using X-ray Fluorescence Spectroscopy. Gregory Wohl^{1*}, Cheryl Druchok¹, Ashlie Altman², David Chettle³, Ana Pejovic-Milic⁴, Colin Webber⁵, Jonathan Adachi⁶, Karen Beattie¹. ¹McMaster University, Canada, ²McMaster University, Canada, ³Department of Medical Physics, McMaster University, Canada, ⁴Department of Physics, Ryerson University, Canada, ⁵Hamilton Health Sciences, Canada, ⁶St. Joseph's Hospital, Canada

Introduction: Strontium ranelate is a pharmacologic treatment for osteoporosis indicated for use in Europe and Australia but not in Canada or the US. Strontium citrate is an alternative strontium (Sr) salt available as an over-the-counter nutritional supplement marketed to improve bone health. To measure *in vivo* bone Sr content, a non-invasive X-ray fluorescence spectroscopy (XRF) system has been developed and used in humans. The purpose of this study was to verify XRF measurements in a vehicle-controlled animal study comparing bone Sr levels in rats administered Sr citrate and Sr ranelate.

Methods: Female Sprague Dawley rats (n=18, 19 wk old) were randomly assigned to receive Sr ranelate (625 mg/kg/d, n=6), Sr citrate (676 mg/kg/d, n=7) or vehicle (flavoured gelatin, n=5) over 8 wks. Dosing was based on equivalent daily elemental Sr (Table 1). *In vivo* bone Sr measures were acquired at baseline, 4 and 8 wks. In acquiring XRF measurements, rats were anaesthetized (isoflurane) and the right hind limb was positioned with the anteromedial aspect of the proximal tibia 1-2 mm from the photon source (Fig 1). Backscattered X-ray spectra were measured over 900 sec, and analyzed using a nonlinear least squares, Marquardt based, fitting routine to determine Sr K_{alpha} and K_{beta} peaks (Fig 2). Rats were sacrificed at 10 wks. Group differences in bone Sr were assessed by two-way ANOVA with Bonferroni correction. Post-hoc analyses detected differences between groups (p=0.05). To verify elemental Sr content in each preparation, energy dispersive spectrometer (EDS) microanalyses were performed.

Results: In the vehicle group, bone Sr levels did not change over 8 wk and were significantly lower than bone Sr levels in Sr-dosed rats. In all Sr-dosed rats, bone Sr increased significantly (p<0.05) from baseline to 4 wk, and 4 wk to 8 wk (Table 2). However, bone Sr levels in the Sr citrate group were significantly greater (p<0.05) than the Sr ranelate group. EDS analyses revealed the Sr citrate group actually received 35% more daily elemental Sr than the Sr ranelate group (Table 1). Thus, after controlling for Sr dose, differences in bone Sr between Sr citrate and Sr ranelate groups were not significant (p>0.05).

Conclusions: Our results indicate that we can non-invasively measure bone Sr content in rats using our *in vivo* XRF system. Moreover, based on elemental Sr dose, the 8 wk accumulation of bone Sr in rats is equivalent between Sr citrate and Sr ranelate.

Table 1. Daily Sr dose

| | Molecular formula | Molecular weight [g/mol] | Dose [mg/kg/day] | Calculated† Elemental Sr [mg/kg/day] | Measured‡ Elemental Sr [mg/kg/day] |
|-------------|--|--------------------------|------------------|--------------------------------------|------------------------------------|
| Sr ranelate | C ₁₂ H ₁₆ N ₂ O ₈ SSr ₂ | 513.49 | 625 | 213 | 174.3 |
| Sr citrate | C ₈ H ₆ O ₇ Sr | 277.73 | 676 | 213 | 235.7 |

CXCL5 Stimulation of RANK Ligand Expression in Paget's Disease of Bone. Kumaran Sundaram¹, Sudhaker Rao², William Ries³, Sakamuri Reddy*¹. ¹Charles P. Darby Children's Research Institute, USA, ²Henry Ford Hospital, USA, ³Medical University of South Carolina, USA

Paget's disease of bone (PDB) is a chronic focal skeletal disorder that affects 2-3% of the population over 55 years of age. PDB is inherited as an autosomal dominant trait with genetic heterogeneity and characterized by highly localized areas of bone turnover with increased osteoclast (OCL) activity followed by an exaggerated osteoblast response. Also, pagetic OCL contains paramyxoviral nuclear inclusions and nucleocapsid transcripts. We previously detected expression of measles virus nucleocapsid protein (MVNP) transcripts in OCLs from patients with PDB. MVNP has been shown to induce pagetic phenotype in OCL. Recently, we showed that FGF-2 stimulates RANK ligand (RANKL) expression in PDB. In the present study, gene

expression profiling by Agilent microarray analysis revealed that MVNP significantly increased expression of cytokines/growth factors and signaling molecules in normal human bone marrow derived monocytes, which may play an important role in OCL development/function in PDB. We thus identified MVNP upregulation (72 fold) of the CXC chemokine ligand, CXCL5 [also known as Epithelial neutrophil activating peptide-78] mRNA expression. Bone marrow derived mononuclear cells from patients with PDB also demonstrated elevated (~180 fold) levels of CXCL5 mRNA expression compared to normal subjects. In addition, we identified a 5.0 fold increase in serum levels of CXCL5 in patients with PDB. Real time PCR analysis showed that CXCL5 stimulation (0-50 ng/ml) for 48 h increased (6.8 fold) RANKL mRNA expression in normal human bone marrow derived stromal (SAKA-T) cells. Also, CXCL5 increased (5.2 fold) CXCR1 receptor expression in SAKA-T cells. We further show that CXCL5 treatment elevated the levels of p-ERK1/2 and p-p38 in these cells. Interestingly, CXCL5 stimulation enhanced phosphorylation of CREB (cAMP response element-binding) and inhibition of p-CREB by using protein kinase (PKA) inhibitor H-89 significantly decreased CXCL5 increased hRANKL gene promoter activity. These results suggest that CREB is a downstream effector of CXCL5 signaling and that increased levels of CXCL5 contributes to enhanced RANKL expression in PDB.

Identification and Characterization of A Novel Orally Active Calcium-Sensing Receptor Antagonist. Etsuko Fujita^{*1}, Eiji Ochiai¹, Akiko Takeuchi², Yuri Sakai³, Ryo Matsuyama³, Motoko Hamada³, Gen Unoki³, Yohei Matsueda³, Kei Yamana⁴, Hiroyuki Sugiyama¹, Yoshiaki Azuma¹. ¹Teijin Institute for Biomedical Research, Japan, ²Teijin Institute for Biomedical Research, Japan, ³Teijin Institute for Biomedical Research, Japan, ⁴Teijin Institute for Biomedical Research, Japan

Bone resorption inhibitors such as bisphosphonates are widely used for osteoporosis patients. As bone anabolic agent, intermittent administration of parathyroid hormone (PTH)(1-84) or PTH(1-34) are used and exert potent bone-forming effects in animal models and osteoporosis patients. On the other hand, continuous infusion of PTH increases bone turnover and results in bone loss. Bone anabolic agents are expected to be used for the patient with low bone turnover. Short acting calcium-sensing receptor (CaSR) antagonists are one of the promising candidates, which stimulate endogenous parathyroid hormone (PTH) transiently, mimicking teriparatide. Precedent CaSR inhibitors have failed to prove satisfied effectiveness in clinical studies probably due to prolonged PTH secretion. Here we report the pharmacological characteristics of a novel orally active CaSR antagonist TEI-A.

In human CaSR expressing cells, TEI-A inhibited the calcium stimulated intracellular Ca influx as potent as reference compound (JTT-305/MK5442). TEI-A showed almost the same inhibitory activities against rat, dog, monkey or human CaSR, indicating no species difference. Inhibitory activity of TEI-A was quite specific for CaSR and no significant inhibition was detected in a panel assay containing over 30 GPCRs and enzymes. In female rats, orally administered TEI-A induced PTH secretion in a dose-dependent manner, of which maximal level was comparable to reference compound. However, the time recovered to the basal level was shorter with TEI-A. In conclusion, TEI-A will be a promising candidate of CaSR antagonist as a bone anabolic agent with high potency, specificity and reasonable PTH stimulating activities.

24,25-Dihydroxyvitamin D₃ Signals through Non-vitamin D Receptor Pathways in HepG2 Cells. Kent Wehmeier^{*1}, Sarada Jaimungal², Jaisri Maharaj³, Arshag Mooradian⁴, Michael Haas⁵. ¹University of Florida, College of Medicine, Jacksonville, USA, ²Department of Medicine University of Florida -Jacksonville College of Medicine, USA, ³Department of Medicine, University of Florida-Jacksonville College of Medicine, USA, ⁴Department of Medicine, University of Florida-Jacksonville, College of Medicine, USA, ⁵Department of Medicine, University of Florida Jacksonville, College of Medicine, USA

Epidemiologic studies of cardiovascular disease risk have suggested that vitamin D may have an important role in modulating future cardiovascular events. Our lab has demonstrated that apolipoprotein A-I (apo AI) gene expression and HDL particle secretion in hepatocytes is suppressed by 24, 25-dihydroxyvitamin D₃ (24,25-[OH]₂ D₃) but not 25-hydroxyvitamin D₃. Knockdown of the vitamin D receptor (VDR) did not change the observed effects of 24,25-[OH]₂ D₃ on apo AI gene expression. Responses of resting zone chondrocytes to 24,25-[OH]₂ D₃ were mediated through non-VDR pathways based on previously published studies. Using an in vitro human hepatocyte model we investigated the ability of 24,25-[OH]₂ D₃ to modulate non-VDR signaling pathways that may affect apo AI gene expression. The activities evaluated included PKCa c-jun-N-terminal kinase (JNK) and extracellular regulated kinase ½. Treatment with 50 nM 24, 25-[OH]₂D₃ correlated with c-jun phosphorylation, down regulation of the AP-1 collagenase and apo AI gene promoter activities. Expression of peroxisome proliferator-activated receptor alpha (PPARα) and retinoid-X-receptor (RXR) were suppressed by 24, 25-[OH]₂D₃. These preliminary studies suggest the great complexity of effects of VDR ligands mediated through non-VDR signaling. Discerning effects of Vitamin D on cardiovascular risk requires dissection of the important non-VDR signaling pathways.

Bone Mineral Density in Immigrant Women Living in Stockholm with Low Vitamin D Levels Postpartum. Ingrid Bergstrom^{*1}, Ingrid Dahlman², Paul Gerdhem¹. ¹Karolinska Institutet, Sweden, ²Dept of endocrinology, metabolism & diabetes. Karolinska University Hospital Huddinge, Sweden

Introduction: A fair evidence for a positive association for 25-hydroxy vitamin D (25OHD) levels and BMD is found in older children and older adults. Not many studies are concerning women in reproductive age or in perimenopause. Aim: To find out if the bone health is affected in immigrant women in reproductive age with low levels of vitamin D compared to a Swedish control group. Subjects: We characterized a cohort of 68 pregnant immigrant women in gestational week 12 and compared their vitamin D levels with 51 nonimmigrant pregnant women. Significantly more immigrant women (77.9 %) had levels of 25OHD <25 nmol/l compared with control women, where only a minority (3.9 %) had such low level. A large proportion of the immigrant women (29.4 %) had levels <12 nmol/l compared to none of the controls. Of these women we could include forty-one immigrant women 6 to 12 months postpartum. As controls served 18 of the Swedish women. 25OHD and parathyroid hormone (PTH) levels were remeasured and DXA (hip, spine) and pQCT (radius, tibia) was performed. Neither patients nor controls received any supplementation with vitamin D. Statistical calculations were made with the Mann-Whitney U-test or the Spearman rank correlation test.

Results: Mean postpartum 25OHD was 29 nmol/L in patients and 53 nmol/L in controls. Mean postpartum PTH was 69 ng/L in patients and 38 ng/L in controls. Age in patients was 31.5 years and in controls 32.5 years, p=0.56. Mean BMI was 27.4 kg/m² in patients and 24.8 kg/m² in controls, p=0.041. Mean DXA total hip did not differ between patients and controls (1.02 and 1.00 g/cm²; p=0.78). Mean DXA spine (L1-L4) did not differ between patients and controls (1.13 and 1.17 g/cm²; p=0.26). pQCT cortical density and trabecular density of the tibia did not differ between patients and controls (p>0.61). pQCT Cortical density and trabecular density of the radius did not differ between patients and controls (p>0.59). No significant correlations were found between 25OHD or PTH and the different bone density parameters.

Conclusion: The bone health is not affected by persisting low vitamin D levels in immigrant women living in Stockholm.

from the Phase III Arzoxifene study (Generation) which included 1939 postmenopausal women (60 to 85 years old) with a densitometric diagnosis of osteopenia or osteoporosis. Vitamin D below 25 nmol/L was an exclusion criterion in this study. Blood was obtained at baseline between April and August (Fall and Winter). The sites included Recife, Salvador, Rio de Janeiro, São Paulo, Curitiba and Porto Alegre. Median, maximum and minimum levels of 25OHD as well as median age were calculated for each city (Table 1). Pearson correlation was used for 25OHD and latitude. Although severe Vitamin D deficiency (< 25 nmol/L) was rare (6 subjects, 0.3%), insufficiency (<75 nmol/L) was very common (1,327 subjects, 68.4%), even in those living in a tropical climate, with 56.7% in Recife (8°S) and 49% in Salvador (12°S). The prevalence of insufficiency gradually increased proportionally with latitude, reaching a prevalence of 83% in Porto Alegre (33°S) (Figure 1). On average, there was a reduction of 0.8 nmol/L for each latitudes degree south of the equatorial line. The correlation between 25OHD levels and latitude was high: r=-0.88. In conclusion, Brazil has a high prevalence of inadequacy of vitamin D, even in cities close to the Equator. Prevalence progressively increases with southward latitudes. Nevertheless, vitamin D deficiency in Brazil is clearly endemic and, in part, independent of latitude, emphasizing a multifactorial aspect of vitamin D deficiency. Greater understanding of these other factors could lead to the implementation of effective public health policies.

Correlation between 25 Hydroxyvitamin D (25OHD) Levels and Latitude in a Brazilian Postmenopausal Population with Low Bone Mass: from Arzoxifene Generation Study. Henrique Arantes^{*1}, Alan Chiang², John Bilezikian³, Marise Lazaretti Castro⁴. ¹UNIFESP, Brazil, ²Eli Lilly & Company, USA, ³Columbia University College of Physicians & Surgeons, USA, ⁴Escola Paulista de Medicina, Brazil

Vitamin D is one of the major regulators of calcium homeostasis and is critically important for normal mineralization of bone. Inadequate Vitamin D, as determined by low levels of 25OH D, has become very common despite the ready availability of sunlight at some latitudes. National data from a country that spans a wide range of latitudes would help to determine to what extent latitude or other factors are responsible for vitamin D deficiency. To this end, we investigated vitamin D status in cities located at different latitudes in Brazil, a large continental country, ranging from temperate to equatorial zones. The source of the data is the Brazilian subpopulation

the vitamin D status marker, 25-hydroxyvitamin D (25(OH)D). Renal conversion of the prehormone 25(OH)D to the active metabolite 1,25(OH)₂D is increased by low dietary Ca intake. This adaptation is necessary to protect bone under periods of dietary Ca stress. However, it is unclear whether genetic effects influence the production of 1,25(OH)₂D, especially when dietary Ca is limited. We conducted a study to identify genetic loci controlling serum 25(OH)D and 1,25(OH)₂D levels in the BXD recombinant inbred panel fed either normal and low dietary Ca levels. Male mice from 51 BXD lines were placed on modified AIN93G diets containing 200 IU vitamin D and either 0.5% (the rodent Ca requirement) or 0.25% Ca from 4-12 wks of age (n=8/line/diet). Blood was collected and serum metabolites were measured using commercial RIAs. Body weight was a significant covariate influencing serum metabolites; this effect was removed and residuals were used for all further analyses. ANOVA revealed a significant main effect of genetics (p<0.01) but not diet (p=0.17) on serum 25(OH)D. Heritability (h²) of 25(OH)D on the 0.5% Ca diet was 0.49. On the 0.5% Ca diet, 25(OH)D and 1,25(OH)₂D were not correlated, suggesting novel genetic loci may control serum 1,25(OH)₂D. Main effects of genetics and diet, as well as a gene x diet interaction, were significant for 1,25(OH)₂D (p<0.01). Heritability of 1,25(OH)₂D was 0.67 and 0.65 on the 0.25% and 0.5% Ca diets, respectively. Linkage mapping was conducted using a Bayesian quantitative trait loci (QTL) method and significant loci (Bayes factor>6) were identified. Three QTL affecting 25(OH)D were identified in the 0.5% Ca group chr 1 (mid), 1 (distal), and 6. Previously identified candidate genes (e.g. VDR, GC, CUBN, or LRP2) are not located in these regions. Three unique QTL affecting 1,25(OH)₂D on the 0.5% Ca diet were identified (chr 3, 11, and 13) and 2 in the 0.25% group (chr 7 and 10). QTL on chr 9, 15, 18 were found in both diet populations. The chr 15 locus is centered 200 kb upstream of the VDR, but the other loci contain no obvious candidate genes. Our results indicate that baseline serum 1,25(OH)₂D levels are influenced by genetics and that dietary Ca restriction reveals new QTL controlling this crucial regulator of Ca homeostasis and bone health.

Identification of Cytoskeletal Binding Partners for the 1,25D₃-MARRS Receptor. Tremaine Sterling¹, Ilka Nemere^{*2}. ¹Utah State University, USA, ²Utah State University, USA

We have shown that a membrane receptor, known as the 1,25D₃-MARRS receptor, is necessary for the rapid, pre-genomic effects of 1,25D₃ on phosphate and/or calcium absorption in chick intestines. However, a clear understanding of the proteins involved in the signaling mechanisms or transduction events by which the 1,25D₃-MARRS receptor facilitates 1,25D₃-mediated phosphate or calcium uptake, as well as other cellular effects, is still under investigation. We used co-immunoprecipitation studies and mass spectroscopy to identify proteins that interact with the 1,25D₃-MARRS receptor; we have identified actin and keratin as two binding partners involved in receptor localizations in the presence or absence of 1,25D₃. Using confocal microscopy, we were able to visualize 1,25D₃-MARRS receptor localizations relative to actin and/or keratin distribution in chick enterocytes. Cells cultured in media containing phenol red had the 1,25D₃-MARRS receptor and actin localized largely in the nucleus, which was dispersed upon addition of 1,25D₃. In the absence of phenol red, staining was cytoplasmic. Addition of steroid caused diminished staining at 10 s and 30 s, with a return of intensity between 1 and 5 min. Nuclear staining was observed after 1 min. We found that F-actin concentrations are maximal when 1,25D₃-MARRS receptor localizations within enterocytes are low suggesting that cyclical conversions of F-actin to G-actin are involved in the 1,25(OH)₂D₃-mediated redistribution of the 1,25D₃-MARRS receptor within the cell. We also found that keratin distribution remains constant with 1,25(OH)₂D₃ exposure when F-actin depolymerizes into G-actin, which suggests that actin and keratin work in concert to facilitate hormone-mediated redistribution of the 1,25D₃-MARRS receptor.

Role of Calbindin-D_{9k} as a Facilitator of Calcium Entry via TRPV6. Tibor Rohacs^{*1}, Puneet Dhawan², Yevgen Yudin¹, Baskaran Thyagarajan¹, Sylvia Christakos³. ¹UMDNJ-New Jersey Medical School, USA, ²UMDNJ-New Jersey Medical School, USA, ³University of Medicine & Dentistry & New Jersey - New Jersey Medical School, USA

The major role of 1,25(OH)₂D₃ is intestinal calcium absorption and calbindin-D_{9k} and TRPV6 are still being evaluated as the major intestinal targets of 1,25(OH)₂D₃. Yet studies related to the function of these proteins are limited and an understanding of the mechanisms involved in active intestinal calcium transport remains incomplete. We found that intestinal calcium absorption in response to 1,25(OH)₂D₃ still occurs in TRPV6 or calbindin-D_{9k} single knock out mice but is less efficient in the absence of both proteins [in the double KO mice 1,25(OH)₂D₃ mediated intestinal calcium absorption is reduced by 60% compared to calcium absorption in wild-type (WT) mice; p<0.05], suggesting that calbindin-D_{9k} and TRPV6 act together to affect calcium absorption. Confocal microscopy was done using WT and TRPV6 KO mice. In the duodenum of WT mice immunofluorescent staining for calbindin-D_{9k} showed discrete staining of the brush border of the enterocyte. In the TRPV6 KO mice there was loss of apical surface staining for calbindin-D_{9k}. These findings indicate that the

localization of calbindin at the brush border of the enterocyte is dependent on the presence of TRPV6. Using co-immunoprecipitation and GST pull down assays interaction between calbindin-D_{9k} and TRPV6 was observed. Calcium imaging studies in HEK cells transfected with TRPV6 showed that in response to 2 mM calcium there is an initial fast rise in the evoked calcium signal followed by a lower plateau due to calcium dependent inactivation. In cells co-transfected with calbindin-D_{9k} the plateau phase is higher (p<0.05 compared to cells co-transfected with vector). These results are consistent with calbindin-D_{9k} reducing calcium induced inactivation of TRPV6, resulting in enhanced entry of calcium via TRPV6. Calmodulin also associates with TRPV6 but unlike calbindin, calmodulin inhibits TRPV6 activity. Calmidazolium, an inhibitor of calmodulin, was found to inhibit calcium induced inactivation of TRPV6. These findings suggest novel mechanisms of enhancing intestinal calcium transport. These findings also indicate, for the first time, a functional interrelationship between calbindin-D_{9k} and TRPV6 and that calbindin-D_{9k} acts as a modulator of calcium influx via TRPV6, thus challenging the traditional model of transcellular intestinal calcium absorption and the role of calbindin as a facilitator of calcium diffusion.

UVB Radiation Ameliorates 25 Hydroxyvitamin D Deficiency in a Gender-dependent Manner in Mice: Role of 7-dehydrocholesterol Reductase. Yingben Xue^{*1}, Lee Ying², Gordon Watson², David Goltzman³. ¹Calcium Research Lab, McGill University, Canada, ²Children's Hospital Oakland Research Institute, USA, ³McGill University, Canada

Polymorphisms in the gene encoding 7-dehydrocholesterol reductase (DHCR7), the enzyme that converts 7 dehydrocholesterol (7DHC) to cholesterol, have been associated in human genome wide association studies (GWAS) with reductions in circulating 25 hydroxyvitamin D (25OHD). Inasmuch as 7DHC is the precursor of vitamin D which is then converted to 25OHD, we examined the alterations in serum 25OHD levels in female and male mice after UVB exposure and the potential role that DHCR7 might play. Vitamin D sufficient three week old mice were maintained on a vitamin D deficient (VDD) diet for 8 wks after which serum 25OHD fell from 86.4 to 14.9 nM in females and from 78.5 to 4.4 nM in males. Although renal cyp27B1 mRNA levels were increased 250-fold in females and males on a VDD diet, serum 1,25 dihydroxyvitamin D [1,25(OH)₂D] fell from 175.3 to 25.0 pM in females and from 156.3 to 22.4 pM in males. Concomitantly, hypocalcemia, hypophosphatemia and elevated PTH were seen with skeletal evidence of secondary hyperparathyroidism and osteomalacia. Mice were then exposed to chronic UVB irradiation (2.5 kJ/m² twice weekly, for 6 wks). In females serum 25OHD rose to 53.4 nM, serum 1,25(OH)₂D rose to 139.6 pM and serum calcium, phosphorous, PTH and skeletal abnormalities were reversed. In males serum 25OHD rose only to 23.1 nM and serum 1,25(OH)₂D rose to 86.6 pM; serum calcium, phosphorus and PTH levels improved but did not quite reach levels seen on normal chow. When mice on a VDD diet were exposed to acute UVB radiation (2.5 kJ/m² once daily, for 1 week), serum 25OHD rose from 8.6 to 99.3 nM in females but only from 9.0 to 25.5 nM in males. In females 7DHC to cholesterol ratios in skin rose on the VDD diet and then fell after UVB, whereas in males the ratios remained similar on both normal chow and the VDD diet. Although protein expression of DHCR7 in skin was similar in female and male mice on normal chow, in female mice DHCR7 expression was reduced on a VDD diet but increased after UVB. Such fluctuations were not observed in the male mice. In female transgenic mice overexpressing DHCR7 in skin, reduced increases in 25OHD in response to UVB were observed. The results show gender-dependent differences in UVB-induced 25OHD levels between females and males which appear to result from increased 7-DHC in skin in female vitamin D deficient mice due to decreased expression of DHCR7, and suggest a novel mechanism for regulation of UVB induced vitamin D production in skin.

Differences and Similarities in Treatment Related Effects of Zoledronic Acid in Multiple Myeloma and Breast Cancer Patients with Metastasis to Bone. Kent Soe^{*1}, Jean-Marie Delaisse², Erik H. Jakobsen³, Charlotte T. Hansen⁴, Torben Plesner⁵. ¹Vejle Hospital, University of Southern Denmark, Denmark, ²Vejle Hospital, IRS, University of Southern Denmark, Denmark, ³Vejle Hospital, Department of Oncology, Denmark, ⁴Odense University Hospital, Dept. of Hematology, Denmark, ⁵Vejle Hospital, Medical Department, Denmark

Treatment frequency and duration of cancer patients with the amino-bisphosphonate zoledronic acid (Zol) is frequently debated. Both multiple myeloma (MM) and breast cancer (BC) patients with metastasis to bone receive Zol 4 mg/3-4 weeks although their bone diseases are fundamentally different. In order to get better insight we have compared MM and BC patients in regard to the effect of Zol.

In an investigator initiated phase II clinical protocol we recruited 30 MM and 30 BC patients with metastases to bone (10 Zol naive and 20 with ≥ 6 previous treatments for each disease). Blood samples from day 0 and 14 were analyzed for CTX and bALP while total 48h urine collected immediately post-infusion was used to quantify the amount of Zol excreted and determine the degree of Zol retention.

CTX levels were significantly reduced with an increasing number of Zol treatments for both MM ($p=0.0007$) and BC patients ($p=0.0241$), but the effect was more pronounced for MM. bALP levels were significantly reduced with more Zol treatments in MM ($p=0.004$) but not significantly in BC patients ($p=0.09$). If patients did not receive Zol every month then CTX levels were significantly increased in MM patients (similar trend for BC) while bALP levels significantly increased in BC but not in MM patients. This was furthermore confirmed in a multivariate linear regression analysis combined with a likelihood ratio test on the entire cohort. Treatment frequency was shown to be a highly significant predictor for CTX ($p<0.001$) and bALP levels ($p=0.01$), while the number of treatments was shown to be only a significant contributor for CTX ($p=0.015$). Multivariate linear regression combined with likelihood-ratio tests also showed that for both MM and BC patients, kidney function may be impaired by repeated treatments since the creatinine clearance decreased with the number of Zol treatments ($p=0.014$) (sex, $p=0.001$; and age, $p=0.015$ were also unsurprisingly found to affect the creatinine clearance).

Our results suggest that: 1. MM and BC do not respond in the same way to Zol treatment especially concerning the suppression of bone formation. 2. Zol must be given every month to obtain maximum suppression of bone turn-over, since CTX (for MM) and bALP (for BC) were found to increase significantly if Zol treatment was delayed beyond 4 weeks. 3. Both in MM and in BC patients the kidney function seems to be negatively affected by multiple treatments.

Omega 3 Fatty Acids in Fish Oil Orchestrate a Reciprocal Axis between p53-miR-200c and Zeb1 to Prevent EMT in Breast Cancer Cells. Chandi Mandal^{*1}, Goutam Ghosh Choudhury², Auriole Tamegnon², Triparna Ghosh-Choudhury³, Nandini Ghosh-Choudhury¹. ¹University of Texas Health Science Center at San Antonio, USA, ²University of Texas Health Science Center at San Antonio, USA, ³Baylor College of Medicine, USA

We have recently demonstrated efficacy of fish oil (FO) component $\omega 3$ -fatty acid (docosahexaenoic acid, DHA) to target breast cancer stem cells in preventing tumor growth and osteometastasis in mouse models. Gene expression signature of breast cancer forces the cells to undergo epithelial to mesenchymal transition (EMT) that increases the metastatic proclivity of the tumor cells. Loss of E-cadherin expression by transcriptional mechanism marks the state of EMT, which dictates tumor invasion to distant organs. We investigated the mechanism of fish oil action on EMT. Breast tumors from fish oil-fed mice showed significantly increased expression of E-cadherin mRNA. Incubation of bone metastatic MDA-MB-231 (MDA) human breast cancer cells with DHA markedly enhanced E-cadherin mRNA and protein expression, indicating reversal of EMT. Breast cancer metastasis is associated with increased expression of Zeb1, a repressor for E-cadherin transcription, and decreased levels of the tumor suppressor p53. DHA inhibited the expression of Zeb1 protein and mRNA while it significantly increased levels of p53 mRNA and protein. Importantly, tumors from FO fed mice showed significant reduction in Zeb1 mRNA expression concomitant with marked increase in p53 mRNA and protein. The mechanism by which FO regulates Zeb1 expression is not known. We considered both transcriptional mechanism and post-transcriptional regulation by microRNA (miR). Transient transfection assays using a Zeb1 promoter reporter construct in MDA cells showed significant decrease in transcription of Zeb1 by DHA. 3'UTR of Zeb1 mRNA contains recognition element for miR-200c, which is a target of p53 transcription factor. Level of mature miR-200c is significantly low in MDA cells compared to MCF10A normal breast epithelial cells. FO-fed mice tumors showed increased levels of pre-miR-200c and mature miR-200c, similar to enhanced p53 levels. Similarly, DHA markedly enhanced the expression of both pre and mature miR-200c in MDA cells. Finally, reporter assays using miR-200c promoter in MDA cells showed significant increase in miR-200c transcription in response to DHA. Together our results demonstrate a salutary effect of FO to prevent EMT of breast cancer cells by increased p53 and miR-200c, which dampens the expression of Zeb1 to upregulate E-cadherin.

PGE2 Regulates Breast Cancer Proliferation and Osteoblastic RANKL Production in a Part of Bone Metastasis through its Receptor Subtype of EP4. Satoshi Yokoyama¹, Kenta Watanabe¹, Michiko Hirata², Chiho Matsumoto³, Takayuki Maruyama⁴, Chisato Miyaura³, Masaki Inada^{*3}. ¹Tokyo University of Agriculture & Technology, Japan, ²Tokyo University of Agriculture & Technology, Japan, ³Tokyo University of Agriculture & Technology, Japan, ⁴Ono Pharmaceutical Co., Ltd., Japan

Bone metastasis of breast cancer is accompanied by severe bone destruction with increased bone resorption. We identified that prostaglandin E2 (PGE2)-induced osteoclast formation was mediated by RANKL production in osteoblasts, EP4 is the major PGE receptor in the other three EP subtypes (EP1-EP3). Here we examine the EPs antagonist, a selective inhibitor of EP signaling in metastasized breast cancer cells. When we examined the expression profiles of EPs in mouse breast cancer cell 4T1, EP1 and EP4 expression was found. PGE2-induced 4T1 proliferation was also suppressed in both EP1 and EP4 antagonist treated cells suggesting the 4T1 has a diversity to respond multiple PGE2 signaling channels for the proliferation. To examine mechanisms of 4T1 induced-bone resorption, 4T1 cells were co-cultured with bone marrow cells and osteoblasts to evaluate the supporting capacities of osteoclast formation. First we newly employed the experimental system to evaluate cell-cell interaction by the contact adhesion, co-cultured bone cells on fixated cancer cell with cell membrane. Contact with fixed-4T1 cell was strongly induced RANKL expression and PGE2 production in osteoblasts. Osteoclast formation was seen in the co-culture of bone cells on fixed-4T1 cells, only EP4 antagonist treatment completely inhibited the osteoclast formation. On the other hand, the reverse experiments of cancer cells co-cultured with fixed-osteoblasts increase the levels of PGE2 production in 4T1 cells without RANKL production. PGE2 production was perfectly attenuated by the treatment of a COX2 inhibitor NS398 suggesting the factors from osteoblast cell membrane promote PGE2 production in breast cancer. Finally, 4T1 cells were co-cultured with mouse calvaria to evaluate bone resorbing activities. 4T1 cells attachment to bone surface markedly induced the number of osteoclast and following bone resorption in organ culture, only treatment of EP4 antagonist was attenuated 4T1-induced bone resorption. 3D-micro CT analyses indicated the resorbing trail on calvarial bone surface was suppressed by the treatment of EP4. These results suggest that the interaction of breast cancer among host osteoblast, PGE2 production increased in autocrine manner. EP4 specifically regulates RANKL production in osteoblast that leads osteoclast differentiation and following osteolysis. EP4 antagonist is a candidate for the therapy of breast cancer on bone metastases.

Vitamin D Strongly Influences Skeletal Metastasis Development in Breast Cancer: Comparison of Systemic Vitamin D Deficiency versus Local Ablation of CYP27B1 in Breast Tumor Cells. Aimee-Lee Luco^{*1}, Jiarong Li¹, Rene St-Arnaud², Timothy Reinhardt³, Richard Kremer⁴. ¹McGill University, Canada, ²Shriners Hospital for Children & McGill University, Canada, ³National Animal Disease Center, USDA, ARS, USA, ⁴McGill University, Royal Victoria Hospital, Canada

In advanced cases of breast cancer, the skeleton often bears the major tumor burden causing considerable suffering and morbidity. Once tumors are established in bone they are usually incurable. Vitamin D has been implicated as a possible mediator of breast tumor development and recurrence, however little is known about its possible influence on skeletal metastasis. We hypothesize that vitamin D deficiency could have a profound effect on skeletal metastasis by modulating tumor cell growth within bone directly and indirectly by enhancing bone turnover and the release of local growth factors.

Female FVB wild type mice were put on either a 1000 IU/Kg vitamin D diet or a 25 IU/Kg vitamin D diet after weaning. Six weeks after weaning, the mice (n=15/group) were injected into the right tibia with 500 000 cells suspended in 50 μ l of sterile PBS of either wild type tumor cells from PyMT breast tumors or 1 α -hydroxylase ablated breast tumor cells from PyMT 1 α -hydroxylase flox/flox cre+ mice. Three weeks following tumor cell injections the mice were sacrificed, blood collected and X-rays taken of the lower limbs. Bones were embedded in plastic for histomorphometric analysis of tumor burden. The X-rays were scored according to the following scoring method: 0 (no lesion), 1 (minor changes), 2 (small lesions), 3 (significant lesions with minor peripheral margin breaks), 4 (significant lesions with major peripheral margin breaks).

The mean weights of animals did not differ significantly. 25(OH)D levels were reduced by over 80% in animals on 25 IU/Kg diet vs. 1000 IU/Kg diet (16.7 nmol/L vs.

116 nmol/L, $p \leq 0.001$). PTH levels were significantly elevated in the low vitamin D vs. the normal vitamin D group (259 pg/ml vs. 167 pg/ml, $p = 0.05$). X-ray scores of bone lesions were as follows: 1000 IU/Kg diet injected with wild type tumor cells = 1.714 ± 1.439 , 25 IU/Kg diet injected with wild type tumor cells = 2.278 ± 1.034 , and 1000 IU/Kg diet injected with 1α -hydroxylase ablated tumor cells = 3.167 ± 0.931 . Analysis of tumor burden by histomorphometry revealed striking differences between groups, confirming the X-ray scoring. 1α -hydroxylase flox/flox cre+ tumors grew more aggressively rupturing cortical bone more frequently and invading extra-skeletal tissues. Overall, our data indicate that vitamin D regulates tumor growth within bone and that local metabolism of vitamin D by cancer cells likely plays a dominant role in this process.

Curcumin Induces Cell Apoptosis In Human Chondrosarcoma Through Extrinsic Death Receptor Pathway. Yi-Chin Fong^{*1}, Chih-Hsin Tang². ¹China Medical University Hospital, Taiwan, ²China Medical University, Taiwan

Chondrosarcoma is a soft tissue sarcoma with a poor prognosis that is unresponsive to conventional chemotherapy. Surgical treatment leads to severe disability with high rates of local recurrence and life threat. Curcumin, an active compound in turmeric and curry, has been proven to induce tumor apoptosis and inhibit tumor proliferation, invasion, angiogenesis, and metastasis of cancer cells. In this study, we investigated the anticancer effects of curcumin in human chondrosarcoma cells. Curcumin induced apoptosis in human chondrosarcoma cell lines (JJ012 and SW1353) but not in primary chondrocytes. Curcumin induced upregulation of Fas, FasL, and DR5 expression in chondrosarcoma cells. Transfection of cells with Fas, FasL, or DR5 siRNA reduced curcumin-induced cell death. In addition, p53 involved in curcumin-mediated Fas, FasL, and DR5 expression and cell apoptosis in chondrosarcoma cells. Most importantly, animal studies revealed a dramatic 60% reduction in tumor volume after 21 days of treatment. Thus, curcumin may be a novel anticancer agent for the treatment of chondrosarcoma.

Raman Spectroscopy Demonstrates Radiation-induced Bone Composition Changes in Murine Tibiae. Bo Gong^{*1}, Timothy Damron², Kenneth Mann², Megan Oest³, Joseph Spadaro⁴, Michael Morris¹. ¹University of Michigan, USA, ²SUNY Upstate Medical University, USA, ³SUNY Upstate Medical University, USA, ⁴State University of New York Upstate Medical University, USA

Introduction: Radiation therapy is an established method for treating human metastatic malignancies to bone and soft tissue malignancies near bone. But there are adverse sequelae including poor healing and impaired growth, reduced biomechanical competence leading to insufficiency fractures and high incidence of osteoradionecrosis. These adverse sequelae are not well detected by X-ray based techniques. We use Raman spectroscopy to characterize the chemical composition of post-irradiation murine tibia and demonstrate the presence of abnormal mineral and matrix even twelve weeks post-radiation.

Methods: Under an IACUC-approved protocol, 6 female Balb/c mice underwent radiation of the right tibiae, with a dose of 20 Gy in 4 fractions, using lead shielding to define the irradiation region. The left tibia was used as an internal control. At 12-week post-irradiation, all animals were euthanized and tibiae harvested. Thirty Raman spectra were recorded for each specimen in the region of interest (Raman microprobe, 785 nm excitation). Mineral and collagen Raman bands were analyzed using MATLAB and GRAMS/AI software. Mineral to matrix and carbonate to phosphate ratios, crystallinity (inverse FWHM of phosphate 960 cm^{-1}) and collagen cross-link ratio (amide I envelope) were used as metrics. One-way Anova was used to evaluate statistical significance ($p < 0.05$).

Results and Discussion: Irradiated tibiae exhibited lower mineral to matrix ratio, higher carbonate content and lower crystallinity. The collagen cross-link ratios were higher. The results are consistent with deposition of new mineral, indicating only

partial repair of radiation-induced damage even twelve weeks after irradiation. However, higher collagen cross-link ratio suggests that at least some mineral is deposited on a pre-existing collagen matrix. Our measurements do not establish whether the cross-links are the normal lysine-derived links or include links formed from products of radiation damage. Further measurement of the time course of radiation-induced damage and subsequent recovery is underway. This information may guide development of new dosing protocols and adjuvant therapies. Recent developments in non-invasive spectroscopy suggest it may also be useful for post-irradiation patient monitoring, at least at some sites.

The De-ubiquitinating Enzyme USP45 Is Critical to Epithelial-mesenchymal Transition (EMT) in Breast Cancer Cells Colonized Bone. Soichi Tanaka^{*1}, Toshiyuki Yoneda². ¹Osaka University, Japan, ²Osaka University Graduate School of Dentistry, Japan

Breast cancer frequently spreads to bone. Breast cancer cells disseminated in bone may acquire additional capacities that enhance their aggressiveness via interactions with bone environments. We reasoned that breast cancer cells colonized bone undergo epithelial-mesenchymal transition (EMT), an event known to exacerbate malignant phenotype of cancer cells. To test this, we investigated whether bone environments promote EMT *in vivo*. The MCF-7 human breast cancer cells stably transfected with GFP were inoculated in the mammary fat pad (MF) and tibial marrow cavity (TI). We then examined the expression of the mesenchymal marker Snail and epithelial marker E-cadherin in the tumors developed. Real-Time PCR showed increased Snail mRNA expression in MCF-7 tumors developed in TI compared with MF. In contrast, E-cadherin expression was lower in TI tumors than MF. Snail changed cell shape from epithelial to mesenchymal and reduced E-cadherin expression and induced N-cadherin and vimentin expression. These results suggest that breast cancer cells in bone show EMT and that Snail causes EMT. In search for a factor involved in EMT in bone, we found TGF β caused EMT by changing cell shape from epithelial to mesenchymal with increased Snail expression. Of interest, the bisphosphonate zoledronic acid (ZOL) inhibited TGF β -induced EMT by reversing cell shape and decreasing Snail. Proteasome inhibitor MG132 blocked these effects of ZOL, suggesting that ZOL decreases Snail via proteasomal degradation. Differential microarray between untreated and ZOL-treated breast tumors developed in tibiae identified the de-ubiquitinating enzyme 45 (USP45) as a candidate molecule involved in proteasomal degradation of Snail. USP45 expression was increased in TI tumors compared with MF. USP45 blocked ubiquitin-dependent degradation of Snail. USP45 changed cell shape from epithelial to mesenchymal, promoted cell motility, induced the expression of Snail, N-cadherin and vimentin and decreased E-cadherin expression. ZOL inhibited de-ubiquitination of Snail by USP45. Consistent with these *in vitro* effects, ZOL inhibited metastasis of breast cancer cells from tibiae to lung and liver, presumably by inhibiting EMT in bone. In conclusion, our results suggest bone environments promote EMT in breast cancer cells. ZOL may inhibit EMT in bone via stimulation of Snail degradation by preventing its de-ubiquitination by USP45, leading to the suppression of secondary metastases from bone.

The Effect of Breast Carcinoma Cells on Bone Cells: A Biomechanical Study. Xiuli Chen^{*1}, Sung Yun Park², Taeyong Lee¹. ¹National University of Singapore, Singapore, ²NUS, Singapore

Breast cancer has a strong tendency to develop bone metastases, i.e. 60-70% prevalence for patients with advanced stages of breast cancer [1]. Emerging evidence [2-3] suggests that there are more detrimental effects on osteoblasts due to metastatic cancer cells. In this paper, a biomechanical approach is used to investigate bone cells under the influence of metastatic breast cancer.

30 SD rats were inoculated with W256 breast carcinoma cells in the left femur. Primary tumor culture was isolated from 1 rat which developed a large tumor mass. Normal bone cells were isolated from SD rat bone explants harvested at 50th day. Bone cells exposed to 50% of conditioned medium from W256 and tumor cell culture were monitored for proliferation (MTT assay), alkaline phosphatase (ALP) activity (pNPP method), in-vitro mineralization (Von kossa staining), morphological (actin staining) and mechanical property changes (AFM cell indentation).

Results: Higher inhibition of proliferation, ALP activity and mineralization (Fig 1) were observed in tumor conditioned wells than in W256 conditioned wells. Changes in morphology of bone cells (Fig 1) were observed in W256 and tumor conditioned wells, with increased stretching and less detailed structure of F-actin cytoskeleton observed as compared to control wells. The changes in morphology might be also related to the decreased mineralization in ECM which can affect the cellular attachment on the substrate. Bone cells treated with W256 and tumor conditioned medium have a lower

E modulus compared to untreated cells and with the tumor conditioned bone cells exhibiting a lower E modulus. The mechanical results are likely to be related to the cytoskeletal changes since the cytoskeleton provides the basis for shape and mechanical properties.

Conclusions: Breast carcinoma cells are shown to have the effect of reducing bone cell proliferation, ALP activity and mineralization. The reduction in mineralization may have also affected the cellular attachment and morphology and indirectly, bone cell mechanical properties. Bone cell mechanical property changes may impact its mechanosensing properties and combined with reduction in functionalities, could bear consequences for tissue level changes.

The Therapeutic Effects of Rank-Fc Against Osteosarcoma Target not only Osteoclasts but also Osteosarcoma Cells Directly. Toru Akiyama*¹, Jonathan Clark², Peter Choong². ¹Saitama Medical Center, Jichi Medical University, Japan, ²Department of Orthopaedic Surgery, St. Vincent's Hospital Melbourne, Australia

Introduction: Osteosarcoma is the most common primary malignant bone tumor, which mainly affects adolescents and young adults. The following improvement in osteosarcoma treatment after dramatic advancement via the introduction of modern surgery and systemic chemotherapy in 70's has never been seen over the past 30 years. Thus, novel osteosarcoma therapeutic strategies are urgently required currently. We have focused on the RANKL-osteoclast system as a protagonist of osteosarcoma development. The osteoclast is the sole cell capable of resorbing bone in any bone-associated pathology, including osteosarcoma. The development in bone and metastatic lesion formation due to osteosarcoma essentially requires the induction of osteoclasts in order to degrade surrounding bone. RANKL is a critical factor for osteoclast activity. Furthermore, recent reports indicate that RANKL can support the tumorigenesis. RANK-Fc is a potent RANKL antagonist. Thus, we focused on RANK-Fc as a potent candidate of osteosarcoma therapeutic agent.

Objectives: We studied the therapeutic efficacy of RANK-Fc against osteoclast and osteosarcoma tumor cell in vitro and in vivo. Furthermore, we aimed to reveal the molecular mechanism of the RANK-Fc therapeutic efficacy.

Methods: We used our orthotopic osteosarcoma model as an in vivo treatment model. In vitro primary osteoclast study system and SaOS2 osteosarcoma cell line was used for assays of RANK-Fc efficacy on osteoclast and osteosarcoma tumorigenesis.

Results: In vivo data demonstrated that RANK-Fc suppressed tumor growth in bone with the preservation of bone structure. RANK-Fc administration prevented lung metastasis effectively, even when administered tumor - induced bone destruction started. In vitro studies revealed that RANK-Fc suppressed osteoclast formation, bone resorption activity and RANKL induced anti-apoptotic manner. Furthermore, RANK-Fc suppressed osteosarcoma cell migration, invasion ability, and anchorage-independent ability in type I collagen gel following induction of anoikis and activation of caspase-3. The anti-invasion and anti-metastasis capability of RANK-Fc is attributed to reduce ERK signaling via RANK-Fc.

Conclusions: The therapeutic effects of RANK-Fc against osteosarcoma cell are provided by its inhibition of not only osteoclast but also osteosarcoma cell itself. Our data demonstrated that RANK-Fc is a potential drug candidate for osteosarcoma with mechanisms unparalleled by current chemotherapeutic agents.

Age Related Sexual Dimorphism of Trabecular Bone Loss Is Inversely Associated with Adipogenic and Osteoclastic but not Osteogenic Activities. Beth Bragdon^{*1}, Elise Morgan², Robert Burns³, Amelia Baker⁴, Anna Belkina⁴, Gerald Denis⁴, Jennifer Schlezinger⁵, Louis Gerstenfeld⁴. ¹Boston University School of Medicine Department of Orthopaedics, USA, ²Boston University, USA, ³Boston University School of Medicine, Department of Orthopaedics, USA, ⁴Boston University School of Medicine, USA, ⁵Boston University School of Public Health, USA

Bone mineral density is lower in females than males, and bone quality shows sexually dimorphic differences during aging with female animals having greater loss than males. A mechanistic molecular study was carried out to examine sexual differences in anabolic and catabolic activities during skeletal aging.

Methods: A longitudinal study from 3-18 months of male and female C57BL/6 mice (N=5-7) was carried out. PINP was assayed in serum. Cortical and trabecular bone structure was assessed in the right tibia by μ CT. Quantitative RT-PCR was used to assess the expression of three cassettes of mRNAs for osteoblasts/osteocytes (RUNX2, osterix, osteocalcin, RANKL, DMP1, FGF23), osteoclasts (cathepsin K, Trap5b) and adipocytes (PPAR γ , CEBP α , FABP4, adiponin) from both humeri. Primary bone marrow cultures were prepared from the femurs and left tibia and stimulated to undergo osteogenesis in the absence or presence of rosiglitazone; mRNA expression was assessed.

Results: μ CT showed that both males and females lose bone volume, had decreased trabecular number and had increased cortical area over time, with females having a greater bone loss than the males. qRT-PCR showed osteoblast markers, RUNX2, osterix, osteocalcin, and resorption markers were lower in the females at 3 months, but at 6 and 12 months the females had increased expression compared to the males. At 12 months, DMP1, FGF23, RANKL and SOST were all increased in females compared to males. The expression of adipocyte and osteoclast markers was constant in male mice over time but showed several fold higher expression in females at 6 months. The differences in osteoblastic metabolic activity were confirmed by assessment of serum PINP levels. Interestingly, female-derived bone marrow cultures expressed greater levels of PPAR γ , FABP4 and adiponin following 1 week of osteogenic differentiation than male-derived cultures, and induction of adipogenesis and suppression of osteogenesis by the PPAR γ ligand rosiglitazone was enhanced in female-derived cultures.

Conclusion: These findings suggest that skeletal tissue metabolism is several fold higher in females than males and males are more metabolically efficient in bone acquisition than females. In vitro studies showed the same sex dependent variation in overall metabolic activity in male and female cells even in the absence of estrogen and suggest that sexual dimorphic differences must be epigenetically imprinted within bone marrow stromal cells.

Cell Signaling Pathways Regulate Postnatal Intervertebral Disc Growth and Maintenance. Chitra Dahia^{*1}, Eric Mahoney², Christopher Wylie². ¹Cincinnati Children's Hospital Medical Center, USA, ²Cincinnati Children's Hospital, USA

Degenerative disc disease afflicts 1 in 7 adults and is a major cause of lower back pain. Poor outcome of treatment combined with our limited understanding of normal disc growth and development during the postnatal stages, makes it important to design approaches for its regeneration. It is well established that cross talk between major cell signaling pathways regulates the growth and maintenance of all kinds of cells and tissues. We have previously shown using a mouse model system that the major cell signaling pathways are active in all the components of the disc during postnatal stages. The nucleus pulposus (NP), which originates from the embryonic notochord, was shown to secrete major signaling ligands including sonic hedgehog (Shh), TGF β s, BMPs and Wnts, while the annulus fibrosus (AF) and end plate (EP) surrounding the NP cells responded to these signals. However, the roles of these signaling pathways in disc growth and maintenance is not well understood. We hypothesize that Shh is a key signaling pathway that regulates other major signaling pathways in postnatal disc and that cross talk between these pathways regulates the growth and development of the disc. To test this hypothesis we have established an *in vitro* system to study the molecular control of disc growth and maintenance during the postnatal development of the mouse. Our results show that Shh signaling regulates other major cell signaling pathways like BMP, Wnt, and TGF β in controlling the various cellular functions like cell proliferation, cell differentiation, secretion of matrix and major transcription factors by the disc cells. These data also show that the roles of major cell signaling pathways in postnatal disc growth and development can be studied using specific antagonists and agonists in a simple *in vitro* culture system. It will be important in the future to identify the precise functions of each of these pathways on the growth and differentiation of the disc, the cells releasing and responding to the ligands, and the sites of interaction of the pathways in the disc cells. This will provide crucial information about molecular control of postnatal disc growth and maintenance. Identification of signals controlling postnatal intervertebral disc growth and differentiation offers the opportunity for the development of biological repair as an alternative to surgery.
